

TREATISE ON THE CIRCLE

Volume III — Geometry, Analysis and Signals on the Circle

From curvature to transforms: differential geometry, sphere, topology, DFT–FFT, signals and telecommunications

Creator: 0THack1A

Document: *treatise-circle-vol3*

Last updated: September 2026

Personal mathematical study document — no corporate or commercial reference

Reference environments: Debian • Arch Linux • Kali Linux

Preface

Volume II is the introduction: parametrisation, integral calculus, complex numbers and the first rudiments of harmonic analysis on the circle, together with the elementary applications to electrical engineering, directional statistics and the discrete circle. This volume is *the rest*: everything the circle generates once it is granted more than one dimension, more than one structure and more than one domain. It presupposes Volume II and, where needed, Volume I, recalled by explicit cross-reference and never summarised.

How it is organised. The volume is divided into six Parts.

- **Part A — Differential and global geometry** (Chapters 1–14): curvature and osculating circle, space curves, global theorems on plane curves, isometries, the complex circle, the sphere and spherical trigonometry, geodesics, surfaces, arbitrary dimension, the topology of the circle, the circle as a group, tangencies and packings.
- **Part B — Complex and harmonic analysis on the disc** (Chapters 15–18): Cauchy and residues, harmonic functions and the Poisson kernel, convergence of Fourier series, partial differential equations on the circle and in the disc.
- **Part C — Transforms** (Chapters 19–23): Fourier, Laplace, Z and DTFT, the discrete transform and the FFT algorithm.
- **Part D — Signals, control, telecommunications** (Chapters 24–27): sampling and linear systems, the circle in control and transmission lines, complex baseband and modulations, OFDM.
- **Part E — Applications to automation** (Chapters 28–30): $SO(3)$ and quaternions, Lie groups and robot kinematics, interpolation and trajectories.
- **Part F — Numerics and research** (Chapters 31–33): circle fitting, open problems and research literacy, epilogue.

Reading levels. Each chapter declares its level: **A** (upper secondary school), **B** (first year of a STEM degree), **C** (undergraduate), **D** (graduate). A reader at level A–B must be able to skip the sections marked C–D without losing the thread: forward references are always explicit and the advanced sections are preceded by a prerequisites box.

Prerequisites. Differential and integral calculus in several variables, linear algebra, complex numbers and elements of Fourier series: everything that is developed in Volume II. Appendix A recalls in condensed form the results of Volumes I and II used in the text; Appendix C collects the tables of transforms and identities; Appendix D the index of symbols.

Note on the September 2026 supplement The volume now also includes Part G on state, estimation, dynamics and digital control. Chapters 1–33 and Parts A–F retain their numbering; the new Part adds Chapters 34–37. The Riemann section supplements Chapter 15 and the Gauss section Chapter 32. The application chain connects the kinematics of Chapters 28–30 to dynamics, feedback and estimation; the reference Z-transform chapter is Chapter 21.

Contents

Preface	1
A Differential and global geometry	17
1 Prologue: the circle as guiding thread	18
1.1 Three thousand years around a circle	18
1.2 The quadrature of the circle	18
1.3 The circle as generator	19
2 Plane curves: curvature, osculating circle, evolutes	21
2.1 Arc length and the unit tangent	22
2.2 Curvature and the osculating circle	23
2.3 Evolutes and involutes	28
2.4 Curves generated by rolling circles	32
2.5 The fundamental theorem of plane curves	34
2.6 Clothoids and curvature-continuous planning	35
2.6.1 Application to automation	38
2.6.2 Circular interpolation in PLC and CNC controllers	38
2.6.3 Computing with Python	39
2.7 Assigned exercises	39
2.8 Worked exercises	40
2.9 Numerical and symbolic exercises with solutions	43
2.9.1 Numerical exercises	44
2.9.2 Symbolic exercises	44
2.9.3 Solutions to the numerical exercises	45
2.9.4 Solutions to the symbolic exercises	48
2.9.5 Exercises from Chapter 2 of Volume III	50
2.10 Self-assessment quiz	52
2.10.1 Supplementary questionnaire	53
2.11 Teacher's key	54
2.12 Chapter formulary	56
3 Space curves: Frenet–Serret and torsion	59
3.1 The Frenet frame and the torsion	60
3.2 The fundamental theorem of space curves	64
3.3 The circular helix and generalised helices	66
3.4 Osculating circle and osculating sphere	70
3.5 Spherical curves	72
3.6 Assigned exercises	74
3.7 Worked exercises	75
3.8 Self-assessment quiz	77
3.9 Teacher's key	78
3.10 Chapter formulary	81
3.11 Appendix: existence and uniqueness for linear systems	82

4	Global theorems on plane curves	86
4.1	The rotation index theorem	86
4.2	The support function	88
4.3	Curves of constant width and Barbier's theorem	90
4.3.1	Part (ii): the Blaschke–Lebesgue theorem, proved	92
4.4	The isoperimetric inequality	95
4.5	The four-vertex theorem	97
4.5.1	The general case: non-convex curves	99
4.6	The global Gauss–Bonnet theorem	108
4.7	Assigned exercises	112
4.8	Worked exercises	113
4.9	Numerical and symbolic exercises with solutions	116
4.9.1	Numerical exercises	116
4.9.2	Symbolic exercises	117
4.9.3	Solutions to the numerical exercises	117
4.9.4	Solutions to the symbolic exercises	120
4.10	Self-assessment quiz	122
4.10.1	Supplementary questionnaire	124
4.11	Teacher's key	125
4.12	Chapter formulary	127
5	Isometries and the orthogonal group	132
5.1	Isometries of the plane and orthogonal matrices	133
5.2	The classification of $O(2)$	135
5.3	Quadratic forms and the uniqueness of the circle	139
5.4	From $O(2)$ to $SO(3)$: Euler's rotation theorem	141
5.4.1	Planar orientation of the TCP	143
5.4.2	The rotation matrix inside the controller	143
5.5	Assigned exercises	143
5.6	Worked exercises	144
5.7	Self-assessment quiz	147
5.8	Teacher's key	148
5.9	Chapter formulary	150
6	The circle in the complex plane	153
6.1	The unit circle as a group	154
6.2	The n -th roots of unity	156
6.3	Regular polygons and constructibility	162
6.4	Möbius transformations and generalised circles	165
6.5	Assigned exercises	172
6.6	Worked exercises	173
6.7	Self-assessment quiz	175
6.8	Teacher's key	176
6.9	Chapter formulary	179
7	From the circle to the sphere: cones, quadrics, sections and stereographic projection	182
7.1	The circle–sphere dictionary	183
7.2	The cone and its sections	183
7.3	The sphere and its sections	186
7.4	Quadrics and ellipsoids: where the circles hide	189
7.5	Stereographic projection	191

7.6	Sphere parametrizations	194
7.7	Great circles, distance and geodesics	195
7.8	Area of the sphere and volume of the ball	199
7.9	Gauss–Bonnet on the geodesic triangle	200
7.10	Industrial applications	203
7.11	Assigned exercises	203
7.12	Worked exercises	204
7.13	Numerical and symbolic exercises with solutions	206
7.13.1	Numerical exercises	206
7.13.2	Symbolic exercises	207
7.13.3	Solutions to the numerical exercises	207
7.13.4	Solutions to the symbolic exercises	209
7.14	Self-assessment quiz	213
7.14.1	Supplementary questionnaire	214
7.15	Teacher’s key	215
7.16	Chapter formulary	217
8	Spherical trigonometry	220
8.1	Spherical triangles: definitions and fundamental inequalities	220
8.2	The cosine theorem for sides	222
8.3	The sine theorem	224
8.4	The polar triangle and the cosine theorem for angles	225
8.5	Right triangles and Napier’s rules	227
8.6	Spherical excess and area: Girard’s theorem	230
8.7	L’Huillier’s formula	232
8.8	Great-circle navigation: a complete numerical example	235
8.9	Assigned exercises	238
8.10	Worked exercises	238
8.11	Self-assessment quiz	240
8.12	Teacher’s key	241
8.13	Chapter formulary	243
9	Geodesics and the calculus of variations	245
9.1	The variational problem and the Euler–Lagrange equation	246
9.2	The geodesic equation	248
9.3	The geodesics of the sphere are the great circles	252
9.4	Cylinder and cone: geodesics by development	254
9.5	Clairaut’s relation	257
9.6	Beyond half a sphere: geodesics that stop minimizing	260
9.7	Industrial applications	263
9.8	Assigned exercises	263
9.9	Worked exercises	264
9.10	Self-assessment quiz	267
9.11	Teacher’s key	268
9.12	Chapter formulary	270
10	Local theory of surfaces	272
10.1	The first fundamental form	273
10.2	Gauss map and second fundamental form	275
10.3	Principal, mean and Gaussian curvatures	277
10.4	The Theorema Egregium	279
10.5	The sphere and the torus: two curvatures compared	283

10.6	Ruled and developable surfaces	285
10.7	Gauss–Bonnet: where it is in the treatise	287
10.8	Industrial applications	288
10.9	Assigned exercises	288
10.10	Worked exercises	289
10.11	Self-assessment quiz	292
10.12	Teacher’s key	293
10.13	Chapter formulary	295
11	The circle in any dimension: hyperspheres and concentration of measure	297
11.1	Spheres and balls in $\mathbb{R}^n$	298
11.2	Hyperspheres: volume, surface and surprises	298
11.3	The volume vanishes: the ball against the cube	300
11.4	Concentration of measure	302
11.4.1	Distances in high dimension	305
11.5	Rotations in any dimension	306
11.6	Quaternions and rotations of space	309
11.7	The Hopf fibration, explicitly	311
11.8	Industrial applications	314
11.9	Assigned exercises	314
11.10	Worked exercises	315
11.11	Numerical and symbolic exercises with solutions	318
11.11.1	Numerical exercises	318
11.11.2	Symbolic exercises	319
11.11.3	Solutions to the numerical exercises	319
11.11.4	Solutions to the symbolic exercises	323
11.12	Self-assessment quiz	326
11.12.1	Supplementary questionnaire	327
11.13	Teacher’s key	328
11.14	Chapter formulary	330
12	Topology of the circle: covering, winding number and fundamental group	333
12.1	The circle as a topological space	334
12.2	The circle as the quotient $\mathbb{R}/2\pi\mathbb{Z}$	337
12.3	The exponential covering	338
12.4	Lifting of paths and homotopies	340
12.5	The winding number	343
12.6	The fundamental group of S^1	346
12.7	The degree of maps $S^1 \rightarrow S^1$	349
12.8	Panorama: hairy ball and Hopf fibration	351
12.9	Configuration space and cable twisting	352
12.10	Assigned exercises	353
12.11	Worked exercises	354
12.12	Self-assessment quiz	356
12.13	Teacher’s key	357
12.14	Chapter formulary	359
13	The circle as a group: abstract harmonic analysis	361
13.1	The circle as a topological group	362
13.2	S^1 as a Lie group of dimension 1	363
13.3	The invariant measure $d\theta/2\pi$	366
13.4	The characters of S^1	369

13.5	Closed subgroups and dense subgroups	373
13.6	Assigned exercises	376
13.7	Worked exercises	377
13.8	Self-assessment quiz	380
13.9	Teacher's key	381
13.10	Chapter formulary	383
14	Tangencies and packings: Ford circles, Farey and optimality	386
14.1	Tangency and curvature: what is recalled	387
14.2	Farey fractions	387
14.3	Ford circles	389
14.4	The kissing number in the plane	392
14.5	Packing density	394
14.6	Applications to automation: nesting, cabling, pallets	398
14.7	Assigned exercises	401
14.8	Worked exercises	402
14.9	Self-assessment quiz	405
14.10	Teacher's key	405
14.11	Chapter formulary	408
B	Complex and harmonic analysis on the disc	410
15	Complex analysis on the disk: from Cauchy to residues	411
15.1	Holomorphy, paths, and the two fundamental estimates	412
15.2	Goursat's theorem and Cauchy's theorem on the disk	415
15.3	Holomorphic functions and the circle: from Cauchy to residues	418
15.3.1	Laurent series and residues	422
15.4	Derivatives, analyticity, and Cauchy's estimates	425
15.4.1	Deformation between concentric circles and Cauchy's formula on an annulus	429
15.5	Isolated zeros, the identity principle, and maximum modulus	430
15.6	Schwarz's lemma and the automorphisms of the disk	434
15.7	Classification of isolated singularities	438
15.8	Winding number, the argument principle, and Rouché's theorem	442
15.9	Three real integrals computed with residues	449
15.10	Exercises inherited from Volume II	453
15.11	Conformal mapping: why the disk is a universal model	457
15.11.1	Primitives, logarithms and roots	457
15.11.2	The compactness step: Montel proved here	457
15.11.3	The theorem and the decisive calculation	458
15.11.4	An explicit map and two different checks	459
15.11.5	Exercises with solutions	460
15.12	Assigned exercises	460
15.13	Worked exercises	462
15.14	Self-assessment quiz	465
15.15	Teacher's key	465
15.16	Chapter formulary	469
16	Harmonic functions and the Poisson kernel in the disc	472
16.1	Laplace's equation and harmonic functions	474
16.1.1	Harmonic and holomorphic: the harmonic conjugate	475
16.2	The mean value property	479

16.3	The maximum principle and uniqueness for Dirichlet	480
16.4	The Poisson kernel	483
16.5	The Poisson formula and the Dirichlet problem in the disc	487
16.6	Harnack and Liouville	494
16.6.1	Gradient estimate, a second route to Liouville, reflection	498
16.7	The Fourier series expansion of the solution	500
16.8	Assigned exercises	503
16.9	Worked exercises	504
16.10	Self-assessment quiz	507
16.11	Teacher's key	508
16.12	Formulas of the chapter	511
17	Convergence of Fourier series	514
17.1	Coefficients, partial sums, Riemann–Lebesgue	515
17.2	Convergence of the Fourier series	518
17.2.1	The Dirichlet kernel and the Gibbs phenomenon	519
17.2.2	Pointwise convergence: the Dirichlet–Jordan theorem	520
17.2.3	Uniform convergence	522
17.2.4	The Fejér kernel and Cesàro means	523
17.2.5	The Poisson kernel and Abel summation	525
17.2.6	The Gibbs phenomenon: the exact constant	526
17.3	The Lebesgue constants and logarithmic divergence	528
17.4	Criteria for pointwise convergence: Dini and Dirichlet–Jordan	533
17.4.1	Functions of bounded variation	535
17.5	Uniqueness of the coefficients	539
17.6	The sine-integral: two independent computations	540
17.7	Uniform convergence for regular functions: the remainder estimate	542
17.8	Panorama: what this chapter does not prove	544
17.9	Exercises inherited from Volume II	545
17.10	Assigned exercises	549
17.11	Worked exercises	550
17.12	Self-assessment quiz	554
17.13	Teacher's key	555
17.14	Formulary of the chapter	557
18	Partial differential equations on the circle and in the disc	559
18.1	The Laplacian in polar coordinates	561
18.2	Laplace's equation in the disc: separation of variables	563
18.3	Maximum principle, uniqueness, stability	568
18.4	Application: the heat equation on the circle	570
18.5	The wave equation on the circle	574
18.6	The circular membrane: from separation to Bessel's equation	578
18.7	The Bessel function of the first kind	580
18.8	Vibration modes, Bessel zeros, and frequencies	589
18.9	The heat equation in the disc	594
18.10	Panorama: spectral completeness	596
18.11	Exercises inherited from Volume II	597
18.12	Assigned exercises	599
18.13	Worked exercises	600
18.14	Self-assessment quiz	603
18.15	Teacher's key	604
18.16	Chapter formulary	606

C	Transforms	609
19	The Fourier transform	610
19.1	A single convention, and the dictionary of the others	612
19.2	From the series to the Fourier transform	613
19.3	Elementary properties: translation, modulation, scaling, conjugation	615
19.4	Convolution and autocorrelation	618
19.5	The Riemann–Lebesgue lemma	620
19.6	The Gaussian, computed in full	621
19.7	Rectangle, sinc function, and triangle	623
19.8	The Schwartz class and the inversion formula	625
19.9	The Plancherel theorem	629
19.10	Periodization and the Poisson summation formula	631
19.11	The uncertainty principle	634
19.12	Tempered distributions: the delta and the Dirac comb	635
19.13	The table of transforms, row by row	640
19.14	Exercises inherited from Volume II	642
19.15	Assigned exercises	642
19.16	Solved exercises	643
19.17	Self-assessment quiz	647
19.18	Teacher’s key	648
19.19	Formulary of the chapter	651
20	The Laplace transform	654
20.1	The Laplace transform	655
20.2	Convergence: the half-plane and the two abscissas	658
20.3	Holomorphy of the transform	662
20.4	Computation rules, with the region of convergence	665
20.5	The elementary transforms, computed one by one	669
20.6	Initial value and final value	674
20.7	Inversion: uniqueness, partial fractions, residues	678
20.8	Laplace and Fourier: the restriction to the imaginary axis	684
20.9	Exercises inherited from Volume II	686
20.10	Assigned exercises	687
20.11	Worked exercises	688
20.12	Self-assessment quiz	692
20.13	Teacher’s key	693
20.14	Formulary of the chapter	695
21	The Z-transform and the discrete-time Fourier transform	699
21.1	Discrete signals, LTI systems and convolution	701
21.2	The Z-transform and its region of convergence	702
21.2.1	The Cauchy–Hadamard lemma and the annulus structure	703
21.2.2	Holomorphy, inversion and uniqueness	706
21.3	The five operational properties	708
21.4	The DTFT as the restriction of the zeta transform to the unit circle	711
21.5	BIBO stability: summability, annulus, poles	714
21.5.1	Causal rational systems: the location of the poles	715
21.6	The three planes: Laplace, zeta and Fourier	719
21.6.1	The bilinear transform	721
21.7	Digital filter design: from continuous to discrete	724
21.8	Exercises inherited from Volume II	726

21.9	Assigned exercises	728
21.10	Worked exercises	729
21.11	Self-assessment quiz	733
21.12	Teacher's key	734
21.13	Formulary of the chapter	736
22	The discrete Fourier transform	740
22.1	Definition, convention, first properties	742
22.2	Orthogonality of the discrete exponential vectors	743
22.3	Inversion, proved twice	745
22.4	The DFT matrix: Vandermonde, unitarity, determinant, eigenvalues	746
22.5	Circular convolution and the discrete convolution theorem	751
22.6	Discrete Parseval identity	753
22.7	Conjugate symmetry of real signals	754
22.8	Circulant matrices diagonalized by the DFT	755
22.9	The DFT and the DTFT: spectrum sampling and zero-padding	758
22.10	The Discrete Fourier Transform and the FFT algorithm	762
22.10.1	The Cooley-Tukey algorithm	762
22.10.2	An SCL implementation for PLC	765
22.10.3	Windows and spectral leakage	768
22.11	Windows: coherent gain, equivalent bandwidth, resolution	769
22.12	An eight-point DFT by hand	774
22.12.1	The eight-point example, worked in full	774
22.13	Exercises inherited from Volume II	779
22.14	Assigned exercises	782
22.15	Solved exercises	783
22.16	Self-assessment quiz	786
22.17	Teacher's key	788
22.18	Formulary of the chapter	789
23	The fast Fourier transform	792
23.1	What the definition costs: the exact count	794
23.2	The even-odd decomposition	797
23.3	The butterfly	800
23.4	The radix-2 algorithm with decimation in time	801
23.5	The cost: recurrence, solution, exact count	804
23.6	From recursion to a loop: the bit-reversal permutation	808
23.7	The decimation-in-frequency variant	812
23.8	The example $N = 8$: exact symbolic form	813
23.9	The example $N = 8$: numerical form and checks	816
23.10	The inverse transform requires no second algorithm	819
23.11	Zero-padding: what it adds and what it does not	820
23.12	When N is not a power of two	822
23.12.1	The general factorization	822
23.12.2	Bluestein and Rader: any N , prime N	825
23.13	Round-off error in finite-precision arithmetic	828
23.14	Assigned exercises	833
23.15	Solved exercises	834
23.16	Self-assessment quiz	838
23.17	Teacher key	839
23.18	Formulary of the chapter	842

D	Signals, control, telecommunications	846
24	Signals and linear systems: sampling and frequency response	847
24.1	Signals and systems: linearity and time-invariance	849
24.2	The convolution representation	850
24.3	Complex exponentials are eigenfunctions	855
24.4	BIBO stability	857
24.5	Causality	859
24.6	Frequency response: magnitude and phase	861
24.7	Phase delay and group delay	864
24.8	The Nyquist-Shannon sampling theorem	868
24.9	The reconstruction formula with the sinc function	872
24.10	Aliasing	875
24.11	The analytic signal and the Hilbert transform	877
24.12	Exercises inherited from Volume II	881
24.13	Assigned exercises	882
24.14	Worked exercises	883
24.15	Self-assessment quiz	886
24.16	Teacher's key	887
24.17	Chapter formulary	890
25	The circle in control and transmission lines	893
25.1	Frequency response and transfer function	894
25.2	Bode plots	895
25.3	The argument principle and the Nyquist criterion	897
25.4	The M and N circles	900
25.5	The modulus margin and the sensitivity circle	902
25.6	The circle criterion for nonlinear systems	905
25.7	The root locus	908
25.8	Transmission lines and the reflection coefficient	911
25.9	The Smith chart	913
25.10	Back to the unit circle: discrete-time stability	916
25.11	Numerical exercises	917
25.12	Symbolic exercises	918
25.13	Solutions to the numerical exercises	919
25.14	Solutions to the symbolic exercises	924
25.15	Self-assessment quiz	929
25.16	Chapter formulary	931
25.17	Modulus margin of a third-order loop	933
26	Telecommunications: complex baseband, IQ and modulations	935
26.1	The bandpass signal and its complex envelope	937

Part A

Differential and global geometry

CHAPTER 1

Prologue: the circle as guiding thread

This volume has a single protagonist: the circle. Not as an isolated figure, but as a *seed* from which curvature, isometries, the sphere, geometry in any dimension and even topology sprout — and, on the applied side, robot kinematics and machine motion control. Before entering the mathematics, it is worth recalling where the circle comes from and why it has traversed three thousand years of history remaining at the center of geometric thought.

Unit circle

Figure 1.1. The circle generates the trigonometric functions: a point on the unit circle has coordinates $(\cos \theta, \sin \theta)$; the two projections trace sine and cosine as θ varies — the first, fundamental link between the circle and analysis.

1.1. Three thousand years around a circle

The circle is among the first mathematical objects studied with rigor. Already the Babylonians and Egyptians estimated its area; but the first *scientific* treatment is by Archimedes of Syracuse (287–212 BC), who in *On the Measurement of the Circle* proved, by contradiction and with the method of exhaustion, that the area of a circle equals that of a right triangle with legs the radius and the circumference, i.e. $A = \frac{1}{2}rC$. Using inscribed and circumscribed polygons up to 96 sides, Archimedes enclosed π between $\frac{223}{71} \approx 3.1408$ and $\frac{22}{7} \approx 3.1429$: the first algorithm in history to approximate a constant with controlled precision.

Remark 1.1: The method of exhaustion as ancestor of calculus. Enclosing a curve between polygons that approximate it ever better is, in embryo, the idea of limit and of integral. The same scheme — approximating the curved with the rectilinear and passing to the limit — returns throughout the volume: in arc length (Chapter 1), in the calculation of the area of the sphere (Chapter 9) and in the volume of the n -dimensional ball (Chapter 12).

1.2. The quadrature of the circle

For over two millennia geometers asked whether, with ruler and compass, one could construct a square of area equal to that of a given circle: the celebrated *quadrature of the circle*. The question turned out to be deeper than expected: constructing with ruler and compass is equivalent to

admitting only numbers obtainable from rational operations and square roots, and squaring the circle would require constructing $\sqrt{\pi}$. The breakthrough came in 1882, when Ferdinand von Lindemann proved that π is **transcendental** (it is not the root of any polynomial with rational coefficients): since constructible numbers are algebraic, π is not constructible and the quadrature of the circle is *impossible*.

***Remark 1.2: An anecdote for students: the “law on π ”.** In 1897 an amateur physician convinced the Indiana House to pass a bill (the famous Indiana Pi Bill) which, attempting to “square the circle”, implied wrong values of π (including 3.2). The State Senate, warned by a mathematician passing through, rejected it. The moral: a mathematical constant is not established by decree. The transcendence of π is not a detail, but the deep reason why a circular arc is not a polynomial curve and must be represented, in modern CNC controllers, via rational curves (NURBS, Chapter 15).*

1.3. The circle as generator

The guiding idea of the volume is that almost every geometric object we will encounter is “the circle in a richer context”.

- **Curvature** (Chapter 2): the circle is the only curve with constant curvature, and every curve is locally approximated by its osculating circle.
- **Isometries** (Chapter 4): the circle is the only conic invariant under the whole group $O(2)$; its symmetries are $SO(2) \cong \mathbb{T}$.
- **Sphere** (Chapters 8 and 9): the sphere is the circle “raised” to three dimensions, with great circles in place of lines.
- **Dimension n** (Chapter 12): S^{n-1} generalizes the circle to every dimension, with surprising phenomena.
- **Topology** (Chapter 13): $\pi_1(S^1) = \mathbb{Z}$ makes the circle topologically unique and lies at the root of the Hopf fibration.
- **Robotics and automation**: the constant-curvature arc is the “brick” of circular interpolation; rotations ($SO(3)$, quaternions) preserve the sphere; the topology of the cable governs cable twisting.

Cardioid $r = 1 + \cos \theta$

Figure 1.1: Two curves generated by the motion of a circle: the *cardioid* (trace of a point of a circle rolling on an equal circle) and the *cycloid* (point of a circle rolling on a line). The circle is not only a static figure: in motion it generates an entire family of curves, many of which recur in the volume (the cycloid as brachistochrone and as evolute of itself).

Remark 1.3: Why an automation engineer cares. Every rotary motion of a rotating axis, every G02/G03 interpolation of a machine tool, every orientation of a tool around an axis is, mathematically, an element of the theory of the circle and its symmetries. Understanding the circle deeply — its curvature, its isometries, its extension to the sphere and to $SO(3)$ — means understanding the language with which PLCs and robots are programmed. This volume holds together the two souls: mathematical rigor and industrial application.

Self-assessment quiz

1. Archimedes proved that the area of the circle is: (a) πr (b) $\frac{1}{2}rC$ (c) $2\pi r$ (d) r^2
2. The quadrature of the circle is impossible because π is: (a) irrational (b) transcendental (c) negative (d) very large
3. The method of exhaustion is the ancestor of: (a) linear algebra (b) integral calculus (c) number theory (d) topology
4. A circular arc in CNC is represented exactly with: (a) polynomials (b) NURBS (rational) (c) lines (d) natural splines
5. The group of rotations of the circle in the plane is: (a) $\mathbb{Z}$ (b) $SO(2)$ (c) $SO(3)$ (d) $\mathbb{R}$

Solutions: Q1 (b); Q2 (b) Lindemann 1882; Q3 (b); Q4 (b); Q5 (b) $SO(2) \cong \mathbb{T}$.

CHAPTER 2

Plane curves: curvature, osculating circle, evolutes

In the previous volumes the circle appeared as a set of equidistant points (Volume I), as the multiplicative group of complex numbers of modulus one (Volume II, Chapter 3) and as the domain of harmonic analysis (Volume II, Chapter 4). One last point of view remains, historically the latest and conceptually the deepest: the circle as the *unit of measurement of curvature*. This is the viewpoint of differential geometry, and it grows out of an elementary question — how curved is a curve? — whose answer is: as curved as the circle that resembles it most.

INFO

The idea in one line. To each point of a regular curve one attaches the circle that best approximates it, the *osculating* circle; the reciprocal of its radius is the curvature. The circle is then the curve of constant curvature, and curvature, by the fundamental theorem, determines the curve up to a rigid motion: prescribing it means designing the curve. The *global* theorems that follow from this theory — rotation index, isoperimetric inequality, four vertices — are collected in Chapter 4.

Warning. Conventions of this chapter.

- Curves are *plane*, of class C^2 at least, parametrised by an interval of $\mathbb{R}$; we write $\gamma(t) = (x(t), y(t))$, or $\gamma(s)$ when the parameter is arc length.
- A curve is **regular** if $\gamma'(t) \neq 0$ for every t ; **closed** if it is defined on $[a, b]$ with γ and all derivatives agreeing at the endpoints; **simple** if it is injective on $[a, b]$.
- The positive orientation is counterclockwise; with this choice the curvature of a convex curve traversed counterclockwise is positive.
- We systematically identify $\mathbb{R}^2$ with $\mathbb{C}$, as in Chapter 3, whenever this shortens the computations.

INFO

Level and prerequisites. Level B–C. Sections 2.1 and 2.2 are level B and require only one-variable differential calculus and the dot product in the plane; Sections 2.3 and 2.4 are level B–C and additionally use differentiation of vector-valued functions and the identification $\mathbb{R}^2 \simeq \mathbb{C}$. Prerequisites inside the treatise: circle, tangents and normals (Volume I, Chapters 2 and 4); complex numbers in polar form (Volume II, Chapter 3); the definite integral and Fourier series (Volume II, Chapter 4), the latter used only in Chapter 4. No prior knowledge of differential geometry is assumed.

2.1. Arc length and the unit tangent

Definition 2.1: Arc length and the arc-length parameter. Let $\gamma : [a, b] \rightarrow \mathbb{R}^2$ be regular. The **length** of γ is

$$L = \int_a^b \|\gamma'(t)\| dt, \quad \|\gamma'(t)\| = \sqrt{x'(t)^2 + y'(t)^2},$$

and the **arc-length parameter** is the function

$$s(t) = \int_a^t \|\gamma'(u)\| du.$$

Since $s'(t) = \|\gamma'(t)\| > 0$, the function s is strictly increasing and invertible: one may reparametrise γ by s , obtaining a curve with $\|\gamma'(s)\| = 1$ for every s , said to be **parametrised by arc length**.

Example 2.1: The circle in arc length. For the circle of radius r centred at the origin, $\gamma(t) = (r \cos t, r \sin t)$ with $t \in [0, 2\pi]$:

$$\gamma'(t) = (-r \sin t, r \cos t), \quad \|\gamma'(t)\| = r\sqrt{\sin^2 t + \cos^2 t} = r,$$

a constant. Hence $s(t) = rt$, and the total length is $L = 2\pi r$ — the circumference formula, here *derived* rather than assumed. Reparametrising with $t = s/r$:

$$\gamma(s) = \left(r \cos \frac{s}{r}, r \sin \frac{s}{r} \right), \quad s \in [0, 2\pi r],$$

and indeed $\|\gamma'(s)\| = 1$. ✓

Definition 2.2: Unit tangent and unit normal. For a curve parametrised by arc length one sets

$$T(s) = \gamma'(s) \quad (\text{unit tangent}),$$

and defines the **unit normal** $N(s)$ as the vector obtained by rotating $T(s)$ by $+90^\circ$:

$$T = (T_1, T_2) \implies N = (-T_2, T_1).$$

Under the identification $\mathbb{R}^2 \cong \mathbb{C}$ this is simply $N = iT$ (Theorem (Volume II, Chapter 3) of Chapter 3).

Lemma 2.1: The derivative of a unit vector is orthogonal to it. Let $v : I \rightarrow \mathbb{R}^2$ be differentiable with $\|v(s)\| = c$ constant. Then $\langle v(s), v'(s) \rangle = 0$ for every s .

Proof. From $\|v\|^2 = \langle v, v \rangle = c^2$, differentiating and using bilinearity and symmetry of the scalar product,

$$0 = \frac{d}{ds} \langle v, v \rangle = 2\langle v, v' \rangle,$$

which is the claim. Geometrically: a vector of fixed length can only rotate, and the velocity of rotation is perpendicular to the vector itself. □

2.2. Curvature and the osculating circle

Definition 2.3: Curvature. Let γ be a plane curve of class C^2 parametrised by arc length. By Lemma 2.1, $T'(s)$ is orthogonal to $T(s)$, hence parallel to $N(s)$: there is a unique scalar function $k(s)$ with

$$T'(s) = k(s) N(s).$$

The function k is the **signed curvature** of γ . Its absolute value $|k|$ is the **geometric curvature**; where $k(s) \neq 0$, the number

$$\rho(s) = \frac{1}{|k(s)|}$$

is the **radius of curvature**.

Theorem 2.1: Frenet formulas in the plane. For a plane C^2 curve parametrised by arc length,

$$T'(s) = k(s) N(s), \quad N'(s) = -k(s) T(s).$$

Proof. **Step 1 — the first formula.** This is Definition 2.3.

Step 2 — the second. Since $\|N\| = 1$, Lemma 2.1 gives $N' \perp N$, hence N' is parallel to T : there is $\lambda(s)$ with $N' = \lambda T$.

Step 3 — determining λ . From $\langle T, N \rangle = 0$, differentiating:

$$0 = \langle T', N \rangle + \langle T, N' \rangle = k \langle N, N \rangle + \lambda \langle T, T \rangle = k + \lambda,$$

whence $\lambda = -k$.

Step 4 — the complex reading. Identifying $\mathbb{R}^2$ with $\mathbb{C}$ and writing $T(s) = e^{i\vartheta(s)}$ (legitimate because $|T| = 1$, by Theorem (Volume II, Chapter 3) of Chapter 3),

$$T'(s) = i\vartheta'(s)e^{i\vartheta(s)} = \vartheta'(s) N(s),$$

hence $k = \vartheta'$: **curvature is the angular velocity of the tangent**. This formulation, which we shall use repeatedly, shows that the whole Frenet calculus in the plane reduces to differentiating a complex exponential. $\square$

Theorem 2.2: Curvature of the circle. The circle of radius r traversed counterclockwise has constant curvature $k = 1/r$; traversed clockwise, $k = -1/r$. A straight line has zero curvature.

Proof. **Step 1 — direct computation.** From Example 2.1, $\gamma(s) = (r \cos(s/r), r \sin(s/r))$, hence

$$T(s) = \left(-\sin \frac{s}{r}, \cos \frac{s}{r} \right), \quad T'(s) = \left(-\frac{1}{r} \cos \frac{s}{r}, -\frac{1}{r} \sin \frac{s}{r} \right).$$

Step 2 — comparison with N . Rotating T by $+90^\circ$ as in Definition 2.2:

$$N(s) = \left(-\cos \frac{s}{r}, -\sin \frac{s}{r} \right),$$

the unit vector pointing *towards the centre*. Comparing, $T' = \frac{1}{r}N$, i.e. $k = 1/r$.

Step 3 — clockwise. Substituting $s \mapsto -s$ changes the sign of T but not that of T' with respect to s ; repeating the computation gives $k = -1/r$.

Step 4 — the line. For $\gamma(s) = p + sv$ with $\|v\| = 1$ we have $T = v$ constant, hence $T' = 0$ and $k = 0$.

Step 5 — dimensional check. k has the dimensions of an inverse length: m^{-1} . A large circle is barely curved, a small one very much so: the curvature of a circle of radius 1 km is 10^{-3} m^{-1} , that of a circle of radius 1 mm is 10^3 m^{-1} . ✓ □

Theorem 2.3: Curvature formula for arbitrary parametrisations. Let $\gamma(t) = (x(t), y(t))$ be regular of class C^2 , not necessarily parametrised by arc length. Then

$$k(t) = \frac{x'(t)y''(t) - y'(t)x''(t)}{(x'(t)^2 + y'(t)^2)^{3/2}}.$$

In particular, for the graph of a function $y = f(x)$,

$$k(x) = \frac{f''(x)}{(1 + f'(x)^2)^{3/2}}.$$

Proof. Step 1 — change of parameter. Let $v(t) = \|\gamma'(t)\|$, so $ds/dt = v$. By the chain rule,

$$T = \frac{d\gamma}{ds} = \frac{\gamma'(t)}{v}, \quad \frac{dT}{ds} = \frac{1}{v} \frac{d}{dt} \left(\frac{\gamma'}{v} \right) = \frac{\gamma''v - \gamma'v'}{v^3}.$$

Step 2 — projection onto N . The curvature is the component of dT/ds along $N = \frac{1}{v}(-y', x')$:

$$k = \left\langle \frac{dT}{ds}, N \right\rangle = \frac{1}{v^4} \left\langle \gamma''v - \gamma'v', (-y', x') \right\rangle.$$

The term with γ' gives $\langle (x', y'), (-y', x') \rangle = 0$, so only

$$k = \frac{v}{v^4} \left\langle (x'', y''), (-y', x') \right\rangle = \frac{x'y'' - y'x''}{v^3}$$

survives, which is the stated formula since $v^3 = (x'^2 + y'^2)^{3/2}$.

Step 3 — the graph case. With $x = t$, $y = f(t)$: $x' = 1$, $x'' = 0$, $y' = f'$, $y'' = f''$, whence $k = f''/(1 + f'^2)^{3/2}$.

Step 4 — check on the circle. With $\gamma(t) = (r \cos t, r \sin t)$:

$$x' = -r \sin t, \quad y' = r \cos t, \quad x'' = -r \cos t, \quad y'' = -r \sin t,$$

$$x'y'' - y'x'' = r^2 \sin^2 t + r^2 \cos^2 t = r^2, \quad (x'^2 + y'^2)^{3/2} = r^3,$$

hence $k = r^2/r^3 = 1/r$, in agreement with Theorem 2.2. ✓ □

Definition 2.4: Osculating circle. Let γ be of class C^2 with $k(s_0) \neq 0$. The **osculating circle** of γ at $\gamma(s_0)$ is the circle of radius $\rho(s_0) = 1/|k(s_0)|$ and centre

$$c(s_0) = \gamma(s_0) + \frac{1}{k(s_0)} N(s_0),$$

called the **centre of curvature**. The centre lies on the side towards which the curve bends.

Theorem 2.4: Characterisation of the osculating circle. Among all circles tangent to γ at $P = \gamma(s_0)$, the osculating circle is the only one having second-order contact with γ : that is, the only one for which the distance between curve and circle is $o((s - s_0)^2)$ as $s \rightarrow s_0$. Equivalently, it is the limit of the circles through three points of the curve as the

three points tend to P .

Proof. Step 1 — Taylor expansion of the curve. Set $s_0 = 0$ and $P = \gamma(0)$. By Taylor to second order, using $\gamma' = T$ and $\gamma'' = T' = kN$:

$$\gamma(s) = P + sT(0) + \frac{s^2}{2}k(0)N(0) + o(s^2).$$

Step 2 — expansion of the osculating circle. The circle with centre $c = P + \frac{1}{k(0)}N(0)$ and radius $\rho = 1/|k(0)|$, parametrised by its own arc length from P and with the same tangent, has by Theorem 2.2 constant curvature $k(0)$; its Taylor expansion at P is therefore, by the same computation as in Step 1,

$$\sigma(s) = P + sT(0) + \frac{s^2}{2}k(0)N(0) + o(s^2).$$

Step 3 — comparison. The two expansions agree up to and including second order: $\gamma(s) - \sigma(s) = o(s^2)$.

Step 4 — uniqueness. A circle tangent at P with radius $\rho' \neq \rho$ has curvature $k' \neq k(0)$; its expansion differs from that of γ already in the degree-2 term, by $\frac{s^2}{2}(k' - k(0))N(0) \neq o(s^2)$. So the contact is only of first order.

Step 5 — the limit of circles through three points. Let A, B, C be three distinct points of γ near P . By the circumscribed circle theorem (Volume I) there is a unique circle through them. As A, B, C tend to P , the perpendicular bisectors of AB and BC tend to lines perpendicular to the tangent at P , and their intersection tends to the point at distance $\lim \frac{|AB||BC||CA|}{4 \text{Area}(ABC)}$ from P : applying the circumradius formula and expanding as in Step 1 gives exactly $1/|k(0)|$. The details are Exercise S2.

Step 6 — why “osculating”. The name, introduced by Leibniz, comes from the Latin *osculari*, “to kiss”: the circle does not merely touch the curve (first-order contact, i.e. tangency), but adheres to it to second order. $\square$

Remark 2.1: Curvature as a “local circle”. Theorem 2.4 justifies the definition of curvature: to measure how curved a curve is means to find the circle that resembles it most, and read off its radius. In this sense the circle is not one curve among others, but the unit of measurement of the curvature of all the others — just as the straight line is the unit of measurement of direction. That is why this chapter belongs in a treatise on the circle.

Example 2.2: Curvature of a parabola and of an ellipse. Parabola $y = x^2$. By Theorem 2.3, with $f' = 2x$ and $f'' = 2$:

$$k(x) = \frac{2}{(1 + 4x^2)^{3/2}}.$$

At the vertex $x = 0$: $k = 2$, hence $\rho = 0.5$: the osculating circle has radius $1/2$ and centre $(0, 0.5)$. For $x = 1$: $k = 2/5^{3/2} = 2/11.1803 = 0.178885$, hence $\rho = 5.5902$: the parabola “straightens out” quickly as one moves from the vertex.

Ellipse $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$. With $\gamma(t) = (a \cos t, b \sin t)$:

$$x' = -a \sin t, \quad y' = b \cos t, \quad x'' = -a \cos t, \quad y'' = -b \sin t,$$

$$x'y'' - y'x'' = ab \sin^2 t + ab \cos^2 t = ab,$$

$$k(t) = \frac{ab}{(a^2 \sin^2 t + b^2 \cos^2 t)^{3/2}}.$$

At the ends of the major axis ($t = 0$, point $(a, 0)$): $k = ab/b^3 = a/b^2$, hence $\rho = b^2/a$. At the ends of the minor axis ($t = \pi/2$): $k = b/a^2$, $\rho = a^2/b$.

Numerical check. With $a = 3$, $b = 2$: $\rho(0) = 4/3 = 1.\overline{33}$ and $\rho(\pi/2) = 9/2 = 4.5$. The ratio of the two extreme radii of curvature is $(a/b)^3 = (1.5)^3 = 3.375$, and indeed $4.5/1.\overline{33} = 3.375$. ✓

Degeneracy check. For $a = b = r$ both formulas give $\rho = r$, the circle: the curvature is constant and the ellipse degenerates into the circle, as it must. ✓

Theorem 2.5: Characterisation of the circle by curvature. Let γ be a connected plane curve of class C^2 with constant curvature k . Then:

- (i) if $k = 0$, γ is contained in a straight line;
- (ii) if $k \neq 0$, γ is contained in a circle of radius $1/|k|$.

Proof. (i) If $k \equiv 0$ then $T' = 0$, hence T is a constant v and $\gamma(s) = \gamma(0) + sv$: a line.

(ii) Let $k \neq 0$ be constant. Consider

$$c(s) = \gamma(s) + \frac{1}{k} N(s),$$

the centre of curvature of Definition 2.4. Differentiating and using the Frenet formulas (Theorem 2.1),

$$c'(s) = T(s) + \frac{1}{k} N'(s) = T(s) + \frac{1}{k} (-kT(s)) = 0.$$

So c is constant, say c_0 . But then

$$\|\gamma(s) - c_0\| = \left\| -\frac{1}{k} N(s) \right\| = \frac{1}{|k|}$$

for every s : all points of γ are at distance $1/|k|$ from the fixed point c_0 , so by the very definition of a circle (Volume I), γ lies on the circle with centre c_0 and radius $1/|k|$.

Step 3 — the role of the C^2 hypothesis. The proof uses only the existence and differentiability of N , guaranteed by $\gamma \in C^2$. The curve need not be closed: an open curve of constant curvature is an *arc* of a circle.

Step 4 — consistency check. The computation also displays the geometric meaning: when the curvature is constant, the centre of curvature does not move. When it varies, the centre of curvature describes a curve — the evolute — the subject of the next section. □

Best practice. To check that a curve is a circle, the computation of Theorem 2.5(ii) — showing that the centre of curvature is constant — is almost always quicker than manipulating the equation of the curve directly. It also works in reverse: if in some problem the centre of curvature turns out to be constant, one has already proved that the curve is an arc of a circle, with no further computation.

Proposition 2.1: Tait–Kneser theorem. Let $\gamma : [a, b] \rightarrow \mathbb{R}^2$ be of class C^3 , parametrised by arc length, with curvature $k > 0$ and free of vertices, that is $k'(s) \neq 0$ for every s . Then for $a \leq s_1 < s_2 \leq b$ the osculating disc at $\gamma(s_1)$ is contained in the interior of the one at $\gamma(s_2)$, or vice versa, according to the direction in which $\rho = 1/k$ is monotone. In particular the osculating circles at two distinct points of the arc are disjoint and nested.

Proof. Step 1 — velocity of the evolute. Let $e(s) = \gamma(s) + \rho(s)N(s)$ be the centre of curvature, that is the evolute. By Theorem 2.6(i),

$$e'(s) = \rho'(s) N(s).$$

Since $k > 0$ and $k' \neq 0$, the derivative $\rho' = -k'/k^2$ never vanishes either and, being continuous, it has constant sign on $[a, b]$: ρ is strictly monotone.

Step 2 — estimate of the distance between the centres. Integrating,

$$e(s_2) - e(s_1) = \int_{s_1}^{s_2} \rho'(\sigma) N(\sigma) d\sigma,$$

and by the triangle inequality for integrals of vector-valued functions,

$$\|e(s_2) - e(s_1)\| \leq \int_{s_1}^{s_2} |\rho'(\sigma)| d\sigma = |\rho(s_2) - \rho(s_1)|,$$

where the last equality uses that ρ' has constant sign (Step 1).

Step 3 — the inequality is strict. Suppose by contradiction that equality holds and let u be the unit vector of $e(s_2) - e(s_1)$ (non-zero, otherwise $\rho(s_2) = \rho(s_1)$, against strict monotonicity). Then

$$\int_{s_1}^{s_2} (|\rho'(\sigma)| - \rho'(\sigma) \langle N(\sigma), u \rangle) d\sigma = 0,$$

and the integrand is continuous and non-negative, because $|\langle N, u \rangle| \leq 1$; hence it vanishes identically, which together with $\rho'(\sigma) \neq 0$ forces $\langle N(\sigma), u \rangle = \pm 1$, that is $N(\sigma) = \pm u$ constant on $[s_1, s_2]$. But then $N' \equiv 0$, whereas the Frenet formulae (Theorem 2.1) give $N' = -kT$ with $\|N'\| = k > 0$: a contradiction. Therefore

$$\|e(s_2) - e(s_1)\| < |\rho(s_2) - \rho(s_1)|.$$

Step 4 — from the inequality to the nesting. Two closed discs $D(c_1, r_1)$ and $D(c_2, r_2)$ satisfy $D(c_1, r_1) \subset \text{int } D(c_2, r_2)$ if and only if $\|c_2 - c_1\| < r_2 - r_1$: indeed for every $x \in D(c_1, r_1)$ one has $\|x - c_2\| \leq \|x - c_1\| + \|c_1 - c_2\| < r_1 + (r_2 - r_1) = r_2$, and conversely the point $c_1 + r_1 \frac{c_1 - c_2}{\|c_1 - c_2\|}$ (or any boundary point if $c_1 = c_2$) realises the distance $\|c_1 - c_2\| + r_1$, which must stay $< r_2$. If ρ is increasing one applies Step 3 with $c_1 = e(s_1)$, $r_1 = \rho(s_1)$, $c_2 = e(s_2)$, $r_2 = \rho(s_2)$; if it is decreasing the roles are exchanged.

Step 5 — independent numerical check. On the logarithmic spiral $\gamma(t) = e^t(\cos t, \sin t)$ one has $\rho(t) = \sqrt{2}e^t$ and $e(t) = e^t(-\sin t, \cos t)$ (Exercise 2.18 and a direct computation of the centre of curvature). For $t = 0$ and $t = 1$:

$$\|e(1) - e(0)\| = 2.334881 < \rho(1) - \rho(0) = 3.844231 - 1.414214 = 2.430017. \checkmark$$

The two values are recomputed independently in the script `verifica_cap02_cap04.py` (block [C2-7]), where the centre of curvature is obtained from the general formula $\gamma + \frac{1}{k}N$ and not from the closed form. $\square$

Remark 2.2: Why it looks impossible. The osculating circles all «kiss» the same curve, and yet they never meet: the curve is contained in none of them, it crosses each of them passing from the inside to the outside. The apparent paradox dissolves once one observes that the contact is of second order but not of third: where $k' \neq 0$, the osculating circle cuts the curve instead of staying on one side of it (Theorem 2.4). The family of osculating circles of a vertex-free arc therefore fills an annular region of the plane in layers, like the skins of an onion.

Example 2.3: Curvature of the catenary. For the catenary $y = a \cosh(x/a)$, with $a > 0$, one has $y' = \sinh(x/a)$, $y'' = \frac{1}{a} \cosh(x/a)$ and $1 + y'^2 = \cosh^2(x/a)$; the formula for graphs (Theorem 2.3) gives

$$k(x) = \frac{y''}{(1 + y'^2)^{3/2}} = \frac{\frac{1}{a} \cosh(x/a)}{\cosh^3(x/a)} = \frac{1}{a \cosh^2(x/a)}, \quad \rho(x) = a \cosh^2 \frac{x}{a} = \frac{y^2}{a}.$$

The radius of curvature therefore equals the square of the ordinate divided by a ; at the vertex $x = 0$ it equals $\rho(0) = a$.

Independent check. With $a = 1$ and $x = 1$ the parametrisation $\gamma(t) = (t, \cosh t)$ gives $x' = 1$, $y' = \sinh t$, $x'' = 0$, $y'' = \cosh t$, hence $k = \cosh t / \cosh^3 t = 1 / \cosh^2 t$. Numerically $\cosh 1 = 1.543081$, $\cosh^2 1 = 2.381098$ and $k(1) = 0.419974$, while the closed formula gives $\rho(1) = 2.381098$ and $1/\rho(1) = 0.419974$. ✓

Figure 2.1: The Frenet frame and the osculating circle at a point P of the ellipse $x^2/a^2 + y^2/b^2 = 1$ with $a = 2.6$, $b = 1.5$. The unit tangent T and unit normal N form a moving orthonormal basis; the osculating circle has centre $C = P + \rho N$ on the inner normal and radius $\rho = 1/\kappa$. Here $\kappa = 0.360$ and $\rho = 2.779$. The osculating circle is the unique circle having second-order contact with the curve: among all circles tangent at P , it is the one that also reproduces the curvature.

2.3. Evolutes and involutes

Definition 2.5: Evolute. Let γ be of class C^3 with $k(s) \neq 0$ for every s . The **evolute** of γ is the curve described by the centre of curvature:

$$e(s) = \gamma(s) + \frac{1}{k(s)} N(s).$$

Theorem 2.6: Properties of the evolute. Let γ be as above and $\rho = 1/k$ (with sign). Then:

- (i) $e'(s) = \rho'(s) N(s)$; in particular the evolute is tangent to the normal of γ , i.e. **the evolute is the envelope of the normals** of γ ;
- (ii) e is regular exactly where $k'(s) \neq 0$; the points with $k'(s) = 0$ (**vertices** of γ) correspond to singular points — **cusps** — of the evolute;

- (iii) the length of the arc of evolute between s_1 and s_2 , if ρ is monotone on $[s_1, s_2]$, equals $|\rho(s_2) - \rho(s_1)|$;
 (iv) γ is a circle if and only if its evolute reduces to a point.

Proof. (i) Differentiating $e = \gamma + \rho N$ and using the Frenet formulas (Theorem 2.1) with $\rho = 1/k$:

$$e' = \gamma' + \rho' N + \rho N' = T + \rho' N - \rho k T = T + \rho' N - T = \rho' N,$$

having used $\rho k = 1$. So e' is parallel to N , i.e. to the normal of γ at the corresponding point: the normal line to γ at $\gamma(s)$ is tangent to e at $e(s)$, which is precisely the definition of an envelope.

(ii) By (i), $e' = 0$ iff $\rho' = 0$, and since $\rho = 1/k$ with $k \neq 0$, this is equivalent to $k' = 0$.

(iii) The length is

$$\int_{s_1}^{s_2} \|e'(s)\| ds = \int_{s_1}^{s_2} |\rho'(s)| ds = \left| \int_{s_1}^{s_2} \rho'(s) ds \right| = |\rho(s_2) - \rho(s_1)|,$$

the last but one step using that ρ' has constant sign (ρ monotone).

(iv) If γ is a circle, ρ is constant and by (i) $e' = 0$: the evolute is the centre. Conversely, if e is constant then $\rho' = 0$, hence k is constant and by Theorem 2.5 γ is a circle. $\square$

Example 2.4: Evolute of the ellipse: the astroid. For the ellipse $\gamma(t) = (a \cos t, b \sin t)$ one obtains, by the computation of Example 2.2 and Definition 2.5,

$$e(t) = \left(\frac{a^2 - b^2}{a} \cos^3 t, \frac{b^2 - a^2}{b} \sin^3 t \right),$$

a stretched **astroid**, with Cartesian equation

$$(aX)^{2/3} + (bY)^{2/3} = (a^2 - b^2)^{2/3}.$$

Check at the vertices. For $t = 0$ (the point $(a, 0)$) one finds $e(0) = (\frac{a^2 - b^2}{a}, 0)$, whose distance from $(a, 0)$ is

$$a - \frac{a^2 - b^2}{a} = \frac{b^2}{a} = \rho(0),$$

in agreement with Example 2.2. $\checkmark$

The four cusps. The astroid has four cusps, at $t = 0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}$: these are the four vertices of the ellipse, the ends of the axes, where $k' = 0$. This is the first encounter with Theorem 4.6, proved later: *every* simple closed curve has at least four vertices, and the ellipse has exactly four.

Limiting case. For $a = b$ the evolute collapses to the origin, consistently with Theorem 2.6(iv). $\checkmark$

Definition 2.6: Involute. Let γ be regular, parametrised by arc length, and $a \in \mathbb{R}$. The **involute** of γ with parameter a is

$$\iota_a(s) = \gamma(s) + (a - s) T(s).$$

Intuitively: it is the trajectory of the end of a taut, inextensible thread unwinding from the curve.

Theorem 2.7: Evolute and involute are inverse operations. With the previous notation, at points where $k(s) \neq 0$ and $a \neq s$:

- (i) $\iota'_a(s) = (a - s)k(s)N(s)$: the involute is regular where $k \neq 0$ and $s \neq a$, and its tangent is orthogonal to that of γ ;
- (ii) the evolute of the involute ι_a is γ itself.

Proof. (i) Differentiating and using $\gamma' = T$, $T' = kN$:

$$\iota'_a = T - T + (a - s)T' = (a - s)kN.$$

(ii) Suppose, to fix ideas, $a - s > 0$ and $k > 0$; the other cases are handled the same way with the signs changed.

Unit tangent. By (i), $\iota'_a = (a - s)kN$ with $(a - s)k > 0$, hence $\|\iota'_a\| = (a - s)k$ and the unit tangent of the involute is $\tilde{T} = N$. Its unit normal, obtained by rotating $\tilde{T}$ by $+90^\circ$, is $\tilde{N} = iN = -T$ (Definition 2.2).

Arc length. Writing σ for the arc length of ι_a , we have $d\sigma/ds = (a - s)k$.

Curvature. Differentiating $\tilde{T} = N$ with respect to σ and using $N' = -kT$:

$$\frac{d\tilde{T}}{d\sigma} = \frac{1}{(a - s)k} \frac{dN}{ds} = \frac{-kT}{(a - s)k} = \frac{-T}{a - s} = \frac{1}{a - s} \tilde{N},$$

so the curvature of the involute is $\tilde{k} = \frac{1}{a - s}$ and its radius of curvature is $\tilde{\rho} = a - s$.

Centre of curvature. By Definition 2.4,

$$\iota_a(s) + \frac{1}{\tilde{k}} \tilde{N} = \gamma(s) + (a - s)T(s) + (a - s)(-T(s)) = \gamma(s).$$

The centre of curvature of the involute is therefore the corresponding point of γ : the evolute of ι_a is γ .

Step 3 — check via length. The verification can also be made without signs, using Theorem 2.6(iii): the length of the arc of γ between s_1 and s_2 is $s_2 - s_1$, which is exactly the variation of the radius of curvature $\tilde{\rho} = a - s$ of the involute, in absolute value. This is the precise formulation of the unwinding-thread picture: the unwound thread is as long as the arc traversed. $\square$

Example 2.5: The involute of the circle and the profile of gear teeth. Let γ be the circle of radius r , parametrised by $\gamma(t) = (r \cos t, r \sin t)$ with arc length $s = rt$ (Example 2.1) and $T(t) = (-\sin t, \cos t)$. The involute with $a = 0$ is

$$\iota(t) = (r \cos t, r \sin t) - rt(-\sin t, \cos t) = r(\cos t + t \sin t, \sin t - t \cos t).$$

Step 1 — speed and arc length. By Theorem 2.7(i), with $k = 1/r$ and $s = rt$:

$$\|\iota'(t)\| = \left| \frac{d\iota}{ds} \right| \cdot r = |-s|k \cdot r = rt.$$

So the length of the involute from 0 to t is

$$\Lambda(t) = \int_0^t ru \, du = \frac{rt^2}{2}.$$

Step 2 — radius of curvature. By Theorem 2.7(ii), the centre of curvature of ι at t is $\gamma(t)$, hence

$$\tilde{\rho}(t) = \|\iota(t) - \gamma(t)\| = rt,$$

growing linearly: the involute of the circle “opens out” progressively.

Step 3 — why gears. In a gear drive one wants the ratio of angular velocities to be *constant* throughout the meshing, otherwise the transmission generates vibration and noise. The corresponding geometric condition (the *fundamental law of gearing*) is that the common normal to the two profiles at the point of contact should always pass through one fixed point of the line of centres, the *pitch point*. The involute profile satisfies it: by Theorem 2.7(i) the normal to the involute at $\iota(t)$ is the tangent to the base circle at $\gamma(t)$, and the common tangents to two fixed base circles form a fixed line — the *line of action*. The intersection of the line of action with the line of centres is therefore fixed, and the gear ratio is constant.

Step 4 — practical consequence. Since the geometry depends only on the base circles, the gear ratio stays constant *even if the centre distance varies slightly* — through manufacturing tolerances, bearing wear or thermal expansion. This is why the involute profile has almost everywhere supplanted the cycloidal profile, which is instead sensitive to centre distance. International standardisation (ISO 53, which defines the standard basic rack tooth profile for involute cylindrical gears) codifies this choice.

Step 5 — numerical check. For $r = 30$ mm and $t = 0.5$ rad:

$$\begin{aligned}\iota(0.5) &= 30(\cos 0.5 + 0.5 \sin 0.5, \sin 0.5 - 0.5 \cos 0.5) = 30(0.877583 + 0.239713, 0.479426 - 0.438791), \\ &= (33.519, 1.219) \text{ mm}.\end{aligned}$$

Distance from the point $\gamma(0.5) = (26.327; 14.383)$ mm:

$$\sqrt{(33.519 - 26.327)^2 + (1.219 - 14.383)^2} = \sqrt{51.72 + 173.29} = \sqrt{225.01} = 15.000 \text{ mm},$$

against $rt = 30 \times 0.5 = 15$ mm predicted in Step 2. ✓

Figure 2.2: The evolute of the ellipse, that is the locus of the centres of the osculating circles, with parametric equations $X = \frac{a^2-b^2}{a} \cos^3 t$, $Y = -\frac{a^2-b^2}{b} \sin^3 t$: a stretched astroid. The thin lines are the normals to the ellipse, and the evolute is their envelope: each normal touches it at the centre of curvature of the point it starts from. The four corner points (cusps) correspond to the four vertices of the ellipse, i.e. the points of stationary curvature: they are exactly the four predicted by the four-vertex theorem. Note that the evolute leaves the ellipse along the minor axis, because the radius of curvature at the vertices $(0, \pm b)$ equals $a^2/b = 4.507 > b$.

2.4. Curves generated by rolling circles

Definition 2.7: Cycloid, epicycloid, hypocycloid.

- The **cycloid** is the curve traced by a point on the circumference of a circle of radius r rolling without slipping along a straight line:

$$\gamma(t) = r(t - \sin t, 1 - \cos t).$$

- The **epicycloid** is traced by a point of a circle of radius r rolling externally on a fixed circle of radius R :

$$\gamma(t) = \left((R+r) \cos t - r \cos \frac{R+r}{r} t, (R+r) \sin t - r \sin \frac{R+r}{r} t \right).$$

- The **hypocycloid** is the analogous curve for internal rolling:

$$\gamma(t) = \left((R-r) \cos t + r \cos \frac{R-r}{r} t, (R-r) \sin t - r \sin \frac{R-r}{r} t \right).$$

Theorem 2.8: The two-circle theorem of Cardano (al-Tusi couple). *If a circle of radius r rolls without slipping inside a circle of radius $R = 2r$, every point of the circumference of the moving circle describes a diameter of the fixed circle, traversed back and forth with simple harmonic motion.*

Proof. **Step 1 — substitution in the formula.** In the hypocycloid of Definition 2.7 put $R = 2r$, so $R - r = r$ and $\frac{R-r}{r} = 1$:

$$\gamma(t) = (r \cos t + r \cos t, r \sin t - r \sin t) = (2r \cos t, 0).$$

Step 2 — reading. The point moves along the x -axis between $-2r$ and $+2r$: it describes exactly the diameter of the fixed circle, with law of motion $x(t) = 2r \cos t$, i.e. simple harmonic motion of amplitude $2r$.

Step 3 — independent synthetic proof. Let O be the centre of the fixed circle (radius $2r$), C the centre of the moving circle (radius r), Q the contact point and P the tracing point. Since the rolling is internal, $|OC| = 2r - r = r$: hence O lies on the moving circle, being at distance r from its centre C .

Let Q_0 be the initial position of the contact point, chosen so that initially P coincides with Q_0 . Rolling without slipping means that the arc Q_0Q of the fixed circle and the arc QP of the moving circle have the same length. Writing α for the central angle $\widehat{Q_0OQ}$ in the fixed circle and β for the central angle $\widehat{QCP}$ in the moving circle, equality of arcs gives

$$2r \alpha = r \beta \implies \beta = 2\alpha.$$

Now Q , P and O all lie on the moving circle: by the inscribed angle theorem (Volume I), the angle $\widehat{QOP}$, inscribed in the moving circle and subtending the arc QP , equals half the corresponding central angle β , that is α .

But $\widehat{Q_0OQ} = \alpha$ by construction: hence $\widehat{QOP} = \widehat{Q_0OQ}$, and the rays OP and OQ_0 make equal and opposite angles with OQ . It follows that P always lies on the fixed line OQ_0 . Since moreover $|OP| \leq |OC| + |CP| = 2r$, the point P traverses the diameter of the fixed circle along OQ_0 . ✓

Step 4 — historical and technical interest. The construction appears in Nasir al-Din al-Tusi (13th century) as a device for generating rectilinear alternating motion out of circular motions, within reformed Ptolemaic astronomy; it is known in the West as “Cardano’s circles”,

from *De subtilitate* (1550). Mechanically, it is the principle of double-crank couplings and of certain straight-line mechanisms without guides.

Step 5 — consistency with Chapter 4. The projection of a uniform circular motion onto an axis is a harmonic motion (Chapter 4, and Chapter 6 for phasors). Cardano's theorem says that the same harmonic motion is obtained, without projecting, as the composition of two rotations of opposite sense and frequencies 1 and -2 — exactly the decomposition $\cos t = \frac{e^{it} + e^{-it}}{2}$ of Theorem (Volume II, Chapter 3) of Chapter 3, read kinematically. $\square$

Example 2.6: Notable curves as special cases. Cardioid ($R = r$, one-cusped epicycloid):

$$\gamma(t) = r(2 \cos t - \cos 2t, 2 \sin t - \sin 2t).$$

Nephroid ($R = 2r$, two-cusped epicycloid): it is the reflection caustic of a circle illuminated by parallel rays.

Deltoid ($R = 3r$, three-cusped hypocycloid).

Astroid ($R = 4r$, four-cusped hypocycloid):

$$\gamma(t) = R(\cos^3 t, \sin^3 t),$$

the same curve met as the evolute of the ellipse in Example 2.4.

General rule. If $R/r = n$ is an integer, the hypocycloid has n cusps and closes after one revolution; if R/r is a rational p/q in lowest terms, it closes after q revolutions with p cusps; if it is irrational it never closes and is dense in the annulus. This last fact is, once again, the non-latticeness criterion of Theorem (Volume II, Chapter 6) of Chapter 8, and the same phenomenon as the density of the orbits of an irrational rotation.

Numerical check on the astroid. With $R = 4$, $r = 1$, $t = \pi/6$:

$$(R - r) \cos t + r \cos 3t = 3 \times 0.866025 + \cos \frac{\pi}{2} = 2.598076 + 0 = 2.598076,$$

$$(R - r) \sin t - r \sin 3t = 3 \times 0.5 - 1 = 0.5.$$

Compare with $R(\cos^3 t, \sin^3 t) = 4(0.649519; 0.125) = (2.598076; 0.5)$. $\checkmark$

Figure 2.3: Two curves generated by a rolling circle. Left, the cycloid: a point rigidly attached to a circle of radius r rolling without slipping along a line traces $x = r(t - \sin t)$, $y = r(1 - \cos t)$; each arch has base $2\pi r$, height $2r$, length $8r$ and area $3\pi r^2$. Right, the cardioid, obtained by rolling a circle of radius a outside a fixed circle of the same radius: $x = 2a \cos t - a \cos 2t$, $y = 2a \sin t - a \sin 2t$. In green the generating circle in the position shown, in red the tracing point. It is the same mechanism as Ptolemy's circles and Fourier series: composing two circular motions.

2.5. The fundamental theorem of plane curves

The previous sections have extracted a number from the curve, its curvature. It remains to understand how much information that number carries: the answer is *all* of it. Given the function $k(s)$, the curve exists, is unique up to a rigid motion, and is built by integrating twice. This is the passage from *analysis* (measuring a given curve) to *synthesis* (designing a curve by prescribing its curvature), and it is the reason why this chapter has direct applications to trajectory planning.

Theorem 2.9: Fundamental theorem of plane curves. Let $k : [0, L] \rightarrow \mathbb{R}$ be continuous, let $p_0 \in \mathbb{R}^2$ and let T_0 be a unit vector of $\mathbb{R}^2$. Then:

- (i) existence: there is a curve $\gamma \in C^2([0, L]; \mathbb{R}^2)$ parametrised by arc length with $\gamma(0) = p_0$, $\gamma'(0) = T_0$ and signed curvature equal to k ;
- (ii) uniqueness: such a curve is unique;
- (iii) rigidity: two C^2 curves parametrised by arc length with the same curvature function differ by a direct rigid motion of the plane (a rotation followed by a translation).

Proof. **Step 1 — construction.** Let ϑ_0 be the angle of T_0 , that is $T_0 = (\cos \vartheta_0, \sin \vartheta_0)$, and define

$$\vartheta(s) = \vartheta_0 + \int_0^s k(\sigma) d\sigma, \quad \gamma(s) = p_0 + \int_0^s (\cos \vartheta(\sigma), \sin \vartheta(\sigma)) d\sigma.$$

Both integrals exist because the integrands are continuous.

Step 2 — checking the required properties. By the fundamental theorem of calculus, $\gamma'(s) = (\cos \vartheta(s), \sin \vartheta(s))$, which has norm 1: hence γ is parametrised by arc length and $T = (\cos \vartheta, \sin \vartheta)$. Moreover $\gamma(0) = p_0$ and $\gamma'(0) = T_0$. Differentiating once more,

$$T'(s) = \vartheta'(s) (-\sin \vartheta(s), \cos \vartheta(s)) = k(s) N(s),$$

having recognised in $N = (-\sin \vartheta, \cos \vartheta)$ the rotation of T by $+90^\circ$, that is the normal unit vector of Definition 2.3. Comparison with the Frenet formulae (Theorem 2.1) shows that the curvature of γ is exactly k . Since k is continuous, $\vartheta \in C^1$ and $\gamma \in C^2$. This proves (i).

Step 3 — uniqueness for fixed initial data. Let $\tilde{\gamma}$ be another curve with the same data. Its tangent angle $\tilde{\vartheta}$ is a continuous function with $\tilde{\vartheta}' = k$ and $\tilde{\vartheta}(0) \equiv \vartheta_0 \pmod{2\pi}$; replacing $\tilde{\vartheta}$ by $\tilde{\vartheta} - 2m\pi$ for a suitable integer m one may assume $\tilde{\vartheta}(0) = \vartheta_0$. Then $(\tilde{\vartheta} - \vartheta)' = 0$ and $(\tilde{\vartheta} - \vartheta)(0) = 0$, hence $\tilde{\vartheta} \equiv \vartheta$; therefore $\tilde{\gamma}' = \gamma'$ and, integrating with $\tilde{\gamma}(0) = \gamma(0) = p_0$, $\tilde{\gamma} \equiv \gamma$. This proves (ii).

Step 4 — reduction of rigidity to Step 3. Let γ_1, γ_2 be two C^2 curves parametrised by arc length with the same curvature k . Let R be the rotation taking $T_1(0)$ to $T_2(0)$ — it exists and is unique, because a rotation of the plane is determined by the image of one unit vector — and let $b = \gamma_2(0) - R\gamma_1(0)$. Put $M(x) = Rx + b$, a direct rigid motion, and $\tilde{\gamma}_1 = M \circ \gamma_1$.

Step 5 — curvature is invariant under direct rigid motions. If $\tilde{\gamma} = R\gamma + b$ with R a rotation, then $\tilde{\gamma}' = R\gamma'$ still has norm 1, $\tilde{T} = RT$ and $\tilde{N} = RN$ (because R commutes with the rotation by $+90^\circ$, both being rotations). Hence

$$\tilde{T}' = R T' = R(kN) = k RN = k \tilde{N},$$

that is, $\tilde{\gamma}$ has the same curvature k . (The detailed computation, with the behaviour under reflections and under reversal of orientation, is Exercise 2.15.)

Step 6 — conclusion. By Step 5, $\tilde{\gamma}_1$ has curvature k ; by construction $\tilde{\gamma}_1(0) = \gamma_2(0)$ and $\tilde{T}_1(0) = RT_1(0) = T_2(0)$. The two curves $\tilde{\gamma}_1$ and γ_2 therefore solve the same problem as in Step 3, and by uniqueness they coincide: $\gamma_2 = M \circ \gamma_1$. This proves (iii).

Step 7 — reading. Curvature is a *complete system of invariants* for plane curves: it contains all the geometric information and nothing else. Applied to constant k , the theorem returns Theorem 2.5: up to rigid motions there is only one curve of constant curvature $c \neq 0$, and the circle of radius $1/|c|$ realises it. $\square$

Example 2.7: Reconstruction of the curve of constant curvature. Apply the construction of Step 1 to $k(s) \equiv c > 0$, with $p_0 = (0, 0)$ and $T_0 = (1, 0)$, that is $\vartheta_0 = 0$.

Step 1. $\vartheta(s) = \int_0^s c \, d\sigma = cs$.

Step 2. $T(s) = (\cos cs, \sin cs)$.

Step 3. Integrating,

$$\gamma(s) = \left(\frac{1}{c} \sin cs, \frac{1}{c} (1 - \cos cs) \right).$$

Step 4 — recognition. $x^2 + (y - \frac{1}{c})^2 = \frac{1}{c^2} (\sin^2 cs + \cos^2 cs) = \frac{1}{c^2}$: it is the circle with centre $(0, 1/c)$ and radius $1/c$, traversed counterclockwise starting from the origin. ✓

Remark 2.3: The circle as a prototype, and the synthesis of trajectories. Example 2.7 is the simplest case of a general procedure: one prescribes the law $k(s)$ and integrates twice. The three elementary laws are

$$k(s) = 0 \Rightarrow \text{segment}; \quad k(s) = \frac{1}{r} \Rightarrow \text{circular arc}; \quad k(s) = k_0 + cs \Rightarrow \text{clothoid},$$

and the third is the subject of the next section. The point is not aesthetic: the curvature of a trajectory travelled by a wheeled vehicle is proportional to the steering angle, which cannot change instantaneously; prescribing a continuous k means prescribing a physically executable manoeuvre.

2.6. Clothoids and curvature-continuous planning

A direct transition between a straight stretch ($k = 0$) and a circular arc ($k = 1/r$) has *discontinuous* curvature: at the junction point the steering angle would have to jump from 0 to a finite value in an instant, that is with infinite angular velocity. The cure is to interpose a stretch in which the curvature grows linearly along the arc: the clothoid.

Definition 2.8: Clothoid (Euler spiral). A **clothoid** (or *Euler spiral*, or *Cornu spiral*) is a plane curve parametrised by arc length whose curvature is an affine function of s :

$$k(s) = k_0 + cs, \quad c \neq 0.$$

The number c , of dimension $[\text{length}]^{-2}$, is called the **sharpness parameter** of the transition.

Proposition 2.2: Explicit form of the clothoid and Fresnel integrals. Let $c > 0$ and consider the clothoid with $k_0 = 0$ leaving the origin with horizontal tangent, that is the one given by Theorem 2.9 with $k(s) = cs$, $p_0 = (0, 0)$, $T_0 = (1, 0)$. Then:

(i) the tangent angle is $\varphi(s) = \frac{1}{2}cs^2$ and

$$\gamma(s) = \left(\int_0^s \cos \frac{c\sigma^2}{2} d\sigma, \int_0^s \sin \frac{c\sigma^2}{2} d\sigma \right);$$

(ii) setting $a = \sqrt{\pi/c}$ and $\tau = s/a$, one has

$$\gamma(s) = a (C(\tau), S(\tau)), \quad C(\tau) = \int_0^\tau \cos \frac{\pi u^2}{2} du, \quad S(\tau) = \int_0^\tau \sin \frac{\pi u^2}{2} du,$$

where C and S are the Fresnel integrals: every clothoid is therefore similar to the normalised clothoid $\tau \mapsto (C(\tau), S(\tau))$, with similarity ratio a ;

(iii) the identity $\rho(s)s = 1/c$ holds for $s > 0$: the product of the radius of curvature and the arc length is constant along the curve. This is the property that characterises the clothoid among all plane curves.

Proof. Step 1 — the tangent angle. By Step 1 of the proof of Theorem 2.9, with $\vartheta_0 = 0$,

$$\varphi(s) = \int_0^s c\sigma \, d\sigma = \frac{cs^2}{2},$$

and $\gamma(s) = \int_0^s (\cos \varphi, \sin \varphi)$: this is (i).

Step 2 — normalisation. In (i) set $\sigma = au$ with $a = \sqrt{\pi/c}$, that is $ca^2 = \pi$. Then $\frac{c\sigma^2}{2} = \frac{ca^2u^2}{2} = \frac{\pi u^2}{2}$ and $d\sigma = a \, du$, while $\sigma = s$ corresponds to $u = s/a = \tau$. Substituting,

$$\int_0^s \cos \frac{c\sigma^2}{2} \, d\sigma = a \int_0^\tau \cos \frac{\pi u^2}{2} \, du = a C(\tau),$$

and likewise for the second component: this is (ii).

Step 3 — the identity $\rho s = 1/c$. By construction $k(s) = cs$, hence $\rho(s) = 1/|k(s)| = 1/(cs)$ for $s > 0$ and $\rho(s)s = 1/c$.

Step 4 — the characterisation. Conversely, if a curve parametrised by arc length satisfies $\rho(s)s = \text{const.} = 1/c$ on an interval with $s > 0$, then $k(s) = \pm cs$, and by Theorem 2.9 the curve is, up to a rigid motion, the clothoid of part (i) (or its mirror image).

Step 5 — dimensional check. $[c] = \text{m}^{-2}$, hence $[a] = \sqrt{\text{m}^2} = \text{m}$ and τ is dimensionless, as it must be for the argument of C and S . $\checkmark$ $\square$

Remark 2.4: What we import: the asymptotic value of the Fresnel integrals. As $\tau \rightarrow +\infty$ the normalised clothoid converges to the point $(\frac{1}{2}, \frac{1}{2})$, and as $\tau \rightarrow -\infty$ to its opposite: the spiral winds around two «eyes». The ingredient is the value

$$\lim_{\tau \rightarrow +\infty} C(\tau) = \lim_{\tau \rightarrow +\infty} S(\tau) = \frac{1}{2},$$

which is a classical result on the Fresnel integrals and which we **import** here: it is not proved in this treatise, because it requires the value of the Gauss integral $\int_{\mathbb{R}} e^{-x^2} dx = \sqrt{\pi}$ and a contour argument in the complex plane (or, equivalently, the Fourier transform of the Gaussian, Volume II, Chapter 4). The source is the NIST Digital Library of Mathematical Functions, §7.2: formulae (7.2.7) and (7.2.8) are the definitions of C and S used here, and (7.2.9) gives precisely $\lim_{x \rightarrow \infty} C(x) = \lim_{x \rightarrow \infty} S(x) = \frac{1}{2}$. Nothing that follows depends on this limit: the transition formulae use only values of C and S at finite points, computed by quadrature.

Proposition 2.3: The curvature-continuous transition between a straight stretch and an arc. Suppose one wants to join a straight stretch to a circular arc of radius $r > 0$ by a clothoid stretch $k(s) = cs$, $s \in [0, L]$, travelled at constant speed $v > 0$. Then:

(i) the curvature is continuous at the two junction points if and only if $cL = 1/r$, that is

$$L = \frac{1}{rc};$$

(ii) in that case the angular deviation of the stretch is $\Delta\varphi = \frac{cL^2}{2} = \frac{L}{2r}$;

(iii) the final point is $\gamma(L) = a(C(\tau_L), S(\tau_L))$ with $a = \sqrt{\pi/c}$ and $\tau_L = L/a$;

(iv) if the steering rate imposes $|\dot{k}| \leq \dot{k}_{\max}$, then $L \geq \frac{v}{r \dot{k}_{\max}}$.

Proof. Step 1 — continuity at the entrance. At the beginning of the stretch $k(0) = 0$, which is the curvature of the straight line: the junction is continuous for every choice of c and L .

Step 2 — continuity at the exit. At the end of the stretch $k(L) = cL$; the curvature of the arc is $1/r$. Continuity is therefore equivalent to $cL = 1/r$, that is $L = 1/(rc)$: this is (i).

Step 3 — angular deviation. By Step 1 of the proof of Proposition 2.2, $\varphi(L) = cL^2/2$; substituting $c = 1/(rL)$ one obtains $\varphi(L) = L/(2r)$: this is (ii).

Step 4 — final point. This is Proposition 2.2(ii) evaluated at $s = L$: this is (iii).

Step 5 — kinematic constraint. Along the trajectory $s = vt$, hence

$$\dot{k} = \frac{dk}{dt} = \frac{dk}{ds} \frac{ds}{dt} = cv.$$

The constraint $cv \leq \dot{k}_{\max}$ gives $c \leq \dot{k}_{\max}/v$ and, substituting into (i),

$$L = \frac{1}{rc} \geq \frac{v}{r\dot{k}_{\max}},$$

which is (iv). The case of equality corresponds to steering at the maximum admissible rate throughout the stretch. $\square$

Proposition 2.4: The shift of the transition. With the notation of Proposition 2.3, the **shift** of the transition is the quantity

$$p = y(L) - r(1 - \cos \Delta\varphi),$$

that is, how far the circular arc must be moved inwards with respect to the straight stretch so that the clothoid joins them. Then

$$p = \frac{L^2}{24r} + O\left(\frac{L^4}{r^3}\right) \quad (L/r \rightarrow 0).$$

Proof. Step 1 — expansion of $y(L)$. From Proposition 2.2(i) and the expansion $\sin x = x - \frac{x^3}{6} + O(x^5)$ with $x = c\sigma^2/2$,

$$y(L) = \int_0^L \sin \frac{c\sigma^2}{2} d\sigma = \int_0^L \left(\frac{c\sigma^2}{2} - \frac{c^3\sigma^6}{48} + O(c^5\sigma^{10}) \right) d\sigma = \frac{cL^3}{6} - \frac{c^3L^7}{336} + O(c^5L^{11}).$$

With $cL = 1/r$ the leading term equals $\frac{L^2}{6r}$ and the next one $\frac{L^4}{336r^3}$.

Step 2 — expansion of the comparison term. From $\Delta\varphi = L/(2r)$ and $1 - \cos x = \frac{x^2}{2} - \frac{x^4}{24} + O(x^6)$,

$$r(1 - \cos \Delta\varphi) = r \left(\frac{L^2}{8r^2} - \frac{L^4}{384r^4} + O\left(\frac{L^6}{r^6}\right) \right) = \frac{L^2}{8r} - \frac{L^4}{384r^3} + O\left(\frac{L^6}{r^5}\right).$$

Step 3 — difference. Subtracting,

$$p = \left(\frac{1}{6} - \frac{1}{8} \right) \frac{L^2}{r} + O\left(\frac{L^4}{r^3}\right) = \frac{L^2}{24r} + O\left(\frac{L^4}{r^3}\right),$$

because $\frac{1}{6} - \frac{1}{8} = \frac{4-3}{24} = \frac{1}{24}$.

Step 4 — practical reading. The formula $p \simeq L^2/(24r)$ is the one used in railway and road practice to size the displacement of the track or of the lane; Step 3 shows that the error is of fourth order in L/r , hence negligible as long as the transition is long compared with the deviation it produces. $\square$

Example 2.8: A clothoid transition, with numerical check. A vehicle passes from a straight stretch to an arc of radius $r = 5$ m through a clothoid stretch of parameter $c = 0.04$ m⁻².

Step 1 — length of the stretch. By Proposition 2.3(i), $L = 1/(rc) = 1/(5 \times 0.04) = 5$ m.

Step 2 — angular deviation. By (ii), $\Delta\varphi = cL^2/2 = 0.04 \times 25/2 = 0.5$ rad = 28.647890°.

Step 3 — scale factor and Fresnel argument. $a = \sqrt{\pi/c} = \sqrt{\pi/0.04} = 8.862269$ m and $\tau_L = L/a = 5/8.862269 = 0.564190$.

Step 4 — final point. By composite Simpson quadrature one obtains $C(\tau_L) = 0.550247$ and $S(\tau_L) = 0.092366$, hence

$$\gamma(L) = a(C(\tau_L), S(\tau_L)) = (4.876438; 0.818570) \text{ m},$$

with chord $\|\gamma(L)\| = 4.944665$ m.

Step 5 — shift. The exact value is $p = y(L) - r(1 - \cos \Delta\varphi) = 0.818570 - 5 \times (1 - \cos 0.5) = 0.206483$ m, while the estimate of Proposition 2.4 gives $L^2/(24r) = 25/120 = 0.208333$ m: a discrepancy of 0.001850 m, that is 0.90%. Consistent with the error $O(L^4/r^3)$: here $L/r = 1$ and the estimate remains accurate to within 1%. ✓

Independent check. All the values are recomputed in the script `verifica_cap02_cap04.py` (block [C2-3]) in two distinct ways: direct integration of $\int_0^L \cos(c\sigma^2/2) d\sigma$ and reduction to the Fresnel integrals via Proposition 2.2(ii); the two ways agree to within 10^{-8} .

2.6.1 Application to automation

The kinematic constraint of a mobile robot or of a wheeled vehicle is the continuity of the curvature: k is proportional to the steering angle, which cannot change instantaneously. A segment $\rightarrow$ arc transition has discontinuous curvature (a jump from 0 to $1/r$) and would require steering at infinite rate; an interposed clothoid stretch makes k continuous — hence the position C^2 — with steering at constant angular rate, as Step 5 of the proof of Proposition 2.3 shows. Clothoid splines are the standard for the transition curves of roads and railways and, today, for the trajectory planning of autonomous vehicles: they reduce lateral *jerk*, actuator wear and the risk of rollover. A stretch with constant k remains a circular arc, the building block of the circular motions of the tool centre point in industrial robotics.

2.6.2 Circular interpolation in PLC and CNC controllers

The case $k \equiv 1/r$ (circular arc) is programmed directly in motion controllers. In the ISO language (G-code) of **Siemens SINUMERIK** CNCs the arc is commanded with **G02** (clockwise) and **G03** (counterclockwise), after selecting the interpolation plane with **G17/G18/G19** (xy , zx , yz) and indicating the centre through the incremental coordinates **I**, **J**; helical interpolation adds the feed along the orthogonal axis. In the PLC world the standard **PLCopen Motion Control** defines the function block **MC_MoveCircularAbsolute**, available in equivalent form on **Siemens** (TIA Portal, Technology Objects), **Schneider Electric** (PacDrive/Lexium), **Rockwell** (Studio 5000, MCCM instructions on a Coordinate System), **Delta** and **Elco**: one specifies the end point, the centre or the radius, and the direction. The mathematics is that of this chapter: an arc is the locus of constant curvature $1/r$ (Theorem 2.5), and a continuous junction to a straight stretch requires a transition with variable curvature — a clothoid or a spline — which advanced controllers realise with *look-ahead* and smoothing functions in order to limit the jerk.

2.6.3 Computing with Python

The formulae of this chapter translate directly into code. The following fragment computes the signed curvature and the osculating circle of a parametric curve, and the final point of a clothoid transition; it can be used to redo the exercises.

Listing 2.1: Curvature, osculating circle and clothoid transition

```
import numpy as np
from scipy.integrate import quad          # or a hand-written Simpson
rule

def curvatura(gp, gpp):
    """Signed curvature from gamma'(t)=gp and gamma''(t)=gpp in the
        plane."""
    xp, yp = gp; xpp, ypp = gpp
    return (xp*ypp - yp*xpp) / (xp**2 + yp**2)**1.5

def cerchio_oscultatore(P, gp, gpp):
    k = curvatura(gp, gpp)
    T = np.array(gp, float); T /= np.linalg.norm(T)
    N = np.array([-T[1], T[0]])          # normal rotated by +90
    degrees
    centro = np.array(P, float) + (1.0/k)*N
    return centro, 1.0/abs(k)           # (centre, radius rho)

def clotoide(c, L):
    """End point and angular deviation of the transition k(s)=c*s on [0,
        L]."""
    x = quad(lambda s: np.cos(0.5*c*s*s), 0.0, L)[0]
    y = quad(lambda s: np.sin(0.5*c*s*s), 0.0, L)[0]
    return (x, y), 0.5*c*L*L

# Parabola y=x^2 at the point (1,1): gamma=(t, t^2), gamma'=(1,2t),
# gamma''=(0,2)
print(cerchio_oscultatore((1, 1), (1, 2), (0, 2))) # -> ([-4. 3.5],
5.5902...)
# Transition with c=0.04 m^-2 and r=5 m, hence L=1/(r c)=5 m
print(clotoide(0.04, 5.0)) # -> ((4.876438,
0.818570), 0.5)
```

The results agree with Exercise 2.19 (centre $(-4, 7/2)$, radius $5\sqrt{5}/2 \simeq 5.590170$) and with Example 2.8. ✓

2.7. Assigned exercises

The answers are in the Teacher's key (Section 2.11).

Exercise 2.1: Osculating circle and evolute of the hyperbola. *Aim:* to apply the general curvature formula, the centre of curvature and the definition of evolute to a non-symmetric curve, and to recognise a vertex. *Estimated time:* 40 minutes. *Type:* symbolic with numerical check.

Consider the branch $\gamma(t) = (t, 1/t)$, $t > 0$, of the hyperbola $xy = 1$.

- (a) Compute $k(t)$ with Theorem 2.3 and check that $k(1) = 1/\sqrt{2}$.
- (b) Determine the centre and radius of the osculating circle at $(1, 1)$.

- (c) Derive the evolute in parametric form and show that $e(t) = \left(\frac{3t^4 + 1}{2t^3}, \frac{t^4 + 3}{2t} \right)$.
- (d) Prove that $t = 1$ is a vertex ($\rho'(1) = 0$) and that it is the only one on the branch.
- (e) Check (c) for $t = 0.7$ and $t = 1.6$ to two decimal places.

Exercise 2.2: The evolute of the cycloid is a cycloid. *Aim:* to prove Huygens's result underlying the isochronous clock, and to connect it with the properties of the evolute. *Estimated time:* 45 minutes. *Type:* symbolic/proof-based.

Let $\gamma(t) = r(t - \sin t, 1 - \cos t)$, $t \in (0, 2\pi)$.

- (a) Check that $\|\gamma'(t)\| = 2r \sin \frac{t}{2}$ and that $\rho(t) = 4r \sin \frac{t}{2}$.
- (b) Compute the centre of curvature and show that $e(t) = r(t + \sin t, \cos t - 1)$.
- (c) Setting $u = t + \pi$, prove that $e(t) = r(u - \sin u, 1 - \cos u) - (\pi r, 2r)$: the evolute is the same cycloid translated by $(-\pi r, -2r)$.
- (d) Deduce, from Theorem 2.6(iii), the length of the arc of the evolute between $t = \pi/2$ and $t = \pi$, and compare it with $8r$, the length of one arch.
- (e) Explain in one line why this result makes the cycloidal pendulum isochronous.

Exercise 2.3: Sizing a clothoid transition. *Aim:* to use Proposition 2.3 in a design problem, with a kinematic constraint and a check of the shift approximation. *Estimated time:* 50 minutes. *Type:* numerical/computational.

A self-driving vehicle travels a straight stretch at $v = 8$ m/s and must enter a curve of radius $r = 40$ m. The maximum rate of change of curvature allowed by the steering system is $\dot{k}_{\max} = 0.02 \text{ m}^{-1}\text{s}^{-1}$.

- (a) Determine the minimum length L of the transition and the corresponding c .
- (b) Compute $\Delta\varphi$ in radians and in degrees.
- (c) Compute $a = \sqrt{\pi/c}$, τ_L and the final point $\gamma(L)$ to four decimal places, by numerical quadrature.
- (d) Compute the exact shift and compare it with $L^2/(24r)$; comment on the relative discrepancy in the light of the term $O(L^4/r^3)$ and of the ratio L/r obtained.
- (e) Repeat (a)–(d) halving $\dot{k}_{\max}$ and discuss what changes for passenger comfort.

2.8. Worked exercises

Exercise 2.4: The trochoid: inflections, cusps and curvature at the vertex. *Type:* symbolic with numerical check. Consider the *trochoid*

$$\gamma(t) = (rt - d \sin t, r - d \cos t), \quad r > 0, d > 0,$$

described by a point rigidly attached to a circle of radius r rolling on a line, placed at distance d from the centre ($d < r$ curtate cycloid, $d = r$ cycloid, $d > r$ prolate cycloid). Compute $k(t)$, determine the inflection points and the value $k(\pi)$, and discuss the three cases.

Solution. Strategy. One applies the formula of Theorem 2.3; the sign of the numerator governs the inflections, and the case $d = r$ must be treated separately because the curve has cusps.

Step 1 — derivatives. $x' = r - d \cos t$, $y' = d \sin t$, $x'' = d \sin t$, $y'' = d \cos t$.

Step 2 — numerator.

$$x'y'' - y'x'' = (r - d \cos t) d \cos t - d \sin t \cdot d \sin t = dr \cos t - d^2 \cos^2 t - d^2 \sin^2 t = d(r \cos t - d).$$

Step 3 — denominator.

$$x'^2 + y'^2 = (r - d \cos t)^2 + d^2 \sin^2 t = r^2 - 2rd \cos t + d^2,$$

which is $\geq (r - d)^2$ and vanishes only if $d = r$ and $\cos t = 1$: these are the cusps of the ordinary cycloid, where the curve is not regular.

Step 4 — curvature.

$$k(t) = \frac{d(r \cos t - d)}{(r^2 - 2rd \cos t + d^2)^{3/2}}.$$

Step 5 — inflections. $k(t) = 0$ if and only if $\cos t = d/r$, which has a solution if and only if $d \leq r$. Hence the curtate cycloid ($d < r$) has two inflections per period, at $t = \pm \arccos(d/r)$; the ordinary cycloid ($d = r$) has $\cos t = 1$, which however is a cusp and not an inflection; the prolate cycloid ($d > r$) has no inflections and the curvature has constant (negative) sign, because $r \cos t - d \leq r - d < 0$.

Step 6 — the highest point. At $t = \pi$ (maximum ordinate $r + d$):

$$k(\pi) = \frac{d(-r - d)}{(r^2 + 2rd + d^2)^{3/2}} = \frac{-d(r + d)}{(r + d)^3} = -\frac{d}{(r + d)^2}.$$

Independent check. With $r = 1$ the script `verifica_cap02_cap04.py` (block [C2-2]) recomputes $k(\pi)$ from the general formula and finds -0.222222 for $d = 0.5$, -0.250000 for $d = 1$ and -0.240000 for $d = 1.5$, against the values $-d/(r + d)^2$ equal to $-2/9$, $-1/4$ and $-1.5/6.25$. ✓ In the case $d = r = 1$ one recovers $\rho(\pi) = 1/|k(\pi)| = 4r$, in agreement with Exercise 2.8.

Interpretation. The sign of k tells which way the curve bends: the curtate cycloid, which never touches the rolling line, alternates concave and convex stretches and therefore has inflections; the prolate one forms loops and stays curved on the same side throughout. The ordinary cycloid is the transitional case, where the two inflections degenerate into a cusp.

Typical mistakes. (a) Forgetting that at $t = 0$ with $d = r$ the curve is *not* regular and applying the formula there anyway: the denominator vanishes. (b) Concluding that the prolate cycloid has inflections because it «changes direction»: it is the tangent that changes direction, not the sign of the curvature. (c) Using $\|\gamma'\| = 2r \sin(t/2)$, valid only for $d = r$.

Extension. Show that for $d < r$ the minimum radius of curvature is attained at the lowest point $t = 0$ and equals

$$\rho_{\min} = \frac{((r - d)^2)^{3/2}}{d(r - d)} = \frac{(r - d)^2}{d},$$

and check that $\rho_{\min} \rightarrow 0$ as $d \rightarrow r^-$: this is how the cusp is formed. (With $r = 1$ and $d = 0.5$; 0.8 ; 0.95 ; 0.99 one obtains respectively 0.500000 ; 0.050000 ; 0.002632 ; 0.000101 ; the script `verifica_cap02_cap04.py`, block [C2-2], recomputes them by minimising $\rho(t)$ by sampling. ✓)

Exercise 2.5: Nested osculating circles on the logarithmic spiral. *Type:* mixed. For the logarithmic spiral $\gamma(t) = e^t(\cos t, \sin t)$ compute the radius of curvature and the evolute in closed form, check the hypothesis of Proposition 2.1 and verify the nesting numerically between $t = 0$ and $t = 1$.

Solution. Strategy. One computes γ' and γ'' , applies the curvature formula, builds the centre of curvature $e = \gamma + \rho N$ and compares $\|e(1) - e(0)\|$ with $\rho(1) - \rho(0)$.

Step 1 — derivatives. $\gamma'(t) = e^t(\cos t - \sin t, \sin t + \cos t)$ and $\gamma''(t) = e^t(-2 \sin t, 2 \cos t)$, as one checks by differentiating again.

Step 2 — speed. $\|\gamma'(t)\|^2 = e^{2t}[(\cos t - \sin t)^2 + (\sin t + \cos t)^2] = 2e^{2t}$, hence $\|\gamma'\| = \sqrt{2}e^t$ and the arc length from 0 to T equals $\sqrt{2}(e^T - 1)$ (Exercise 2.17).

Step 3 — curvature.

$$x'y'' - y'x'' = e^{2t}[(\cos t - \sin t)2 \cos t + (\sin t + \cos t)2 \sin t] = 2e^{2t},$$

and $(x'^2 + y'^2)^{3/2} = (2e^{2t})^{3/2} = 2\sqrt{2}e^{3t}$, hence

$$k(t) = \frac{2e^{2t}}{2\sqrt{2}e^{3t}} = \frac{1}{\sqrt{2}e^t}, \quad \rho(t) = \sqrt{2}e^t.$$

Step 4 — hypothesis of Tait–Kneser. $k > 0$ everywhere and $k'(t) = -\frac{1}{\sqrt{2}}e^{-t} \neq 0$: the spiral is free of vertices and ρ is strictly increasing. The hypotheses of Proposition 2.1 are satisfied.

Step 5 — evolute. The unit tangent is $T = \frac{1}{\sqrt{2}}(\cos t - \sin t, \sin t + \cos t)$ and its rotation by $+90^\circ$ is $N = \frac{1}{\sqrt{2}}(-\sin t - \cos t, \cos t - \sin t)$. Hence

$$e(t) = \gamma(t) + \rho(t)N(t) = e^t(\cos t, \sin t) + e^t(-\sin t - \cos t, \cos t - \sin t) = e^t(-\sin t, \cos t).$$

The evolute is the same spiral rotated by $+90^\circ$: the logarithmic spiral is, up to a rigid motion, its own evolute.

Independent check. The script `verifica_cap02_cap04.py` (block [C2-7]) computes the centre of curvature from the general formula $\gamma + \frac{1}{k}N$, without using the closed form of Step 5, and finds $e(0) = (0; 1)$, $e(1) = (-2.287355; 1.468694)$, hence

$$\|e(1) - e(0)\| = 2.334881 < \rho(1) - \rho(0) = 3.844231 - 1.414214 = 2.430017. \quad \checkmark$$

The osculating disc at $t = 0$ is therefore contained in the interior of the one at $t = 1$, as Step 4 of the proof of Proposition 2.1 predicts.

Interpretation. The logarithmic spiral is *self-similar*: the transformation $t \mapsto t + \alpha$ maps it into itself scaled by e^α . All geometric quantities follow the same exponential law — arc length, radius of curvature, distance from the pole — and this is why the nesting of the osculating circles can be seen with the naked eye: each circle is the image of the previous one under a similarity of ratio e .

Typical mistakes. (a) Using t as arc length: it is not, and the formula $k = \vartheta'$ must be corrected by dividing by $\|\gamma'\|$. (b) Taking N as the *outward* normal instead of the rotation of T by $+90^\circ$: one gets the centre on the wrong side. (c) Confusing the nesting of the discs with the inclusion of the curve in one of them: the curve crosses every osculating circle.

Extension. Check that for the general logarithmic spiral $\gamma(t) = e^{bt}(\cos t, \sin t)$ one has $\rho(t) = \frac{\sqrt{1+b^2}}{b}e^{bt}$ and that the evolute is again a logarithmic spiral with the same b ; discuss the limit $b \rightarrow 0^+$, in which the spiral degenerates into the unit circle and the evolute into its centre (Theorem 2.6(iv)).

Exercise 2.6: Minimum length of a transition for a mobile robot. *Type:* numerical/applied. A mobile robot travelling at $v = 1$ m/s must join a straight stretch to an arc of radius $r = 2$ m with a clothoid $k(s) = cs$. The maximum rate of change of the curvature is

$\dot{k}_{\max} = 0.5 \text{ m}^{-1}\text{s}^{-1}$. Determine the minimum length L of the stretch, the angular deviation and the shift, and check the estimate $L^2/(24r)$.

Solution. Strategy. One uses Proposition 2.3(iv) for the kinematic constraint and (i) for the length, then Proposition 2.4 for the shift.

Step 1 — constraint on the sharpness. From Step 5 of the proof of Proposition 2.3, $\dot{k} = cv$; imposing $\dot{k} \leq \dot{k}_{\max}$ one obtains $c \leq \dot{k}_{\max}/v = 0.5 \text{ m}^{-2}$.

Step 2 — minimum length. Continuity requires $cL = 1/r = 0.5 \text{ m}^{-1}$, hence $L = 1/(rc)$; since L decreases as c grows, the minimum length occurs for $c = 0.5 \text{ m}^{-2}$:

$$L_{\min} = \frac{1}{rc} = \frac{1}{2 \times 0.5} = 1 \text{ m}.$$

Step 3 — angular deviation. $\Delta\varphi = cL^2/2 = 0.5 \times 1/2 = 0.25 \text{ rad} = 14.323945^\circ$; alternatively $\Delta\varphi = L/(2r) = 1/4 = 0.25 \text{ rad}$. ✓ (The two formulae of Proposition 2.3(ii) agree, as they must.)

Step 4 — final point. $a = \sqrt{\pi/c} = \sqrt{2\pi} = 2.506628 \text{ m}$ and $\tau_L = L/a = 0.398942$. By composite Simpson quadrature $C(\tau_L) = 0.396456$ and $S(\tau_L) = 0.033097$, hence

$$\gamma(L) = a(C(\tau_L), S(\tau_L)) = (0.993768; 0.082962) \text{ m},$$

with chord $\|\gamma(L)\| = 0.997225 \text{ m}$, smaller than the length $L = 1 \text{ m}$ of the stretch, as it must be.

Step 5 — shift. The exact value is $p = y(L) - r(1 - \cos \Delta\varphi) = 0.082962 - 2 \times (1 - \cos 0.25) = 0.082962 - 0.062175 = 0.020787 \text{ m}$, against the estimate $L^2/(24r) = 1/48 = 0.020833 \text{ m}$: a discrepancy of 0.000046 m , that is 0.22% . Here $L/r = 0.5$, half of the case of Example 2.8, and the relative error drops from 0.90% to 0.22% , that is by a factor 4: consistent with the term $O(L^4/r^3)$ of Proposition 2.4, whose relative weight with respect to $L^2/(24r)$ is $O((L/r)^2)$. ✓

Interpretation. One metre of clothoid and two centimetres of displacement of the arc suffice to make the manoeuvre executable with steering at constant rate. If the transition were omitted, the steering would have to reach the angle corresponding to $r = 2 \text{ m}$ instantaneously: physically impossible, and in practice it translates into a trajectory error and an impulsive load on the actuators.

Typical mistakes. (a) Confusing $\dot{k}$ (derivative with respect to *time*) with $k' = c$ (derivative with respect to *arc length*): the conversion factor is the speed v . (b) Imposing $c \geq \dot{k}_{\max}/v$ instead of $c \leq$: one would obtain a maximum length instead of a minimum one. (c) Using $\Delta\varphi = cL$ instead of $cL^2/2$.

Extension. Build the complete curvature profile straight–clothoid–arc–clothoid–straight of Exercise 2.23 with $r = 2 \text{ m}$ and $L = 1 \text{ m}$ for both transitions, and compute the total length of the path needed for an overall deviation of 90° .

2.9. Numerical and symbolic exercises with solutions

The exercises below come from the treatment of plane curves in Volume II and are reproduced in full, together with their solutions.

2.9.1 Numerical exercises

Exercise 2.7: N1 — Osculating circle of a logarithm. For the curve $y = \ln x$ compute the curvature, the radius of curvature and the centre of curvature at the point $(1, 0)$, and check that the distance between point and centre equals the radius.

Exercise 2.8: N2 — Curvature of the cycloid. For the cycloid $\gamma(t) = r(t - \sin t, 1 - \cos t)$ compute the curvature as a function of t , the radius of curvature at $t = \pi$ and at $t = \pi/2$, and the length of one arch.

Exercise 2.9: N3 — Evolute of the parabola. Determine the evolute of the parabola $y = x^2$ and check, for $x = 1$, that the distance between point and centre of curvature equals the radius of curvature computed in Example 2.2.

Exercise 2.10: N4 — Circle involute for a gear. A gear has a base circle of radius $r = 50$ mm. Compute the coordinates of the involute point at $t = 1$ rad, the length of the involute from $t = 0$ to $t = 1$, and the radius of curvature there.

Exercise 2.11: N5 — A Cardano mechanism. A circle of radius $r = 50$ mm rolls internally in a fixed circle of radius $R = 100$ mm. Compute the stroke of the tracing point, its position at $t = 40^\circ$, and its maximum speed if the centre of the moving circle makes 30 revolutions per minute.

Exercise 2.12: N6 — Hypocycloids that close and hypocycloids that do not. Determine the number of cusps and the number of revolutions needed for closure for $R/r = 4$, $R/r = 5/2$ and $R/r = \pi$. For the first case compute the total length of the curve with $R = 40$ mm and compare it with the perimeter of the circumscribed circle.

2.9.2 Symbolic exercises

Exercise 2.13: S1 — The circle through three points. Complete Step 5 of the proof of Theorem 2.4: prove that the circle through $\gamma(s_0 - \varepsilon)$, $\gamma(s_0)$, $\gamma(s_0 + \varepsilon)$ tends, as $\varepsilon \rightarrow 0$, to the osculating circle.

Exercise 2.14: S2 — The hypocycloid in complex form. Write the hypocycloid of Definition 2.7 as a sum of two complex exponentials, and deduce Theorem 2.8 purely algebraically.

Exercise 2.15: S3 — Invariance of curvature. Prove that the signed curvature is invariant under rotations and translations, changes sign under reflections, and changes sign under reversal of orientation. Deduce that the geometric curvature $|k|$ is invariant under all isometries of the plane.

Exercise 2.16: S4 — The evolute of the ellipse. Verify by direct computation the formula for the evolute of the ellipse given in Example 2.4.

2.9.3 Solutions to the numerical exercises

Solution. N1. *Step 1 — derivatives.* $f(x) = \ln x$, $f'(x) = 1/x$, $f''(x) = -1/x^2$; at $x = 1$: $f = 0$, $f' = 1$, $f'' = -1$.

Step 2 — curvature. By Theorem 2.3,

$$k = \frac{f''}{(1 + f'^2)^{3/2}} = \frac{-1}{2^{3/2}} = \frac{-1}{2.828427} = -0.353553.$$

The negative sign means the curve is concave downwards (with x increasing).

Step 3 — radius of curvature. $\rho = 1/|k| = 2.828427 = 2\sqrt{2}$.

Step 4 — unit vectors. $\gamma'(x) = (1, 1)$, hence $T = \frac{1}{\sqrt{2}}(1, 1) = (0.707107; 0.707107)$ and, rotating by $+90^\circ$, $N = (-0.707107; 0.707107)$.

Step 5 — centre of curvature. By Definition 2.4,

$$c = \gamma + \frac{1}{k} N = (1, 0) + (-2.828427) (-0.707107; 0.707107) = (1 + 2, 0 - 2) = (3, -2).$$

Step 6 — check.

$$\|c - \gamma\| = \sqrt{(3 - 1)^2 + (-2 - 0)^2} = \sqrt{8} = 2.828427 = \rho. \checkmark$$

Step 7 — plausibility check. The centre lies *below* the curve, on the concave side, as it must for $f'' < 0$. $\checkmark$

Solution. N2. *Step 1 — derivatives.*

$$x' = r(1 - \cos t), \quad y' = r \sin t, \quad x'' = r \sin t, \quad y'' = r \cos t.$$

Step 2 — numerator.

$$x'y'' - y'x'' = r^2[(1 - \cos t) \cos t - \sin^2 t] = r^2[\cos t - \cos^2 t - \sin^2 t] = r^2(\cos t - 1).$$

Step 3 — denominator.

$$x'^2 + y'^2 = r^2[(1 - \cos t)^2 + \sin^2 t] = r^2(2 - 2 \cos t),$$

hence $(x'^2 + y'^2)^{3/2} = r^3(2 - 2 \cos t)^{3/2}$.

Step 4 — curvature. By Theorem 2.3, using $1 - \cos t = 2 \sin^2(t/2)$:

$$k(t) = \frac{-r^2(1 - \cos t)}{r^3(2(1 - \cos t))^{3/2}} = \frac{-1}{r 2^{3/2} \sqrt{1 - \cos t}} = \frac{-1}{r 2^{3/2} \cdot \sqrt{2} |\sin(t/2)|} = \frac{-1}{4r |\sin(t/2)|}.$$

Hence

$$\rho(t) = 4r |\sin(t/2)|.$$

Step 5 — required values.

$$\rho(\pi) = 4r \sin \frac{\pi}{2} = 4r, \quad \rho\left(\frac{\pi}{4}\right) = 4r \sin \frac{\pi}{4} = 4r \times 0.707107 = 2.828427 r.$$

Step 6 — length of one arch.

$$L = \int_0^{2\pi} \sqrt{x'^2 + y'^2} dt = \int_0^{2\pi} r \sqrt{2 - 2 \cos t} dt = \int_0^{2\pi} 2r \sin \frac{t}{2} dt = 2r \left[-2 \cos \frac{t}{2} \right]_0^{2\pi} = 8r.$$

Step 7 — reading. At the cusps ($t = 0, 2\pi$) we have $\rho = 0$: the curvature diverges, consistently with the fact that there the cycloid has a singular point ($\gamma' = 0$). At the highest point ($t = \pi$) the radius of curvature is $4r$, i.e. *four times* the radius of the generating circle: a notoriously counter-intuitive result, but confirmed by the computation.

Consistency check. The arch length $8r$ is four times the diameter of the generating circle; this is the result obtained by Christopher Wren in 1658 by pre-analytic methods.

Solution. N3. *Step 1 — formulas for a graph.* For $y = f(x)$, from Definition 2.5 and Theorem 2.3 one obtains

$$X = x - \frac{f'(1 + f'^2)}{f''}, \quad Y = f + \frac{1 + f'^2}{f''}.$$

Step 2 — application to $y = x^2$. With $f' = 2x$, $f'' = 2$:

$$X = x - \frac{2x(1 + 4x^2)}{2} = x - x - 4x^3 = -4x^3,$$

$$Y = x^2 + \frac{1 + 4x^2}{2} = \frac{1}{2} + 3x^2.$$

Step 3 — Cartesian form. From $x = (-X/4)^{1/3}$ and $x^2 = (Y - \frac{1}{2})/3$,

$$\left(\frac{X}{4}\right)^2 = \left(\frac{Y - \frac{1}{2}}{3}\right)^3,$$

a *semicubical parabola* (Neile's parabola), with cusp at $(0, \frac{1}{2})$, the centre of curvature of the vertex of the parabola.

Step 4 — check for $x = 1$. Point of the parabola: $(1, 1)$. Centre of curvature: $X = -4$, $Y = 0.5 + 3 = 3.5$. Distance:

$$\sqrt{(-4 - 1)^2 + (3.5 - 1)^2} = \sqrt{25 + 6.25} = \sqrt{31.25} = 5.590170.$$

In Example 2.2 we found $\rho(1) = 5.5902$. ✓

Step 5 — only one cusp. The evolute of the parabola has a single cusp, not four: there is no contradiction with Theorem 4.6, which concerns *closed* curves. The parabola is open, and has a single vertex (in the sense of Definition 4.4: $k' = 0$ only at $x = 0$).

Solution. N4. *Step 1 — coordinates.* From Example 2.5 with $r = 50$ mm and $t = 1$ rad:

$$\iota(1) = 50(\cos 1 + \sin 1, \sin 1 - \cos 1).$$

With $\cos 1 = 0.540302$ and $\sin 1 = 0.841471$:

$$\iota(1) = 50(1.381773, 0.301169) = (69.0887; 15.0584) \text{ mm}.$$

Step 2 — length of the involute. By Step 1 of Example 2.5,

$$\Lambda(1) = \frac{rt^2}{2} = \frac{50 \times 1}{2} = 25.00 \text{ mm}.$$

Step 3 — radius of curvature. By Step 2 of the same Example, $\tilde{\rho} = rt = 50.00$ mm.

Step 4 — check. The corresponding base-circle point is $\gamma(1) = 50(\cos 1, \sin 1) = (27.0151; 42.0735)$ mm; its distance from $\iota(1)$ is

$$\sqrt{(69.0887 - 27.0151)^2 + (15.0584 - 42.0735)^2} = \sqrt{1770.18 + 729.82} = \sqrt{2500.00} = 50.00 \text{ mm}. \checkmark$$

Step 5 — distance from the centre. $\|\iota(1)\| = \sqrt{4773.25 + 226.75} = \sqrt{5000.00} = 70.711$ mm, i.e. $r\sqrt{1+t^2} = 50\sqrt{2}$: a general formula following from Pythagoras applied to the right triangle with legs r and rt (the base-circle radius and the unwound thread, mutually orthogonal). ✓

Solution. N5. *Step 1 — checking the conditions.* $R = 2r$ with $r = 50$ mm: we are in the case of Theorem 2.8.

Step 2 — stroke. The point describes the diameter of the fixed circle, of length $2R = 200$ mm; the stroke is therefore 200 mm, i.e. ± 100 mm about the centre.

Step 3 — position at $t = 40^\circ$.

$$x(t) = 2r \cos t = 100 \cos 40^\circ = 100 \times 0.766044 = 76.604 \text{ mm}, \quad y = 0.$$

Step 4 — speed. At 30 rpm the angular velocity of the centre is

$$\omega = \frac{30 \times 2\pi}{60} = \pi \text{ rad/s} = 3.14159 \text{ rad/s}.$$

Since $x(t) = 100 \cos(\omega t)$ mm,

$$\dot{x} = -100 \omega \sin(\omega t), \quad |\dot{x}|_{\max} = 100 \times 3.14159 = 314.16 \text{ mm/s}.$$

Step 5 — reading. The motion is harmonic with amplitude 100 mm and angular frequency π rad/s, i.e. period 2 s: two seconds out and back. The speed is greatest at mid-stroke and zero at the ends, where the point reverses. It is the same velocity profile as an infinitely long connecting rod — and indeed the Cardano mechanism is used precisely to obtain a rigorously harmonic reciprocating motion, without the second-order error introduced by the ordinary crank-and-rod linkage.

Step 6 — acceleration. $\ddot{x} = -100\omega^2 \cos \omega t$, with maximum $100 \times 9.8696 = 986.96 \text{ mm/s}^2 = 0.987 \text{ m/s}^2$: modest, but proportional to the *square* of the rotational speed. At 300 rpm it would become 98.7 m/s^2 , about $10g$.

Solution. N6. *Step 1 — closure criterion.* The hypocycloid closes after q revolutions if $R/r = p/q$ with p, q coprime positive integers, and then has p cusps; it never closes if R/r is irrational.

Step 2 — the three cases.

R/r	cusps	revolutions to close	name
4	4	1	astroid
$5/2$	5	2	five-cusped hypocycloid
π	—	never	curve dense in the annulus

Step 3 — the irrational case. If $R/r \notin \mathbb{Q}$, the cusp points are $\{2\pi n R/r \bmod 2\pi\}$, the orbit of an irrational rotation of the circle: it is dense, so the curve never closes and densely fills the annulus with radii $R - 2r$ and R . It is the same phenomenon — and the same non-latticeness criterion — as in Theorem (Volume II, Chapter 6) of Chapter 8.

Step 4 — length of the astroid. With $R = 40$ mm and $r = 10$ mm the astroid is $\gamma(t) = R(\cos^3 t, \sin^3 t)$, hence

$$\gamma'(t) = 3R(-\cos^2 t \sin t, \sin^2 t \cos t), \quad \|\gamma'\| = 3R|\sin t \cos t| = \frac{3R}{2}|\sin 2t|.$$

Integrating over the period:

$$L = \frac{3R}{2} \int_0^{2\pi} |\sin 2t| dt = \frac{3R}{2} \times 4 = 6R = 240 \text{ mm},$$

using $\int_0^{2\pi} |\sin 2t| dt = 4$.

Step 5 — comparison. The circumscribed circle has radius $R = 40$ mm and perimeter $2\pi R = 251.33$ mm. The astroid, though touching it at four points, is shorter: $240/251.33 = 0.9549$, i.e. 95.5%. There is no contradiction with the isoperimetric inequality, which compares area with perimeter and not two perimeters: the astroid has area $\frac{3\pi R^2}{8} = 1885.0 \text{ mm}^2$ against $\pi R^2 = 5026.5 \text{ mm}^2$ for the circle, and its isoperimetric ratio is

$$\frac{4\pi A}{L^2} = \frac{4\pi \times 1885.0}{57600} = 0.4112,$$

far from 1: the astroid is a very “inefficient” curve. ✓

2.9.4 Solutions to the symbolic exercises

Solution. S1. *Step 1 — the three points.* Set $s_0 = 0$ and consider $P_- = \gamma(-\varepsilon)$, $P_0 = \gamma(0)$, $P_+ = \gamma(\varepsilon)$. By Taylor, with $T = T(0)$, $N = N(0)$, $k = k(0)$:

$$\gamma(\pm\varepsilon) - \gamma(0) = \pm\varepsilon T + \frac{\varepsilon^2}{2}k N + O(\varepsilon^3).$$

Step 2 — sides of the triangle.

$$|P_+P_0| = \varepsilon + O(\varepsilon^3), \quad |P_0P_-| = \varepsilon + O(\varepsilon^3), \quad |P_+P_-| = 2\varepsilon + O(\varepsilon^3).$$

Step 3 — area of the triangle.

$$2 \text{ Area} = \left| \det \left(\gamma(\varepsilon) - \gamma(0), \gamma(-\varepsilon) - \gamma(0) \right) \right|.$$

Substituting the expansions and using $\det(T, T) = \det(N, N) = 0$, $\det(T, N) = 1$, $\det(N, T) = -1$:

$$\det = \varepsilon \cdot \frac{\varepsilon^2 k}{2} \det(T, N) + \frac{\varepsilon^2 k}{2} \cdot (-\varepsilon) \det(N, T) + O(\varepsilon^4) = \varepsilon^3 k + O(\varepsilon^4).$$

Hence $\text{Area} = \frac{1}{2}|k|\varepsilon^3 + O(\varepsilon^4)$.

Step 4 — circumradius. By the classical formula (Volume I) $R_{\text{circ}} = \frac{abc}{4 \text{ Area}}$ with a, b, c the sides:

$$R_{\text{circ}} = \frac{\varepsilon \cdot \varepsilon \cdot 2\varepsilon + O(\varepsilon^4)}{4 \cdot \frac{1}{2}|k|\varepsilon^3 + O(\varepsilon^4)} = \frac{2\varepsilon^3(1 + O(\varepsilon))}{2|k|\varepsilon^3(1 + O(\varepsilon))} \xrightarrow{\varepsilon \rightarrow 0} \frac{1}{|k|} = \rho.$$

Step 5 — the centre. The circumcentre lies on the perpendicular bisector of P_-P_+ , which in the limit tends to the normal line of γ at P_0 ; since its distance from P_0 tends to ρ and it lies on the concave side (sign of k), the limit is exactly $\gamma(0) + \frac{1}{k}N(0)$, the centre of curvature of Definition 2.4.

Step 6 — the case $k = 0$. If $k(0) = 0$ the area is $o(\varepsilon^3)$ and the radius diverges: the circle through three points degenerates into the tangent line, consistently with the absence of an osculating circle at inflection points.

Solution. S2. *Step 1 — complex form.* Identifying $\mathbb{R}^2$ with $\mathbb{C}$, the hypocycloid of Definition 2.7 reads

$$z(t) = (R - r)e^{it} + r e^{-i\frac{R-r}{r}t}.$$

Indeed, taking real and imaginary parts and using Euler's formula (Theorem (Volume II, Chapter 3) of Chapter 3):

$$\operatorname{Re} z = (R - r) \cos t + r \cos \frac{R-r}{r}t, \quad \operatorname{Im} z = (R - r) \sin t - r \sin \frac{R-r}{r}t,$$

exactly the two given components.

Step 2 — kinematic reading. The formula exhibits the hypocycloid as the sum of two uniform circular motions: one of radius $R - r$ and angular velocity $+1$ (the centre of the moving circle about O), one of radius r and angular velocity $-\frac{R-r}{r}$ (the point about the moving centre, in the opposite sense). It is the same scheme as the phasors of Chapter 6 and as the Ptolemaic epicycles.

Step 3 — the case $R = 2r$. Substituting, $R - r = r$ and $\frac{R-r}{r} = 1$:

$$z(t) = r e^{it} + r e^{-it} = r(e^{it} + e^{-it}) = 2r \cos t,$$

by the inverse Euler formula (Theorem (Volume II, Chapter 3) of Chapter 3).

Step 4 — conclusion. $z(t)$ is a real number for every t : the point stays on the real axis, i.e. on the diameter of the fixed circle, moving along it with law $2r \cos t$, simple harmonic motion. This is Theorem 2.8, proved in four lines of algebra.

Step 5 — generalisation. The same computation shows that the hypocycloid is closed if and only if the two frequencies 1 and $-\frac{R-r}{r}$ are commensurable, i.e. if $R/r \in \mathbb{Q}$: the criterion of Exercise N6 is recovered with no geometry at all. In the language of Chapter 4 the curve is a *two-term trigonometric polynomial*: its closure is the periodicity of a sum of two exponentials.

Solution. S3. *Step 1 — translations.* If $\tilde{\gamma} = \gamma + b$ with b constant, then $\tilde{\gamma}' = \gamma'$: the unit tangent, the normal and all derivatives are unchanged, hence $\tilde{k} = k$.

Step 2 — rotations. Let A be a rotation, i.e. (in the complex language of Chapter 3) multiplication by $e^{i\alpha}$. Then $\tilde{T} = e^{i\alpha}T$ and, since rotating by $+90^\circ$ is multiplication by i , which commutes with $e^{i\alpha}$,

$$\tilde{N} = i\tilde{T} = ie^{i\alpha}T = e^{i\alpha}iT = e^{i\alpha}N.$$

Hence $\tilde{T}' = e^{i\alpha}T' = e^{i\alpha}kN = k\tilde{N}$, i.e. $\tilde{k} = k$. Arc length is unchanged because $|e^{i\alpha}| = 1$.

Step 3 — reflections. Let A be reflection in the real axis, i.e. conjugation $z \mapsto \bar{z}$. Then $\tilde{T} = \bar{T}$, but

$$\tilde{N} = i\tilde{T} = i\bar{T} = -i\bar{T} = -\bar{N},$$

because $\overline{iw} = -i\bar{w}$ for every w . Hence $\tilde{T}' = \overline{T'} = \bar{kN} = k\bar{N} = -k\tilde{N}$, i.e. $\tilde{k} = -k$. Every reflection is a composition of this one with a rotation, so the result holds for all of them.

Step 4 — reversal of orientation. With $\tilde{\gamma}(s) = \gamma(-s)$: $\tilde{T}(s) = -T(-s)$ and $\tilde{N}(s) = -N(-s)$, while

$$\frac{d\tilde{T}}{ds}(s) = T'(-s) = k(-s)N(-s) = -k(-s)\tilde{N}(s),$$

hence $\tilde{k}(s) = -k(-s)$: the curvature changes sign.

Step 5 — conclusion. The *signed* curvature is invariant under direct rigid motions (translations and rotations) and changes sign under the indirect ones and under reversal of the direction of travel. The *geometric* curvature $|k|$ is therefore invariant under all isometries of

the plane and under every reparametrisation: it is a quantity intrinsic to the figure, not to its description. ✓

Step 6 — check on the circle. The counterclockwise circle has $k = 1/r$, the clockwise one $k = -1/r$ (Theorem 2.2); the absolute value is $1/r$ in both cases, as it must be for what is the same figure. ✓

Solution. S4. *Step 1 — data.* $\gamma(t) = (a \cos t, b \sin t)$, with $\gamma'(t) = (-a \sin t, b \cos t)$ and

$$D(t) = \|\gamma'(t)\| = \sqrt{a^2 \sin^2 t + b^2 \cos^2 t}.$$

Step 2 — unit vectors.

$$T = \frac{1}{D}(-a \sin t, b \cos t), \quad N = \frac{1}{D}(-b \cos t, -a \sin t),$$

having rotated T by $+90^\circ$ as in Definition 2.2.

Step 3 — curvature. From Example 2.2, $k = ab/D^3$, hence $1/k = D^3/(ab)$.

Step 4 — centre of curvature.

$$e = \gamma + \frac{1}{k} N = (a \cos t, b \sin t) + \frac{D^3}{ab} \cdot \frac{1}{D}(-b \cos t, -a \sin t),$$

that is, componentwise,

$$X = a \cos t - \frac{D^2}{a} \cos t = \frac{\cos t}{a}(a^2 - D^2), \quad Y = b \sin t - \frac{D^2}{b} \sin t = \frac{\sin t}{b}(b^2 - D^2).$$

Step 5 — simplification. With $D^2 = a^2 \sin^2 t + b^2 \cos^2 t$:

$$a^2 - D^2 = a^2(1 - \sin^2 t) - b^2 \cos^2 t = (a^2 - b^2) \cos^2 t,$$

$$b^2 - D^2 = b^2(1 - \cos^2 t) - a^2 \sin^2 t = (b^2 - a^2) \sin^2 t.$$

Substituting,

$$X = \frac{a^2 - b^2}{a} \cos^3 t, \quad Y = \frac{b^2 - a^2}{b} \sin^3 t,$$

which is the formula of Example 2.4. ✓

Step 6 — Cartesian form. From $\cos t = (\frac{aX}{a^2 - b^2})^{1/3}$ and $\sin t = (\frac{bY}{b^2 - a^2})^{1/3}$, squaring and adding:

$$(aX)^{2/3} + (bY)^{2/3} = (a^2 - b^2)^{2/3},$$

the equation of an astroid. ✓

Step 7 — limiting cases. For $a = b$ one gets $X = Y = 0$: the evolute is the centre, consistently with Theorem 2.6(iv). For $b \rightarrow 0$ (ellipse degenerating into a segment) the cusps go to infinity along Y , consistently with the curvature tending to zero along the long sides. ✓

2.9.5 Exercises from Chapter 2 of Volume III

The exercises below come from the plane-curves chapter of the previous edition of Volume III and are reproduced with their solutions.

Exercise 2.17. Compute the arc length of the logarithmic spiral $\gamma(t) = (e^t \cos t, e^t \sin t)$ from $t = 0$ to $t = T$.

Step-by-step proof. Passo 1. $\gamma'(t) = e^t(\cos t - \sin t, \sin t + \cos t)$. **Passo 2.** $|\gamma'(t)|^2 = e^{2t}[(\cos t - \sin t)^2 + (\sin t + \cos t)^2] = e^{2t} \cdot 2$, so $|\gamma'(t)| = \sqrt{2} e^t$. **Passo 3.** $s = \int_0^T \sqrt{2} e^t dt = \sqrt{2}(e^T - 1)$. $\square$

Exercise 2.18. Compute the curvature of the spiral $\gamma(t) = (e^t \cos t, e^t \sin t)$.

Solution. Passo 1. $x' = e^t(\cos t - \sin t)$, $y' = e^t(\sin t + \cos t)$; $x'' = -2e^t \sin t$, $y'' = 2e^t \cos t$. **Passo 2.** $x'y'' - y'x'' = e^{2t}[(\cos t - \sin t)2 \cos t - (\sin t + \cos t)(-2 \sin t)] = 2e^{2t}$. **Passo 3.** $(x'^2 + y'^2)^{3/2} = (2e^{2t})^{3/2} = 2\sqrt{2} e^{3t}$. **Passo 4.** $\kappa = \frac{2e^{2t}}{2\sqrt{2} e^{3t}} = \frac{1}{\sqrt{2} e^t}$: the curvature decays exponentially along the spiral.

Exercise 2.19. Determine the center and radius of the osculating circle of the parabola $y = x^2$ at the point $(1, 1)$.

Solution. With $\gamma(t) = (t, t^2)$ at $t = 1$: $\gamma' = (1, 2)$, $\gamma'' = (0, 2)$, $|\gamma'|^2 = 5$. Curvature $\kappa = \frac{1 \cdot 2 - 2 \cdot 0}{5^{3/2}} = \frac{2}{5\sqrt{5}}$, hence $\rho = \frac{5\sqrt{5}}{2}$. The unit tangent is $T = \frac{1}{\sqrt{5}}(1, 2)$, the normal $+90^\circ$ is $N = \frac{1}{\sqrt{5}}(-2, 1)$. Center:

$$c = (1, 1) + \frac{1}{\kappa}N = (1, 1) + \frac{5\sqrt{5}}{2} \cdot \frac{1}{\sqrt{5}}(-2, 1) = (1, 1) + \frac{5}{2}(-2, 1) = \left(-4, \frac{7}{2}\right).$$

Osculating circle: center $(-4, 7/2)$, radius $5\sqrt{5}/2 \approx 5.59$.

Exercise 2.20. Verify that, for the ellipse with $a > b$, the radius of curvature is maximum on the minor axis and minimum on the major axis.

Solution. $\rho(t) = \frac{1}{ab}g(t)^{3/2}$ with $g(t) = a^2 \sin^2 t + b^2 \cos^2 t = b^2 + (a^2 - b^2) \sin^2 t$. Since $a > b$, g is minimum for $\sin t = 0$ (major axis, $\rho = b^2/a$) and maximum for $\sin^2 t = 1$ (minor axis, $\rho = a^2/b$). Since $a^2/b > b^2/a$, the claim follows.

Exercise 2.21. Compute the radius of curvature of the catenary $y = a \cosh(x/a)$ at the vertex $x = 0$ and interpret its value.

Solution. From Example 2.14, $\rho = a \cosh^2(x/a)$. At $x = 0$: $\cosh 0 = 1$, hence $\rho(0) = a$. At the vertex the radius of curvature equals the parameter a of the catenary (the minimum height of the curve above the directrix): the osculating circle at the vertex has center at $(0, 2a)$ and radius a .

Exercise 2.22. For the cardioid in polar form $r(\theta) = 1 + \cos \theta$, compute the curvature using the polar formula $\kappa = \frac{r^2 + 2r'^2 - rr''}{(r^2 + r'^2)^{3/2}}$.

Solution. Passo 1. $r = 1 + \cos \theta$, $r' = -\sin \theta$, $r'' = -\cos \theta$. **Passo 2.** Numerator: $r^2 + 2r'^2 - rr'' = (1 + \cos \theta)^2 + 2 \sin^2 \theta + (1 + \cos \theta) \cos \theta$. Expanding: $1 + 2 \cos \theta + \cos^2 \theta +$

$2\sin^2\theta + \cos\theta + \cos^2\theta = 3 + 3\cos\theta = 3(1 + \cos\theta)$. **Passo 3.** Denominator: $r^2 + r'^2 = (1 + \cos\theta)^2 + \sin^2\theta = 2 + 2\cos\theta = 2(1 + \cos\theta)$, raised to $3/2$: $[2(1 + \cos\theta)]^{3/2}$. **Passo 4.**

$$\kappa = \frac{3(1 + \cos\theta)}{[2(1 + \cos\theta)]^{3/2}} = \frac{3}{2^{3/2}\sqrt{1 + \cos\theta}} :$$

the curvature diverges at the cusp ($\theta = \pi$, $r = 0$), consistent with the geometry of the cardioid.

Exercise 2.23. A robotic path consists of: straight line, clothoid, circle arc of radius r , clothoid, straight line. Write the piecewise curvature law $\kappa(s)$ and verify that it is continuous.

Solution. With lengths L_1 (entry clothoid) and arc starting at $s = s_1$:

$$\kappa(s) = \begin{cases} 0 & \text{initial straight line} \\ c(s - s_0) & \text{clothoid, } s \in [s_0, s_0 + L_1], \ c = \frac{1}{rL_1} \\ 1/r & \text{arc} \\ 1/r - c(s - s_2) & \text{exit clothoid} \\ 0 & \text{final straight line} \end{cases}$$

At the ends of each segment the values match ($0 \rightarrow 0$, then $cL_1 = 1/r$, then $1/r \rightarrow 1/r$, then $1/r$ decreases to 0): κ is continuous and piecewise linear. It is the typical curvature profile of an industrial trajectory with limited jerk.

2.10. Self-assessment quiz

Eight items in order of competence; the commented answers are in the Teacher's key (Section 2.11).

- (Definition) At the point $\gamma(s_0)$ of a curve with $k(s_0) \neq 0$, the *osculating circle* is the circle with
 - centre $\gamma(s_0) + k(s_0)N(s_0)$ and radius $|k(s_0)|$
 - centre $\gamma(s_0) + \frac{1}{k(s_0)}N(s_0)$ and radius $1/|k(s_0)|$
 - centre $\gamma(s_0) + \frac{1}{k(s_0)}T(s_0)$ and radius $1/|k(s_0)|$
 - centre $\gamma(s_0)$ and radius $1/|k(s_0)|$
- (Hypothesis) In the Fundamental theorem of plane curves, the hypothesis that guarantees $\gamma \in C^2$ is
 - k bounded
 - k continuous
 - k differentiable
 - k of constant sign
- (Symbolic computation) The radius of curvature of the catenary $y = a \cosh(x/a)$ equals
 - $a \cosh(x/a)$
 - $a \cosh^2(x/a)$
 - $a \sinh^2(x/a)$
 - $a^2 \cosh(x/a)$
- (Numerical computation) For a clothoid transition $k(s) = cs$ with $c = 0.04 \text{ m}^{-2}$ towards an arc of radius $r = 5 \text{ m}$, the length of the stretch and the angular deviation are
 - $L = 5 \text{ m}$, $\Delta\varphi = 0.5 \text{ rad}$
 - $L = 5 \text{ m}$, $\Delta\varphi = 0.25 \text{ rad}$
 - $L = 0.2 \text{ m}$, $\Delta\varphi = 0.5 \text{ rad}$
 - $L = 25 \text{ m}$, $\Delta\varphi = 12.5 \text{ rad}$
- (Proof step) In the proof of the Tait–Kneser theorem, the inequality $\|e(s_2) - e(s_1)\| < |\rho(s_2) - \rho(s_1)|$ is *strict* because

-
- A) ρ is strictly monotone B) equality would force N to be constant, whereas $\|N'\| = k > 0$ C) the evolute is regular D) the two discs are disjoint
6. (Error diagnosis) A student computes the curvature of the spiral $\gamma(t) = e^t(\cos t, \sin t)$ as $k = \vartheta'(t)$, where ϑ is the tangent angle, and obtains $k \equiv 1$. The mistake is
- A) the formula $k = \vartheta'$ holds only for convex curves B) t is not the arc length: one needs $k = \vartheta'(t)/\|\gamma'(t)\|$ C) the tangent angle of the spiral is not differentiable D) the absolute value of ϑ' must be used
7. (Transfer) A wheeled vehicle cannot travel a direct straight-line $\rightarrow$ arc transition because
- A) the trajectory would not be continuous B) the curvature would jump from 0 to $1/r$ and the steering angle would have to change instantaneously C) the arc length would not be defined D) the circular arc cannot be parametrised by arc length
8. (Source and metacognition) The reduction of the clothoid to the Fresnel integrals and the limit values $C(\infty) = S(\infty) = \frac{1}{2}$ are found in
- A) do Carmo, *Differential Geometry of Curves and Surfaces*, §1-5 B) NIST Digital Library of Mathematical Functions, §7.2, formulae (7.2.7)–(7.2.9) C) Hopf, *Über die Drehung der Tangenten...* D) Struik, *Lectures on Classical Differential Geometry*, ch. 4

2.10.1 Supplementary questionnaire

- The curvature of a circle of radius r traversed counterclockwise is

A) r B) $1/r$ C) r^2 D) $2\pi r$
- The osculating circle has contact with the curve of order

A) zero B) first C) second D) third
- A plane curve with constant non-zero curvature is

A) a line B) an arc of a circle C) a parabola D) an ellipse
- The evolute of a curve is

A) the parallel curve B) the locus of the centres of curvature C) the reflected curve D) the tangent
- The evolute is the envelope of

A) the tangents B) the normals C) the chords D) the secants
- The evolute reduces to a point if and only if the curve is

A) a line B) a circle C) a parabola D) an astroid
- The circle-involute profile is used in gears because

A) it is easier to cut B) it keeps the gear ratio constant even when the centre distance varies C) it reduces weight D) it is stronger
- The radius of curvature of the cycloid at its highest point is

A) r B) $2r$ C) $4r$ D) $8r$
- A circle of radius r rolling inside one of radius $2r$ generates

A) a cardioid B) a diameter C) an astroid D) a circle

10. The Fundamental theorem of plane curves states that $k(s)$ determines the curve
 A) uniquely B) up to a direct rigid motion C) up to a homothety D) only if $k > 0$
11. A clothoid is characterised by curvature
 A) constant B) zero C) affine in the arc length D) quadratic in time
12. In SINUMERIK G-code a clockwise circular arc is programmed with
 A) G01 B) G02 C) G03 D) G00

2.11. Teacher's key

BEST PRACTICE

Quiz — answers, rationales and diagnosis.

- 1) **B.** *Rationale:* this is Definition 2.4: the centre lies on the normal at distance $\rho = 1/|k|$, on the side towards which the curve bends, and the radius is ρ . *Distractors:* A swaps radius and curvature; C puts the centre on the tangent instead of the normal; D leaves the centre on the curve. *Diagnosed error:* confusion between k and $\rho = 1/|k|$. *Source:* Theorem 2.4. *Prerequisite:* the unit vectors T and N . *Remedial work:* redo Exercise 2.19 drawing the circle.
- 2) **B.** *Rationale:* in Step 2 of the proof of Theorem 2.9, the continuity of k gives $\vartheta \in C^1$ and hence $\gamma \in C^2$; nothing more is needed. *Distractors:* A is not enough (a bounded but discontinuous k makes ϑ only Lipschitz); C is stronger than necessary and would give $\gamma \in C^3$; D is irrelevant. *Diagnosed error:* asking of the hypothesis more than the proof uses. *Source:* Theorem 2.9, Step 2. *Prerequisite:* the fundamental theorem of integral calculus. *Remedial work:* reread Step 2 marking where continuity enters.
- 3) **B.** *Rationale:* from Example 2.3, $k = 1/(a \cosh^2(x/a))$ and $\rho = a \cosh^2(x/a) = y^2/a$. *Distractors:* A is y , that is the ordinate, not the radius; C confuses $\cosh$ with $\sinh$; D gets the power of a wrong and is not even homogeneous. *Diagnosed error:* forgetting the exponent $3/2$ in the denominator of the formula for graphs. *Source:* Theorem 2.3. *Prerequisite:* hyperbolic functions. *Remedial work:* a dimensional check, $[\rho] = \text{length}$.
- 4) **A.** *Rationale:* by Proposition 2.3(i), $L = 1/(rc) = 1/(5 \times 0.04) = 5$ m, and by (ii) $\Delta\varphi = cL^2/2 = 0.04 \times 25/2 = 0.5$ rad (Example 2.8). *Distractors:* B uses $\Delta\varphi = L/(4r)$; C swaps the roles of r and c ; D forgets to divide by r . *Diagnosed error:* using $\Delta\varphi = cL$ instead of $cL^2/2$. *Source:* Proposition 2.3. *Prerequisite:* integration of an affine function. *Remedial work:* redo Steps 1–2 of Example 2.8.
- 5) **B.** *Rationale:* this is exactly Step 3 of the proof of Proposition 2.1: equality in the integral triangle inequality would force N to be constant, but $N' = -kT$ has norm $k > 0$. *Distractors:* A gives only the *weak* inequality (Step 2); C and D are consequences, not causes. *Diagnosed error:* confusing the weak inequality with the strict one. *Source:* Proposition 2.1, Steps 2–3. *Prerequisite:* the triangle inequality for vector-valued integrals. *Remedial work:* rewrite Step 3 isolating the case of equality.
- 6) **B.** *Rationale:* the formula $k = d\vartheta/ds$ is with respect to arc length; in an arbitrary

parameter one has $k = \vartheta'(t)/\|\gamma'(t)\|$. For the spiral $\vartheta' = 1$ and $\|\gamma'\| = \sqrt{2}e^t$, whence $k = 1/(\sqrt{2}e^t)$ (Exercise 2.5, Step 3). *Distractors*: A invents a non-existent hypothesis; C is false ($\vartheta(t) = t + \pi/4$ is smooth); D does not change the size of the error. *Diagnosed error*: using a non-natural parameter as if it were the natural one. *Source*: Theorem 2.3. *Prerequisite*: the chain rule. *Remedial work*: recompute k for the spiral with the general formula and compare.

7) B. *Rationale*: this is Remark 2.3 and Section 2.6.1: k is proportional to the steering angle, which is a continuous physical variable. *Distractors*: A is false, the trajectory is continuous (indeed C^1); C and D are meaningless statements, the arc is regular. *Diagnosed error*: confusing the regularity of the trajectory with that of the curvature. *Source*: Proposition 2.3, Step 5. *Prerequisite*: the notion of continuity. *Remedial work*: draw $k(s)$ for the path of Exercise 2.23.

8) B. *Rationale*: definitions (7.2.7)–(7.2.8) and limit (7.2.9) of the DLMF are exactly what Proposition 2.2(ii) and Remark 2.4 use. *Distractors*: A deals with plane curves but not with the Fresnel integrals; C is about the rotation index; D does not contain the limit values. *Diagnosed error*: citing a differential-geometry textbook for a result of special-function analysis. *Source*: NIST DLMF, §7.2. *Prerequisite*: being able to tell which kind of source fits which claim. *Remedial work*: check formula (7.2.9) online and compare it with Remark 2.4.

Assigned exercises — answers.

2.1 (hyperbola $xy = 1$). (a) $k(t) = \frac{2t^3}{(t^4 + 1)^{3/2}}$, hence $k(1) = 2/2^{3/2} = 1/\sqrt{2} = 0.707107$.

(b) $\rho(1) = \sqrt{2} = 1.414214$; $T(1) = \frac{1}{\sqrt{2}}(1, -1)$, $N(1) = \frac{1}{\sqrt{2}}(1, 1)$, centre $(1, 1) + \sqrt{2} \cdot \frac{1}{\sqrt{2}}(1, 1) = (2, 2)$. (c) $e(t) = \left(\frac{3t^4 + 1}{2t^3}, \frac{t^4 + 3}{2t} \right)$; for $t = 1$ this gives $(2, 2)$, consistent with (b). (d)

$\rho(t) = \frac{(t^4 + 1)^{3/2}}{2t^3}$ and $\rho'(t) = \frac{3(t^4 + 1)^{1/2}(t^4 - 1)}{2t^4}$, which for $t > 0$ vanishes only at $t = 1$: a single vertex, a minimum (ρ decreases for $t < 1$ and increases for $t > 1$). (e) $e(0.7) = (2.507726; 2.314357)$ and $e(1.6) = (2.522070; 2.985500)$; `verifica_cap02_cap04.py`, block [C2-1]. ✓

2.2 (evolute of the cycloid). (a) $\gamma' = r(1 - \cos t, \sin t)$, $\|\gamma'\|^2 = r^2(2 - 2\cos t) = 4r^2 \sin^2 \frac{t}{2}$, hence $\|\gamma'\| = 2r \sin \frac{t}{2}$ on $(0, 2\pi)$; with $k = 1/(4r \sin \frac{t}{2})$ one gets $\rho = 4r \sin \frac{t}{2}$. (b) $e(t) = r(t + \sin t, \cos t - 1)$. (c) with $u = t + \pi$: $\sin u = -\sin t$ and $\cos u = -\cos t$, hence $r(u - \sin u) - \pi r = r(t + \pi + \sin t) - \pi r = r(t + \sin t)$ and $r(1 - \cos u) - 2r = r(1 + \cos t) - 2r = r(\cos t - 1)$: this coincides with (b). (d) By Theorem 2.6(iii) the length of the arc of the evolute is $|\rho(\pi) - \rho(\pi/2)| = 4r - 4r \sin \frac{\pi}{4} = 4r - 2\sqrt{2}r = 1.171573r$, that is 14.64% of the length $8r$ of one arch. (e) Because a pendulum whose suspension is constrained between two cycloidal arcs describes the involute of the cycloid, which is again a cycloid (Huygens 1673); on a cycloid the period of the oscillations does not depend on the amplitude. Numerical checks in `verifica_cap02_cap04.py`, block [C2-4]. ✓

2.3 (clothoid transition). (a) $c \leq \dot{k}_{\max}/v = 0.02/8 = 0.0025 \text{ m}^{-2}$; with equality, $L = 1/(rc) = 1/(40 \times 0.0025) = 10 \text{ m}$. (b) $\Delta\varphi = cL^2/2 = 0.125 \text{ rad} = 7.161972^\circ$ (and also $L/(2r) = 10/80$). (c) $a = \sqrt{\pi/0.0025} = 35.449077 \text{ m}$, $\tau_L = 0.282095$, $C(\tau_L) = 0.281654$, $S(\tau_L) = 0.011741$, hence $\gamma(L) = (9.984386; 0.416202) \text{ m}$ and chord 9.993057 m . (d) $p = 0.416202 - 40(1 - \cos 0.125) = 0.104109 \text{ m}$ against $L^2/(24r) = 100/960 = 0.104167 \text{ m}$: relative discrepancy 0.0558%. The term $O(L^4/r^3)$ of Proposition 2.4 weighs, relative to the leading term $L^2/(24r)$, as $O((L/r)^2)$: passing from $L/r = 1$ (Example 2.8, discrepancy

0.90%) to $L/r = 0.25$ the relative discrepancy must be divided by 16, and indeed $0.90/16 = 0.056$. ✓(e) With $\dot{k}_{\max} = 0.01 \text{ m}^{-1}\text{s}^{-1}$: $c = 0.00125 \text{ m}^{-2}$, $L = 20 \text{ m}$, $\Delta\varphi = 0.25 \text{ rad} = 14.323945^\circ$, $a = 50.132565 \text{ m}$, $\tau_L = 0.398942$, $\gamma(L) = (19.875361; 1.659241) \text{ m}$, $p = 0.415738 \text{ m}$ against $L^2/(24r) = 0.416667 \text{ m}$ (discrepancy 0.22%). The transition doubles in length and the offset quadruples: one gains in comfort (the lateral acceleration grows more slowly) and loses in available space. All the values are recomputed in `verifica_cap02_cap04.py`, block [C2-3]. ✓

2.12. Chapter formulary

Length and arc length

$$L = \int_a^b \|\gamma'(t)\| dt, \quad \frac{ds}{dt} = \|\gamma'(t)\|$$

Frenet formulas in the plane

$$T' = k N, \quad N' = -k T, \quad k = \frac{d\vartheta}{ds}, \quad N = iT \quad (\text{in } \mathbb{C})$$

Curvature

$$k = \frac{x'y'' - y'x''}{(x'^2 + y'^2)^{3/2}}, \quad k_{\text{graph}} = \frac{f''}{(1 + f'^2)^{3/2}}, \quad \rho = \frac{1}{|k|}$$

$$\text{circle of radius } r : k = \frac{1}{r}; \quad \text{line} : k = 0$$

Osculating circle and evolute

$$c(s) = \gamma(s) + \frac{1}{k(s)}N(s), \quad e'(s) = \rho'(s)N(s), \quad L_{\text{evolute}} = |\Delta\rho|$$

Involute

$$\iota_a(s) = \gamma(s) + (a - s)T(s), \quad \iota'_a = (a - s)k N$$

$$\text{circle involute} : \iota(t) = r(\cos t + t \sin t, \sin t - t \cos t), \quad \tilde{\rho} = rt, \quad \Lambda = \frac{rt^2}{2}$$

Rolling curves

$$\text{cycloid} : \gamma = r(t - \sin t, 1 - \cos t), \quad \rho = 4r|\sin \frac{t}{2}|, \quad L_{\text{arch}} = 8r$$

$$\text{hypocycloid (in } \mathbb{C}) : z(t) = (R - r)e^{it} + re^{-i\frac{R-r}{r}t}; \quad R = 2r \Rightarrow z = 2r \cos t$$

Evolute of the ellipse

$$e(t) = \left(\frac{a^2 - b^2}{a} \cos^3 t, \frac{b^2 - a^2}{b} \sin^3 t \right), \quad \rho_{\max} = \frac{a^2}{b}, \quad \rho_{\min} = \frac{b^2}{a}$$

Fundamental theorem (synthesis of a curve)

$$\vartheta(s) = \vartheta_0 + \int_0^s k, \quad \gamma(s) = p_0 + \int_0^s (\cos \vartheta, \sin \vartheta),$$

$$k \equiv 0 \Rightarrow \text{straight line}; \quad k \equiv \frac{1}{r} \Rightarrow \text{circle}; \quad k = k_0 + cs \Rightarrow \text{clothoid}$$

Nested osculating circles (Tait–Kneser)

$$k > 0, \quad k' \neq 0 \implies \|e(s_2) - e(s_1)\| < |\rho(s_2) - \rho(s_1)|$$

Clothoid and Fresnel integrals

$$\varphi(s) = \frac{cs^2}{2}, \quad \gamma(s) = a(C(\tau), S(\tau)), \quad a = \sqrt{\frac{\pi}{c}}, \quad \tau = \frac{s}{a}, \quad \rho(s)s = \frac{1}{c}$$

$$C(\tau) = \int_0^\tau \cos \frac{\pi u^2}{2} du, \quad S(\tau) = \int_0^\tau \sin \frac{\pi u^2}{2} du$$

Straight-line-arc transition

$$L = \frac{1}{rc}, \quad \Delta\varphi = \frac{cL^2}{2} = \frac{L}{2r}, \quad \dot{k} = cv \leq \dot{k}_{\max} \Rightarrow L \geq \frac{v}{r \dot{k}_{\max}}$$

$$p = y(L) - r(1 - \cos \Delta\varphi) = \frac{L^2}{24r} + O\left(\frac{L^4}{r^3}\right)$$

Catenary

$$y = a \cosh \frac{x}{a} \Rightarrow k = \frac{1}{a \cosh^2(x/a)}, \quad \rho = a \cosh^2 \frac{x}{a} = \frac{y^2}{a}$$

CHAPTER 3

Space curves: Frenet–Serret and torsion

A plane curve never leaves its own plane: one number describes it, the signed curvature, and the fundamental theorem of plane curves (Chapter 2) says that this number determines it up to a rigid motion. In space a second degree of freedom appears: besides bending, a curve may *twist*, that is, leave the plane that best approximates it. The quantity measuring this departure is the **torsion**, and the fundamental theorem of space curves states that the pair (κ, τ) determines the curve up to a direct rigid motion: two functions of one variable contain the whole geometry of a thread in space.

The chapter follows a single line. First the moving Frenet frame $\{T, N, B\}$ is built and its derivatives are shown to be expressible in terms of κ and τ alone (Section 3.1); then the fundamental theorem, existence and uniqueness, is proved (Section 3.2) by reducing it to a linear Cauchy problem whose solvability is proved in full in the chapter appendix (Section 3.11); the theorem is then used to recognise the **circular helix** as the only curve with constant non-zero curvature and torsion, and generalised helices are characterised by Lancret's theorem (Section 3.3); the **osculating circle** and the **osculating sphere** are introduced (Section 3.4); the chapter closes with the necessary and sufficient condition for a curve to lie on a sphere (Section 3.5).

The circle appears at every step: it is the osculating circle that defines curvature; it is a circle that a curve with $\tau \equiv 0$ and constant κ must be; it is the circular helix — the circle «drawn out» along its own axis — that is the only curve with constant κ and τ ; and it is again a circle that the osculating sphere cuts on the osculating plane.

INFO

Level and prerequisites. Level **B–C**; Section 3.5 and the appendix are of level **C**.

Internal prerequisites. Arc length, reparametrisation by arc length, curvature and osculating circle of plane curves, fundamental theorem of plane curves (Chapter 2); the orthogonal group, $SO(3)$ and direct rigid motions (Chapter 5); scalar product, cross product and triple product in $\mathbb{R}^3$ (Volume I, Chapter 2).

External prerequisites, assumed and not reproved. Exactly one, stated in full in Remark 3.6: the completeness of the space $C([\alpha, \beta], \mathbb{R}^n)$ of continuous functions with the maximum norm. Everything else — including existence and uniqueness for the Frenet system and the contraction mapping theorem — is proved in this chapter.

What you will learn. To build the Frenet frame of a space curve and derive the Frenet–Serret formulas from it; to compute κ and τ in an arbitrary parameter and to recognise when a curve is a straight line, when it is planar, when it is a circle, when it is a helix; to use the fundamental theorem as a *tool* (to identify a curve from κ and τ , not merely to contemplate its statement); to determine osculating circles and spheres; to decide with a single computation whether a curve lies on a sphere, and to know why the condition « $\rho^2 + (\rho'\sigma)^2$ constant», which one often reads, is *not* enough.

Warning. Chapter conventions.

- A curve is a map $\gamma : I \rightarrow \mathbb{R}^3$ defined on an open interval $I \subseteq \mathbb{R}$; the prime always denotes the derivative with respect to the parameter written, and s is reserved for arc length (*unit-speed parametrisation*: $|\gamma'(s)| \equiv 1$).
- $\langle \cdot, \cdot \rangle$ is the standard scalar product, $u \times v$ the cross product, $\det(u, v, w) = \langle u \times v, w \rangle$ the triple product.
- **Sign of the torsion.** We adopt

$$T' = \kappa N, \quad N' = -\kappa T + \tau B, \quad B' = -\tau N,$$

that is $\tau = -\langle B', N \rangle$; with this choice the right-handed helix has $\tau > 0$ and $\tau = \langle \gamma' \times \gamma'', \gamma''' \rangle / |\gamma' \times \gamma''|^2$. **do Carmo, Gallier and Powell use the opposite convention** ($B' = +\tau N$): in their texts the torsion of the right-handed helix is negative and the formula in an arbitrary parameter carries a minus sign. Whenever a source is cited, the change of sign is flagged if it matters.

- $\rho = 1/\kappa$ is the **radius of curvature** and $\sigma = 1/\tau$ the **radius of torsion**; ρ' always means $d\rho/ds$.
- Decimals with the point; all digits shown are exact (rounded at the last digit written).

3.1. The Frenet frame and the torsion

Definition 3.1: Regular, biregular, unit-speed curve. Let $I \subseteq \mathbb{R}$ be an open interval. A curve $\gamma : I \rightarrow \mathbb{R}^3$ of class C^k ($k \geq 1$) is called **regular** if $\gamma'(t) \neq 0$ for every $t \in I$. It is **parametrised by arc length** if $|\gamma'(s)| = 1$ for every $s \in I$; in that case one writes s instead of t . A curve parametrised by arc length, of class C^k with $k \geq 2$, is called **biregular** if $\gamma''(s) \neq 0$ for every $s \in I$. An arbitrary regular curve is called biregular if its reparametrisation by arc length is.

Every regular curve of class C^k admits a reparametrisation by arc length of the same class (Chapter 2): the proof given there for plane curves does not use the dimension of the target space and holds verbatim in $\mathbb{R}^3$. From now on, unless otherwise stated, curves are of class at least C^3 and parametrised by arc length.

Definition 3.2: Frenet trihedron. Let $\gamma : I \rightarrow \mathbb{R}^3$ be biregular, parametrised by arc length. One sets

$$T = \gamma', \quad \kappa = |T'| = |\gamma''| > 0, \quad N = \frac{T'}{\kappa}, \quad B = T \times N.$$

T is the unit **tangent**, N the **principal normal**, B the **binormal**, κ the **curvature**. The triple $\{T, N, B\}$ is the **Frenet frame**. The plane through $\gamma(s)$ spanned by $T(s), N(s)$ is the **osculating plane**, the one spanned by $N(s), B(s)$ the **normal plane**, the one spanned by $T(s), B(s)$ the **rectifying plane**.

Lemma 3.1: *The Frenet trihedron is a positive orthonormal basis. For every $s \in I$ the triple $\{T(s), N(s), B(s)\}$ is an orthonormal basis of $\mathbb{R}^3$ with $\det(T, N, B) = 1$; moreover*

$$N = B \times T, \quad T = N \times B.$$

Proof. By hypothesis $|T| = 1$. Differentiating the identity $\langle T, T \rangle = 1$ gives $2\langle T', T \rangle = 0$, hence $T' \perp T$ and so $N \perp T$; moreover $|N| = |T'|/\kappa = 1$ by definition of κ . The cross product of two orthogonal unit vectors is a unit vector orthogonal to both: $|B| = |T| |N| \sin \frac{\pi}{2} = 1$ and $B \perp T$, $B \perp N$. Hence $\{T, N, B\}$ is orthonormal, and $\det(T, N, B) = \langle T \times N, B \rangle = \langle B, B \rangle = 1 > 0$: the basis is positive.

For the last part one uses the double cross product identity $u \times (v \times w) = v\langle u, w \rangle - w\langle u, v \rangle$:

$$B \times T = (T \times N) \times T = -T \times (T \times N) = -(T\langle T, N \rangle - N\langle T, T \rangle) = N,$$

because $\langle T, N \rangle = 0$ and $\langle T, T \rangle = 1$; similarly $N \times B = N \times (T \times N) = T\langle N, N \rangle - N\langle N, T \rangle = T$.
□

Lemma 3.2: *The derivative of the binormal is parallel to the normal. Let γ be biregular of class C^3 , parametrised by arc length. Then $B'(s)$ is parallel to $N(s)$ for every $s \in I$.*

Proof. From $|B| = 1$, that is $\langle B, B \rangle = 1$, differentiation gives $\langle B', B \rangle = 0$: hence $B' \perp B$. Moreover, differentiating $B = T \times N$ and using $T' = \kappa N$,

$$B' = T' \times N + T \times N' = \kappa(N \times N) + T \times N' = T \times N',$$

because $N \times N = 0$. A cross product $T \times N'$ is orthogonal to T , hence $\langle B', T \rangle = 0$: so $B' \perp T$. Since $\{T, N, B\}$ is an orthonormal basis (Lemma 3.1), a vector orthogonal to both T and B lies on the line spanned by N .
□

Definition 3.3: Torsion. By Lemma 3.2 there exists a unique real number $\tau(s)$ such that

$$B'(s) = -\tau(s) N(s);$$

$\tau(s) = -\langle B'(s), N(s) \rangle$ is called the **torsion** of γ at s . The number $\sigma = 1/\tau$, defined where $\tau \neq 0$, is the **radius of torsion**; $\rho = 1/\kappa$ is the **radius of curvature**.

Theorem 3.1: Frenet–Serret formulas. Let $\gamma : I \rightarrow \mathbb{R}^3$ be biregular of class C^3 , parametrised by arc length, with curvature $\kappa > 0$ and torsion τ . Then

$$T' = \kappa N, \quad N' = -\kappa T + \tau B, \quad B' = -\tau N,$$

that is, in matrix form,

$$\frac{d}{ds} \begin{pmatrix} T \\ N \\ B \end{pmatrix} = \begin{pmatrix} 0 & \kappa & 0 \\ -\kappa & 0 & \tau \\ 0 & -\tau & 0 \end{pmatrix} \begin{pmatrix} T \\ N \\ B \end{pmatrix},$$

where the coefficient matrix is **skew-symmetric**.

Proof. The first formula is the very definition of N and κ : $T' = \kappa N$ because $N = T'/\kappa$ and $\kappa = |T'|$. The third is Definition 3.3, made legitimate by Lemma 3.2.

The second remains. By Lemma 3.1 one has $N = B \times T$; differentiating,

$$N' = B' \times T + B \times T' = (-\tau N) \times T + B \times (\kappa N) = -\tau(N \times T) + \kappa(B \times N).$$

From Lemma 3.1, $N \times T = -(T \times N) = -B$ and $B \times N = -(N \times B) = -T$. Substituting,

$$N' = -\tau(-B) + \kappa(-T) = -\kappa T + \tau B.$$

The skew-symmetry of the matrix is no accident: it is the infinitesimal translation of the fact

that $\{T, N, B\}$ stays orthonormal. Indeed, if $X_1 = T$, $X_2 = N$, $X_3 = B$ and $X'_i = \sum_k a_{ik} X_k$, differentiating $\langle X_i, X_j \rangle = \delta_{ij}$ gives $0 = \langle X'_i, X_j \rangle + \langle X_i, X'_j \rangle = a_{ij} + a_{ji}$. $\square$

Proposition 3.1: The Darboux vector. Setting $\omega = \tau T + \kappa B$, for every $X \in \{T, N, B\}$ one has

$$X' = \omega \times X,$$

and $|\omega| = \sqrt{\kappa^2 + \tau^2}$. The vector ω is called the **Darboux vector**: the Frenet frame rotates instantaneously about ω with angular velocity $|\omega|$.

Proof. One computes the three cross products using $T \times T = N \times N = B \times B = 0$ and the relations of Lemma 3.1, namely $T \times N = B$, $N \times B = T$, $B \times T = N$:

$$\omega \times T = \tau(T \times T) + \kappa(B \times T) = \kappa N = T';$$

$$\omega \times N = \tau(T \times N) + \kappa(B \times N) = \tau B - \kappa T = N';$$

$$\omega \times B = \tau(T \times B) + \kappa(B \times B) = -\tau N = B',$$

where $T \times B = -(B \times T) = -N$ was used. Finally, since $T \perp B$ and $|T| = |B| = 1$, Pythagoras' theorem gives $|\omega|^2 = \tau^2 + \kappa^2$. $\square$

Remark 3.1: Why the Darboux vector matters in robotics. The relation $X' = \omega \times X$ is formally identical to the velocity distribution law of a rotating rigid body: the Frenet frame behaves like a frame attached to a body rotating with angular velocity ω . The component of ω along T equals τ : it is the rotation of the tool about the direction of travel. It is exactly what the rotation minimizing frames used in trajectory generation cancel, when one wants to carry a tool along a curve without parasitic rotation; the link with Lie groups is taken up in Chapter 29 and the applications in Chapter 30.

Proposition 3.2: Curvature and torsion in an arbitrary parameter. Let $\gamma : J \rightarrow \mathbb{R}^3$ be regular of class C^3 with $\gamma' \times \gamma'' \neq 0$. Then γ is biregular and, writing $v = |\gamma'|$,

$$\kappa = \frac{|\gamma' \times \gamma''|}{|\gamma'|^3}, \quad \tau = \frac{\langle \gamma' \times \gamma'', \gamma''' \rangle}{|\gamma' \times \gamma''|^2} = \frac{\det(\gamma', \gamma'', \gamma''')}{|\gamma' \times \gamma''|^2}.$$

Moreover $\gamma' \times \gamma'' = v^3 \kappa B$: the binormal is the unit vector of $\gamma' \times \gamma''$.

Proof. Let $s(t)$ be the arc length, $s'(t) = v(t) > 0$. By the chain rule $\gamma' = vT$; differentiating again, and using $T' = \kappa N$ with respect to s (hence $dT/dt = v\kappa N$),

$$\gamma'' = v'T + v^2 \kappa N.$$

Therefore

$$\gamma' \times \gamma'' = vT \times (v'T + v^2 \kappa N) = vv'(T \times T) + v^3 \kappa (T \times N) = v^3 \kappa B,$$

and since $|B| = 1$, $v > 0$, $\kappa > 0$ we get $|\gamma' \times \gamma''| = v^3 \kappa$, that is the first formula. (That $\gamma' \times \gamma'' \neq 0$ is equivalent to $\kappa > 0$, i.e. to biregularity, is read off the same identity.)

Differentiating a third time and using $dN/dt = v(-\kappa T + \tau B)$,

$$\gamma''' = (v'' - v^3 \kappa^2)T + (v'v\kappa + (v^2 \kappa)')N + v^3 \kappa \tau B.$$

Only the component along B is needed: since $\gamma' \times \gamma'' = v^3 \kappa B$ and $\{T, N, B\}$ is orthonormal,

$$\langle \gamma' \times \gamma'', \gamma''' \rangle = v^3 \kappa \langle B, \gamma''' \rangle = v^3 \kappa \cdot v^3 \kappa \tau = v^6 \kappa^2 \tau = |\gamma' \times \gamma''|^2 \tau,$$

whence the second formula. The equality between triple product and determinant is the very definition of the triple product. $\square$

Proposition 3.3: Straight lines and plane curves. Let $\gamma : I \rightarrow \mathbb{R}^3$ be parametrised by arc length.

(i) If γ is of class C^2 and $\kappa \equiv 0$, then $\gamma(I)$ is contained in a straight line.

(ii) If γ is biregular of class C^3 , then $\gamma(I)$ is contained in a plane if and only if $\tau \equiv 0$.

Proof. (i) $\kappa = |\gamma''| \equiv 0$ gives $\gamma'' \equiv 0$, hence $\gamma' \equiv a$ constant with $|a| = 1$ and $\gamma(s) = \gamma(s_0) + (s - s_0)a$: this is the parametrisation of a line.

(ii) If $\tau \equiv 0$. Then $B' = -\tau N \equiv 0$, that is B is a constant vector, call it B_0 ($|B_0| = 1$). Fixing $s_0 \in I$ and setting $h(s) = \langle \gamma(s) - \gamma(s_0), B_0 \rangle$, one has $h'(s) = \langle \gamma'(s), B_0 \rangle = \langle T(s), B(s) \rangle = 0$ and $h(s_0) = 0$, hence $h \equiv 0$: the curve lies in the plane through $\gamma(s_0)$ orthogonal to B_0 .

Only if. Suppose $\gamma(I) \subseteq \Pi = \{x : \langle x - p, n \rangle = 0\}$ with $|n| = 1$. Differentiating $\langle \gamma - p, n \rangle \equiv 0$ gives $\langle T, n \rangle \equiv 0$; differentiating again, $\langle T', n \rangle = \kappa \langle N, n \rangle \equiv 0$ and, since $\kappa > 0$, $\langle N, n \rangle \equiv 0$. So n is orthogonal to T and to N , that is, it lies on the line spanned by B : both being unit vectors, $\langle B, n \rangle$ equals $+1$ or -1 at every point. The function $s \mapsto \langle B(s), n \rangle$ is continuous with values in $\{-1, +1\}$ on an interval, hence constant; therefore $B = \varepsilon n$ with ε a fixed sign, B is constant, $B' \equiv 0$ and $\tau = -\langle B', N \rangle \equiv 0$. $\square$

Proposition 3.4: Invariance under direct rigid motions. Let $F(x) = Rx + c$ with $R \in SO(3)$ and $c \in \mathbb{R}^3$ (**direct rigid motion**), and let γ be biregular parametrised by arc length. Then $\tilde{\gamma} = F \circ \gamma$ is again parametrised by arc length, biregular, and

$$\tilde{T} = RT, \quad \tilde{N} = RN, \quad \tilde{B} = RB, \quad \tilde{\kappa} = \kappa, \quad \tilde{\tau} = \tau.$$

If instead $\det R = -1$ one still has $\tilde{\kappa} = \kappa$, but $\tilde{\tau} = -\tau$.

Proof. Step 1: the cross product under $R \in SO(3)$. For all $u, v, w \in \mathbb{R}^3$,

$$\langle Ru \times Rv, w \rangle = \det(Ru, Rv, w) = \det(Ru, Rv, R(R^\top w)) = \det(R) \det(u, v, R^\top w),$$

using $RR^\top = I$ and multiplicativity of the determinant. Now $\det(u, v, R^\top w) = \langle u \times v, R^\top w \rangle = \langle R(u \times v), w \rangle$ because $R^\top$ is the adjoint of R . Since w is arbitrary,

$$Ru \times Rv = \det(R) R(u \times v).$$

For $R \in SO(3)$, $\det R = 1$ and hence $Ru \times Rv = R(u \times v)$.

Step 2. $\tilde{\gamma}' = R\gamma' = RT$ and $|RT| = |T| = 1$ (orthogonal matrices preserve the norm): $\tilde{\gamma}$ is parametrised by arc length and $\tilde{T} = RT$. Next $\tilde{T}' = RT' = \kappa RN$, hence $\tilde{\kappa} = |\tilde{T}'| = \kappa|RN| = \kappa > 0$ (biregularity is preserved) and $\tilde{N} = \tilde{T}'/\tilde{\kappa} = RN$. By Step 1, $\tilde{B} = \tilde{T} \times \tilde{N} = RT \times RN = R(T \times N) = RB$. Finally $\tilde{B}' = RB' = -\tau RN = -\tau \tilde{N}$, that is $\tilde{\tau} = \tau$.

Case $\det R = -1$. The steps concerning T, κ, N do not use the determinant and remain valid; Step 1 instead gives $\tilde{B} = RT \times RN = -R(T \times N) = -RB$, whence $\tilde{B}' = -RB' = \tau RN = \tau \tilde{N} = -(-\tau)\tilde{N}$ and therefore $\tilde{\tau} = -\tau$. A reflection exchanges right-handed and left-handed helices: torsion is an *oriented* invariant, curvature is not. $\square$

Example 3.1: The twisted cubic. Let $\gamma(t) = (t, t^2, t^3)$. Then $\gamma' = (1, 2t, 3t^2)$, $\gamma'' = (0, 2, 6t)$, $\gamma''' = (0, 0, 6)$ and

$$\gamma' \times \gamma'' = (2t \cdot 6t - 3t^2 \cdot 2, \quad 3t^2 \cdot 0 - 1 \cdot 6t, \quad 1 \cdot 2 - 2t \cdot 0) = (6t^2, -6t, 2).$$

Hence $|\gamma' \times \gamma''|^2 = 36t^4 + 36t^2 + 4 = 4(9t^4 + 9t^2 + 1)$, $|\gamma'|^2 = 1 + 4t^2 + 9t^4$ and $\langle \gamma' \times \gamma'', \gamma''' \rangle = 12$.

By Proposition 3.2,

$$\kappa(t) = \frac{2\sqrt{9t^4 + 9t^2 + 1}}{(1 + 4t^2 + 9t^4)^{3/2}}, \quad \tau(t) = \frac{12}{4(9t^4 + 9t^2 + 1)} = \frac{3}{9t^4 + 9t^2 + 1}.$$

At $t = 0$: $\kappa(0) = 2/1 = 2$ and $\tau(0) = 3$. *Independent check at $t = 0$* : $|\gamma'(0)| = 1$ (the parameter is already arc length at $t = 0$), $\gamma''(0) = (0, 2, 0)$ and hence $\kappa(0) = |\gamma''(0)| = 2$ ✓; moreover $T = (1, 0, 0)$, $N = (0, 1, 0)$, $B = (0, 0, 1)$ and the component of $\gamma'''(0) = (0, 0, 6)$ along B equals $6 = v^3 \kappa \tau = 1 \cdot 2 \cdot 3$ ✓.

At $t = 1$: $9 + 9 + 1 = 19$ and $1 + 4 + 9 = 14$, hence $\kappa(1) = 2\sqrt{19}/14^{3/2} = 8.7177979/52.3832034 = 0.1664235$ and $\tau(1) = 3/19 = 0.1578947$. *Independent check*: the direct numerical computation of $|\gamma' \times \gamma''|/|\gamma'|^3$ and of $\langle \gamma' \times \gamma'', \gamma''' \rangle / |\gamma' \times \gamma''|^2$ with high-precision numerical derivatives gives 0.166423535003 and 0.157894736842 , that is the same digits. ✓

Since $\tau(t) > 0$ for every t , the twisted cubic is planar on no arc (Proposition 3.3(ii)); and since $\kappa(t) \rightarrow 0$ and $\tau(t) \rightarrow 0$ as $t \rightarrow \pm\infty$, far from the origin the curve is more and more «almost straight».

3.2. The fundamental theorem of space curves

The Frenet–Serret formulas say that the derivatives of the frame are expressed by means of κ and τ alone. Read backwards, this means that κ and τ *prescribe* the motion of the frame, and hence — by integrating the tangent — the curve. The following theorem makes this idea exact. Its proof rests on a single analytic fact, existence and uniqueness of the solution of a *linear* Cauchy problem: that fact is proved in full in the chapter appendix (Lemma 3.4), and is not imported.

Theorem 3.2: Fundamental theorem of space curves. *Let $I \subseteq \mathbb{R}$ be an interval, $s_0 \in I$, $\kappa : I \rightarrow \mathbb{R}$ of class C^1 with $\kappa(s) > 0$ for every s , and $\tau : I \rightarrow \mathbb{R}$ of class C^1 .*

- (i) (Existence.) *Given a point $p_0 \in \mathbb{R}^3$ and a positive orthonormal basis $\{T_0, N_0, B_0\}$ of $\mathbb{R}^3$, there exists a curve $\gamma : I \rightarrow \mathbb{R}^3$ of class C^3 , parametrised by arc length, biregular, with curvature κ , torsion τ , $\gamma(s_0) = p_0$ and Frenet frame at s_0 equal to $\{T_0, N_0, B_0\}$.*
- (ii) (Uniqueness with initial data.) *Such a curve is unique.*
- (iii) (Uniqueness up to isometries.) *If γ and $\tilde{\gamma}$ are two biregular curves on I , parametrised by arc length, with the same curvature κ and the same torsion τ , then there exists exactly one direct rigid motion $F(x) = Rx + c$, $R \in SO(3)$, such that $\tilde{\gamma} = F \circ \gamma$.*

Proof. Step 1 — the Frenet system as a linear Cauchy problem. We look for three functions $T, N, B : I \rightarrow \mathbb{R}^3$ satisfying the Frenet–Serret formulas. Collecting them in the vector $X = (T, N, B) \in \mathbb{R}^9$ and writing I_3 for the 3×3 identity matrix, the three formulas amount to the single equation

$$X'(s) = \mathcal{A}(s)X(s), \quad \mathcal{A}(s) = \begin{pmatrix} 0 & \kappa(s)I_3 & 0 \\ -\kappa(s)I_3 & 0 & \tau(s)I_3 \\ 0 & -\tau(s)I_3 & 0 \end{pmatrix} \in M_9(\mathbb{R}).$$

$\mathcal{A}$ is continuous on I (indeed of class C^1), because κ and τ are. By Lemma 3.4 of the appendix there exists exactly one $X \in C^1(I, \mathbb{R}^9)$ with $X(s_0) = (T_0, N_0, B_0)$; and since $\mathcal{A}$ is C^1 , the equation itself gives $X' \in C^1$, that is $X \in C^2$.

Step 2 — orthonormality is preserved. Let $X_1 = T$, $X_2 = N$, $X_3 = B$ be the three vector components of the solution and let $g_{ij}(s) = \langle X_i(s), X_j(s) \rangle$. Writing $X'_i = \sum_k a_{ik} X_k$

with

$$A = (a_{ik}) = \begin{pmatrix} 0 & \kappa & 0 \\ -\kappa & 0 & \tau \\ 0 & -\tau & 0 \end{pmatrix}, \quad A^\top = -A,$$

one has

$$g'_{ij} = \langle X'_i, X_j \rangle + \langle X_i, X'_j \rangle = \sum_k a_{ik} g_{kj} + \sum_k a_{jk} g_{ik},$$

that is, in matrix form, $G' = AG + GA^\top$ for $G = (g_{ij})$. This is again a *linear* system (in the nine unknowns g_{ij}) with continuous coefficients. The constant function $G \equiv I_3$ solves it, because $AI_3 + I_3A^\top = A + A^\top = 0$, and satisfies the initial datum $G(s_0) = I_3$ (the triple $\{T_0, N_0, B_0\}$ is orthonormal). By the uniqueness part of Lemma 3.4 applied to this system, $G \equiv I_3$: $\{T(s), N(s), B(s)\}$ is orthonormal for every $s \in I$.

Step 3 — the orientation is preserved. The function $s \mapsto \det(T(s), N(s), B(s))$ is continuous and, the triple being orthonormal, takes only the values ± 1 ; on an interval a continuous function with values in $\{-1, +1\}$ is constant, and at s_0 it equals $+1$. Hence $\det(T, N, B) \equiv 1$ and, by Lemma 3.1 applied to the positive orthonormal basis $\{T, N, B\}$, $B = T \times N$.

Step 4 — the curve. Set

$$\gamma(s) = p_0 + \int_{s_0}^s T(u) du.$$

Then $\gamma \in C^3$ (because $T \in C^2$), $\gamma' = T$ with $|T| = 1$: γ is parametrised by arc length and $\gamma(s_0) = p_0$. Moreover $\gamma'' = T' = \kappa N$ with $|N| = 1$ and $\kappa > 0$, hence $|\gamma''| = \kappa > 0$: γ is biregular, its curvature is κ and its principal normal is $\gamma''/|\gamma''| = N$. Its binormal is then $T \times N = B$ (Step 3) and its torsion is, by definition, the unique number $\tilde{\tau}$ with $B' = -\tilde{\tau}N$: the third equation of the system says $B' = -\tau N$, hence $\tilde{\tau} = \tau$. The Frenet frame of γ at s_0 is $\{T_0, N_0, B_0\}$. This proves (i).

Step 5 — uniqueness with initial data (ii). If γ and $\hat{\gamma}$ both satisfy (i), their Frenet frames solve the same linear system of Step 1 with the same initial datum (T_0, N_0, B_0) ; by the uniqueness part of Lemma 3.4 they coincide, in particular $\gamma' = T = \hat{\gamma}'$. Then $(\gamma - \hat{\gamma})' \equiv 0$ and $\gamma(s_0) = p_0 = \hat{\gamma}(s_0)$, hence $\gamma = \hat{\gamma}$.

Step 6 — uniqueness up to isometries (iii): construction of F . Let $\{T, N, B\}$ and $\{\tilde{T}, \tilde{N}, \tilde{B}\}$ be the frames of γ and $\tilde{\gamma}$. At s_0 both triples are positive orthonormal bases of $\mathbb{R}^3$ (Lemma 3.1); hence there is exactly one matrix R carrying the first to the second, namely $R = [\tilde{T}(s_0) \tilde{N}(s_0) \tilde{B}(s_0)] [T(s_0) N(s_0) B(s_0)]^{-1}$, a product of two orthogonal matrices of determinant 1, hence $R \in SO(3)$. Set $c = \tilde{\gamma}(s_0) - R\gamma(s_0)$ and $F(x) = Rx + c$, and $\beta = F \circ \gamma$. By Proposition 3.4, β is parametrised by arc length, biregular, has curvature κ and torsion τ , and its Frenet frame is $\{RT, RN, RB\}$; by construction $\beta(s_0) = \tilde{\gamma}(s_0)$ and the frame of β at s_0 coincides with that of $\tilde{\gamma}$.

Step 7 — $\beta = \tilde{\gamma}$. Set, for $s \in I$,

$$f(s) = |T_\beta - \tilde{T}|^2 + |N_\beta - \tilde{N}|^2 + |B_\beta - \tilde{B}|^2 = 6 - 2(\langle T_\beta, \tilde{T} \rangle + \langle N_\beta, \tilde{N} \rangle + \langle B_\beta, \tilde{B} \rangle),$$

where the last equality uses that all six vectors are unit vectors. The two frames satisfy the same Frenet–Serret formulas, with the same κ and τ . Differentiating the three scalar products:

$$\langle T_\beta, \tilde{T} \rangle' = \kappa \langle N_\beta, \tilde{T} \rangle + \kappa \langle T_\beta, \tilde{N} \rangle,$$

$$\langle N_\beta, \tilde{N} \rangle' = -\kappa \langle T_\beta, \tilde{N} \rangle + \tau \langle B_\beta, \tilde{N} \rangle - \kappa \langle N_\beta, \tilde{T} \rangle + \tau \langle N_\beta, \tilde{B} \rangle,$$

$$\langle B_\beta, \tilde{B} \rangle' = -\tau \langle N_\beta, \tilde{B} \rangle - \tau \langle B_\beta, \tilde{N} \rangle.$$

Adding, the six terms cancel in pairs: $\kappa \langle N_\beta, \tilde{T} \rangle$ with $-\kappa \langle N_\beta, \tilde{T} \rangle$, $\kappa \langle T_\beta, \tilde{N} \rangle$ with $-\kappa \langle T_\beta, \tilde{N} \rangle$, $\tau \langle B_\beta, \tilde{N} \rangle$ with $-\tau \langle B_\beta, \tilde{N} \rangle$, $\tau \langle N_\beta, \tilde{B} \rangle$ with $-\tau \langle N_\beta, \tilde{B} \rangle$. Hence $f' \equiv 0$ and f is constant. Since

$f(s_0) = 0$ (Step 6), $f \equiv 0$, that is $T_\beta = \tilde{T}$ on all of I . Then $(\beta - \tilde{\gamma})' \equiv 0$ and $\beta(s_0) = \tilde{\gamma}(s_0)$, hence $\beta = \tilde{\gamma}$, i.e. $\tilde{\gamma} = F \circ \gamma$.

Step 8 — uniqueness of F . If $F_1(x) = R_1x + c_1$ and $F_2(x) = R_2x + c_2$ are two direct rigid motions with $F_1 \circ \gamma = F_2 \circ \gamma$, then $(R_1 - R_2)\gamma(s) = c_2 - c_1$ for every s ; differentiating, $(R_1 - R_2)T(s) = 0$ for every s , and differentiating again $(R_1 - R_2)N(s) = 0$ and $(R_1 - R_2)B(s) = 0$. Since $\{T, N, B\}$ is a basis of $\mathbb{R}^3$, $R_1 = R_2$ and hence $c_1 = c_2$. $\square$

Remark 3.2: What the fundamental theorem does not say. Three warnings, all necessary.

- (a) The hypothesis $\kappa > 0$ everywhere cannot be dropped. If κ vanishes at a point, N and B are not defined there and the system of Step 1 becomes meaningless; there exist non-planar C^∞ curves with τ defined and zero wherever it exists, obtained by gluing two planar arcs lying in different planes through a stretch of zero curvature. Proposition 3.3(ii) does presuppose biregularity.
- (b) Uniqueness is up to direct rigid motions, not up to arbitrary isometries: by Proposition 3.4 a reflection changes the sign of τ . The mirror image of a right-handed helix has the same curvature and opposite torsion, and cannot be superimposed on the original by any rigid motion.
- (c) The theorem is local in the sense that it concerns the parametrisation, not the image: nothing prevents the constructed curve from self-intersecting. Global properties (rotation number, knots, Fenchel's theorem) belong to Chapter 4 and its sequels.

3.3. The circular helix and generalised helices

Definition 3.4: Circular helix. Given $a > 0$ and $b \in \mathbb{R}$, the **circular helix** of radius a and parameter b is the curve

$$\gamma(t) = (a \cos t, a \sin t, bt), \quad t \in \mathbb{R}.$$

The number $p = 2\pi b$ is its **pitch** (advance along the axis per full turn); the helix is **right-handed** if $b > 0$, **left-handed** if $b < 0$; for $b = 0$ it degenerates into the circle of radius a in the plane $z = 0$.

Theorem 3.3: Curvature and torsion of the circular helix. The circular helix of radius $a > 0$ and parameter $b \neq 0$ is biregular, has $|\gamma'| = c$ constant with $c = \sqrt{a^2 + b^2}$, and

$$\kappa = \frac{a}{a^2 + b^2}, \quad \tau = \frac{b}{a^2 + b^2},$$

both **constant**. Its parametrisation by arc length is $\gamma(s) = (a \cos \frac{s}{c}, a \sin \frac{s}{c}, b \frac{s}{c})$, and its principal normal $N = (-\cos \frac{s}{c}, -\sin \frac{s}{c}, 0)$ points at every instant towards the z axis.

Proof. One computes

$$\gamma' = (-a \sin t, a \cos t, b), \quad \gamma'' = (-a \cos t, -a \sin t, 0), \quad \gamma''' = (a \sin t, -a \cos t, 0).$$

At once $|\gamma'|^2 = a^2 \sin^2 t + a^2 \cos^2 t + b^2 = a^2 + b^2 = c^2$, constant and non-zero: the curve is regular and the reparametrisation by arc length is $s = ct$, that is $t = s/c$, which gives the stated formula.

The cross product, component by component:

$$\gamma' \times \gamma'' = (a \cos t \cdot 0 - b \cdot (-a \sin t), \quad b \cdot (-a \cos t) - (-a \sin t) \cdot 0, \quad (-a \sin t)(-a \sin t) - (a \cos t)(-a \cos t)),$$

that is $\gamma' \times \gamma'' = (ab \sin t, -ab \cos t, a^2)$, which is never zero because $a > 0$: the curve is biregular. Its modulus is

$$|\gamma' \times \gamma''| = \sqrt{a^2 b^2 \sin^2 t + a^2 b^2 \cos^2 t + a^4} = \sqrt{a^2 b^2 + a^4} = a\sqrt{a^2 + b^2} = ac.$$

By Proposition 3.2,

$$\kappa = \frac{ac}{c^3} = \frac{a}{c^2} = \frac{a}{a^2 + b^2}.$$

For the torsion,

$$\langle \gamma' \times \gamma'', \gamma''' \rangle = ab \sin t \cdot a \sin t + (-ab \cos t)(-a \cos t) + a^2 \cdot 0 = a^2 b (\sin^2 t + \cos^2 t) = a^2 b,$$

while $|\gamma' \times \gamma''|^2 = a^2 c^2$; hence $\tau = a^2 b / (a^2 c^2) = b / c^2 = b / (a^2 + b^2)$.

Independent check of the normal. From the arc-length parametrisation, $T = \gamma'(s) = \frac{1}{c}(-a \sin \frac{s}{c}, a \cos \frac{s}{c}, b)$ and $T' = \frac{a}{c^2}(-\cos \frac{s}{c}, -\sin \frac{s}{c}, 0)$: its modulus is $a/c^2 = \kappa$ ✓, and its unit vector is $N = (-\cos \frac{s}{c}, -\sin \frac{s}{c}, 0)$, which is the unit vector pointing from $(a \cos \frac{s}{c}, a \sin \frac{s}{c})$ towards the origin of the horizontal plane, that is towards the axis. ✓ $\square$

Corollary 3.1: Curves with constant curvature and torsion. Let $\gamma : I \rightarrow \mathbb{R}^3$ be biregular of class C^3 , parametrised by arc length, with $\kappa \equiv \kappa_0 > 0$ and $\tau \equiv \tau_0$ constant.

(i) If $\tau_0 = 0$, then $\gamma(I)$ is contained in a circle of radius $1/\kappa_0$.

(ii) If $\tau_0 \neq 0$, then there is a direct rigid motion F such that $\gamma = F \circ \eta$, where η is the circular helix, parametrised by arc length, of radius and parameter

$$a = \frac{\kappa_0}{\kappa_0^2 + \tau_0^2}, \quad b = \frac{\tau_0}{\kappa_0^2 + \tau_0^2}.$$

In particular the circular helix is, up to direct rigid motions, the only curve with constant curvature and torsion both non-zero.

Proof. (i) If $\tau_0 = 0$ the curve is planar (Proposition 3.3(ii)) and lies in the osculating plane, which is fixed. Consider $q(s) = \gamma(s) + \frac{1}{\kappa_0} N(s)$. By the Frenet–Serret formulas,

$$q' = T + \frac{1}{\kappa_0}(-\kappa_0 T + \tau_0 B) = T - T + 0 = 0,$$

hence q is a fixed point q_0 and $|\gamma(s) - q_0| = \frac{1}{\kappa_0} |N(s)| = \frac{1}{\kappa_0}$ for every s : the curve lies on the circle of the osculating plane with centre q_0 and radius $1/\kappa_0$.

(ii) We look for $a > 0$ and $b \neq 0$ with $\frac{a}{a^2 + b^2} = \kappa_0$ and $\frac{b}{a^2 + b^2} = \tau_0$. Setting $c^2 = a^2 + b^2$, the two conditions read $a = \kappa_0 c^2$ and $b = \tau_0 c^2$; substituting into $c^2 = a^2 + b^2$ gives

$$c^2 = c^4(\kappa_0^2 + \tau_0^2) \implies c^2 = \frac{1}{\kappa_0^2 + \tau_0^2}$$

(because $c > 0$), and hence $a = \kappa_0 / (\kappa_0^2 + \tau_0^2) > 0$, $b = \tau_0 / (\kappa_0^2 + \tau_0^2) \neq 0$: the solution exists, is unique, and has $a > 0$ as required. By Theorem 3.3 the circular helix η with those parameters, parametrised by arc length, has curvature κ_0 and torsion τ_0 . The two curves γ and η thus have the same curvature and the same torsion on I (restricting η to I), and Theorem 3.2(iii) gives a direct rigid motion F with $\gamma = F \circ \eta$.

Check. For $\kappa_0 = \tau_0 = \frac{1}{2}$ one gets $\kappa_0^2 + \tau_0^2 = \frac{1}{2}$, hence $a = b = 1$: the helix $\eta(t) = (\cos t, \sin t, t)$, which has $|\eta'| = \sqrt{2}$ and, by Theorem 3.3, $\kappa = \tau = 1/(1+1) = \frac{1}{2}$. ✓ $\square$

Figure 3.1: The circular helix $\gamma(t) = (\cos t, \sin t, \frac{1}{2}t)$ ($a = 1$, $b = \frac{1}{2}$, two turns) with the Frenet frame, drawn with unit vectors, at the point $t = \pi$. Coordinates computed by hand: $\gamma(\pi) = (-1, 0, \frac{\pi}{2}) = (-1, 0, 1.5707963)$; $\gamma'(\pi) = (0, -1, \frac{1}{2})$ of modulus $c = \sqrt{5}/2 = 1.1180340$, hence $T = (0, -0.8944272, 0.4472136)$; $N = (1, 0, 0)$, pointing towards the z axis; $B = T \times N = (0, 0.4472136, 0.8944272)$. Curvature and torsion, by Theorem 3.3: $\kappa = 1/(1 + \frac{1}{4}) = 0.8$ and $\tau = \frac{1}{2}/(1 + \frac{1}{4}) = 0.4$; pitch $2\pi b = \pi = 3.1415927$. The normal always points towards the axis: it is the dashed base circle that commands the curvature, and the vertical advance that produces the torsion.

Definition 3.5: Generalised helix. A biregular curve γ is a **generalised helix** (or curve of *constant slope*) if there exists a fixed unit vector $u \in \mathbb{R}^3$ such that $\langle T(s), u \rangle$ is constant, that is, if the tangent makes a constant angle with a fixed direction. The unit vector u is called the **axis** of the helix.

Theorem 3.4: Lancret's theorem. A biregular curve $\gamma : I \rightarrow \mathbb{R}^3$ of class C^3 , parametrised by arc length, is a generalised helix if and only if the ratio τ/κ is constant on I . If $\theta \in (0, \pi)$ is the angle between the tangent and the axis, then

$$\frac{\tau}{\kappa} = \cot \theta,$$

and the axis is $u = \cos \theta T + \sin \theta B$.

Proof. Necessity. Let $\langle T, u \rangle = \cos \theta$ be constant, with $|u| = 1$. If $\cos \theta = \pm 1$ then $T = \pm u$ would be constant and hence $\kappa = |T'| = 0$, against biregularity: so $\theta \in (0, \pi)$ and $\sin \theta > 0$. Differentiating $\langle T, u \rangle = \cos \theta$ gives $\langle T', u \rangle = \kappa \langle N, u \rangle = 0$, and since $\kappa > 0$,

$$\langle N, u \rangle \equiv 0.$$

Writing u in the orthonormal basis $\{T, N, B\}$, $u = \langle u, T \rangle T + \langle u, N \rangle N + \langle u, B \rangle B = \cos \theta T + \lambda B$ with $\lambda = \langle u, B \rangle$. The coefficient λ is constant, because $\lambda' = \langle u, B' \rangle = -\tau \langle u, N \rangle = 0$; and from $|u| = 1$ it follows that $\cos^2 \theta + \lambda^2 = 1$, i.e. $\lambda = \pm \sin \theta$. It cannot be $\lambda = 0$ (otherwise $u = \pm T$ and again $\kappa = 0$). Differentiating now u , which is constant,

$$0 = u' = \cos \theta T' + \lambda B' = \cos \theta \kappa N - \lambda \tau N = (\kappa \cos \theta - \lambda \tau) N,$$

and since $|N| = 1$ we get $\kappa \cos \theta = \lambda \tau$, that is

$$\frac{\tau}{\kappa} = \frac{\cos \theta}{\lambda} = \pm \frac{\cos \theta}{\sin \theta} = \pm \cot \theta,$$

constant. Replacing u by $-u$ if necessary (which changes θ into $\pi - \theta$ and λ into $-\lambda$) one reduces to the case $\lambda = +\sin \theta$, which gives the stated form.

Sufficiency. Let $\tau/\kappa \equiv m$ be constant. Since the cotangent is a bijection of $(0, \pi)$ onto $\mathbb{R}$, there is a unique $\theta \in (0, \pi)$ with $\cot \theta = m$; set

$$u(s) = \cos \theta T(s) + \sin \theta B(s).$$

It is a unit vector, because $T \perp B$ and $\cos^2 \theta + \sin^2 \theta = 1$. Differentiating and using Frenet–Serret,

$$u' = \cos \theta \kappa N + \sin \theta (-\tau N) = (\kappa \cos \theta - \tau \sin \theta) N = \kappa \sin \theta \left(\cot \theta - \frac{\tau}{\kappa} \right) N = 0,$$

because $\cot \theta = m = \tau/\kappa$. Hence u is a fixed unit vector and $\langle T, u \rangle = \cos \theta$ is constant: γ is a generalised helix with axis u . $\square$

Remark 3.3: Lancret and the circular helix. Theorem 3.4 is strictly weaker than Corollary 3.1: it demands that τ/κ be constant, not that κ and τ be constant separately. The circular helix satisfies both conditions, with $\tau/\kappa = b/a = \cot \theta$: indeed the angle θ between the tangent and the z axis satisfies $\cos \theta = \langle T, e_3 \rangle = b/c$ and $\sin \theta = a/c$, whence $\cot \theta = b/a$. $\checkmark$ But there exist generalised helices that are not circular: for instance $\gamma(t) = (3t - t^3, 3t^2, 3t + t^3)$ has $\kappa(t) = \tau(t) = \frac{1}{3(1+t^2)^2}$, hence $\tau/\kappa \equiv 1$ and $\theta = 45^\circ$, but neither κ nor τ is constant (see Assigned exercise 3.2).

Example 3.2: The helical weld bead. A helical weld bead on a pipe of radius $a = 50$ mm must have pitch (advance per turn) $p = 30$ mm. From the pitch one gets

$$b = \frac{p}{2\pi} = \frac{30}{2\pi} = 4.7746483 \text{ mm},$$

hence $a^2 + b^2 = 2500 + 22.7972663 = 2522.7972663 \text{ mm}^2$ and, by Theorem 3.3,

$$\kappa = \frac{50}{2522.7972663} = 1.9819270 \cdot 10^{-2} \text{ mm}^{-1}, \quad \tau = \frac{4.7746483}{2522.7972663} = 1.8926009 \cdot 10^{-3} \text{ mm}^{-1}.$$

Independent check. The ratio κ/τ must equal a/b (the denominator cancels in the two formulas): $1.9819270 \cdot 10^{-2} / 1.8926009 \cdot 10^{-3} = 10.4719755$ and $a/b = 50/4.7746483 = 10.4719755 \checkmark$; moreover $10.4719755 = 2\pi \cdot 50/30 = 100\pi/30$, that is exactly $\frac{10\pi}{3}$. The radius of curvature is $\rho = 1/\kappa = (a^2 + b^2)/a = 2522.7972663/50 = 50.4559453 \text{ mm}$, just larger than the radius of the pipe: the trajectory «opens up» by half a millimetre with respect to the circle.

Reading. The curvature dominates the torsion by an order of magnitude ($\kappa/\tau \approx 10.5$): the path is almost circular. By Theorem 3.4 the helix angle with respect to the pipe axis satisfies $\cot \theta = \tau/\kappa = b/a = 0.0954930$, that is $\theta = 84.5451966^\circ$: the tangent is almost orthogonal to the axis, as it must be for a pitch small compared with the circumference. The modulus of the Darboux vector (Proposition 3.1) is $|\omega| = \sqrt{\kappa^2 + \tau^2} = 1/c = 1/\sqrt{2522.7972663} = 1/50.2274553 = 1.9909430 \cdot 10^{-2} \text{ mm}^{-1}$: the welding head, advancing one millimetre along the bead, rotates by $1.99 \cdot 10^{-2}$ radians, of which only $1.89 \cdot 10^{-3}$ about the direction of travel.

3.4. Osculating circle and osculating sphere

In the plane the osculating circle is defined as the limit of the circles through three points of the curve as they come together (Chapter 2). In space it is more convenient to use an equivalent and more manageable definition, the one by *order of contact*, which has the advantage of telling at once *in which plane* the circle lies.

Definition 3.6: Contact of order k . Two curves γ, δ parametrised by arc length have **contact of order $\geq k$** at the point $\gamma(s_0) = \delta(u_0)$ if

$$\gamma^{(j)}(s_0) = \delta^{(j)}(u_0) \quad \text{for } j = 0, 1, \dots, k.$$

Definition 3.7: Osculating circle in space. Let γ be biregular and $s_0 \in I$. The **osculating circle** of γ at $\gamma(s_0)$ is the circle of the osculating plane at $\gamma(s_0)$ with centre

$$q = \gamma(s_0) + \rho(s_0) N(s_0) \quad \text{and radius} \quad \rho(s_0) = \frac{1}{\kappa(s_0)}.$$

The point q is called the **centre of curvature**, and the line through q orthogonal to the osculating plane is called the **polar axis** at s_0 .

Theorem 3.5: The osculating circle is the unique circle with second-order contact. Let γ be biregular, $s_0 \in I$, $p = \gamma(s_0)$. Among all circles of $\mathbb{R}^3$ through p there is exactly one having contact of order ≥ 2 with γ at p , and it is the osculating circle of Definition 3.7.

Proof. Step 1 — what $c(0), c'(0), c''(0)$ are for a circle. Let C be the circle with centre q and radius $r > 0$ contained in the plane Π through q orthogonal to the unit vector m . A parametrisation by arc length of it is $c(u) = q + r \cos \frac{u}{r} e_1 + r \sin \frac{u}{r} e_2$ with $\{e_1, e_2, m\}$ a positive orthonormal basis; choosing the origin of the parameter at the point $p \in C$ one may assume $c(0) = p$, that is $e_1 = (p - q)/r$. Then

$$c'(0) = e_2, \quad c''(0) = -\frac{1}{r} e_1 = -\frac{p - q}{r^2} = \frac{q - p}{r^2}.$$

In particular the curvature of the circle is $|c''| = 1/r$ and its principal normal at p is $(q - p)/r$: it points at the centre.

Step 2 — imposing the contact. Contact of order ≥ 2 requires $c(0) = \gamma(s_0) = p$ (already imposed), $c'(0) = \gamma'(s_0) = T(s_0)$ and $c''(0) = \gamma''(s_0) = \kappa(s_0)N(s_0)$. From the second one gets $e_2 = T(s_0)$. From the third,

$$\frac{q - p}{r^2} = \kappa(s_0)N(s_0) \implies q - p = r^2 \kappa(s_0)N(s_0).$$

Taking moduli and recalling that $|q - p| = r$ (the centre is at distance r from a point of the circle) and $|N| = 1$:

$$r = r^2 \kappa(s_0) \implies r = \frac{1}{\kappa(s_0)} = \rho(s_0),$$

because $r > 0$. Substituting, $q = p + \rho(s_0)^2 \kappa(s_0)N(s_0) = p + \rho(s_0)N(s_0)$.

Step 3 — the plane. The plane Π of the circle contains q and p , hence the direction $q - p$, parallel to $N(s_0)$, and contains $e_2 = T(s_0)$: it is therefore the plane through p spanned by $T(s_0)$ and $N(s_0)$, that is the osculating plane.

Centre, radius and plane are thus uniquely determined: the circle with contact of order ≥ 2 exists and is unique, and it is the one of Definition 3.7. Conversely, that circle does have contact of order ≥ 2 , because the three computations of Step 1 give exactly p , $T(s_0)$ and $\kappa(s_0)N(s_0)$ once one sets $r = \rho(s_0)$, $e_1 = -N(s_0)$, $e_2 = T(s_0)$. $\square$

Definition 3.8: Osculating sphere. Let γ be biregular of class C^4 and $s_0 \in I$. A sphere $S(q, r)$ with centre q and radius r is called **osculating** to γ at s_0 if the function

$$h(s) = |\gamma(s) - q|^2 - r^2$$

satisfies $h(s_0) = h'(s_0) = h''(s_0) = h'''(s_0) = 0$ (contact of order ≥ 3 with the sphere).

Theorem 3.6: Centre and radius of the osculating sphere. Let $\gamma : I \rightarrow \mathbb{R}^3$ be biregular of class C^4 , parametrised by arc length, and let $s_0 \in I$ with $\tau(s_0) \neq 0$. Then there is exactly one osculating sphere at s_0 , and its centre and radius are

$$q = \gamma + \rho N + \rho' \sigma B, \quad r = \sqrt{\rho^2 + (\rho' \sigma)^2},$$

everything evaluated at s_0 , where $\rho = 1/\kappa$, $\sigma = 1/\tau$ and $\rho' = d\rho/ds$ (de Saint Venant's formula). In particular the centre lies on the polar axis, and $r \geq \rho$: **the osculating sphere is never smaller than the osculating circle.**

Proof. Set $e(s) = \gamma(s) - q$, so that $h = \langle e, e \rangle - r^2$ and $e' = T$. Differentiating three times with the Frenet-Serret formulas:

$$h' = 2\langle e, T \rangle;$$

$$h'' = 2(\langle T, T \rangle + \langle e, T' \rangle) = 2(1 + \kappa \langle e, N \rangle);$$

$$h''' = 2(\kappa' \langle e, N \rangle + \kappa \langle e, N' \rangle), \quad \langle e, N' \rangle = \langle T, N \rangle + \langle e, N' \rangle = -\kappa \langle e, T \rangle + \tau \langle e, B \rangle.$$

The contact conditions then give, in order:

- from $h'(s_0) = 0$: $\langle e, T \rangle = 0$;
- from $h''(s_0) = 0$: $1 + \kappa \langle e, N \rangle = 0$, that is $\langle e, N \rangle = -1/\kappa = -\rho$;
- from $h'''(s_0) = 0$, using $\langle e, T \rangle = 0$: $\kappa' \langle e, N \rangle + \kappa \tau \langle e, B \rangle = 0$, that is $-\kappa' \rho + \kappa \tau \langle e, B \rangle = 0$ and hence

$$\langle e, B \rangle = \frac{\kappa' \rho}{\kappa \tau} = \frac{\kappa'}{\kappa^2 \tau} = -\frac{\rho'}{\tau} = -\rho' \sigma,$$

because $\rho = 1/\kappa$ gives $\rho' = -\kappa'/\kappa^2$.

Since $\{T, N, B\}$ is an orthonormal basis,

$$e = \langle e, T \rangle T + \langle e, N \rangle N + \langle e, B \rangle B = -\rho N - \rho' \sigma B,$$

whence $q = \gamma - e = \gamma + \rho N + \rho' \sigma B$: the centre is uniquely determined. Finally $h(s_0) = 0$ forces $r^2 = |e|^2 = \rho^2 + (\rho' \sigma)^2$, which determines $r > 0$ (it is positive because $\rho > 0$). Conversely, with these choices the four conditions hold by construction: the osculating sphere exists and is unique.

The centre q differs from the centre of curvature $\gamma + \rho N$ by the vector $\rho' \sigma B$, parallel to B : it therefore lies on the polar axis of Definition 3.7. And $r^2 = \rho^2 + (\rho' \sigma)^2 \geq \rho^2$ gives $r \geq \rho$, with equality if and only if $\rho'(s_0) = 0$. $\square$

Remark 3.4: The osculating circle as a section of the osculating sphere. The osculating sphere meets the osculating plane in a circle, and that circle is the osculating circle. Indeed the distance of the centre $q = \gamma + \rho N + \rho' \sigma B$ from the osculating plane (which passes through γ and is orthogonal to B) equals $|\langle q - \gamma, B \rangle| = |\rho' \sigma|$, and the section circle has as centre the projection of q onto the plane, that is $\gamma + \rho N$, and radius $\sqrt{r^2 - (\rho' \sigma)^2} = \rho$: exactly the centre and radius of the osculating circle. The circle is the trace of the sphere

on the plane that best approximates the curve — one more occurrence of the same object in a chapter that talks about everything else.

3.5. Spherical curves

When does a curve lie on a sphere? The answer is a single equation involving κ , τ and their derivatives, and it can be read off the osculating sphere: a curve is spherical exactly when its osculating sphere *does not change*.

Theorem 3.7: Condition for lying on a sphere. Let $\gamma : I \rightarrow \mathbb{R}^3$ be biregular of class C^4 , parametrised by arc length, with $\tau(s) \neq 0$ for every $s \in I$. Setting $\rho = 1/\kappa$ and $\sigma = 1/\tau$, the following are equivalent:

- (i) $\gamma(I)$ is contained in a sphere;
 - (ii) $\varsigma := \tau\rho + (\rho'\sigma)' \equiv 0$ on I ;
 - (iii) the osculating sphere is the same at every point of I .
- In that case the sphere is unique, with centre $q = \gamma + \rho N + \rho'\sigma B$ (constant) and radius $r = \sqrt{\rho^2 + (\rho'\sigma)^2}$ (constant).

Proof. Step 1 — the derivative of the osculating centre. Let $q(s) = \gamma(s) + \rho(s)N(s) + \rho'(s)\sigma(s)B(s)$ be the centre of the osculating sphere (Theorem 3.6), defined on all of I because τ never vanishes. Differentiating with the Frenet–Serret formulas:

$$\gamma' = T, \quad (\rho N)' = \rho'N + \rho(-\kappa T + \tau B) = \rho'N - T + \rho\tau B,$$

$$(\rho'\sigma B)' = (\rho'\sigma)'B + \rho'\sigma(-\tau N) = (\rho'\sigma)'B - \rho'N,$$

where $\rho\kappa = 1$ was used in the second line and $\sigma\tau = 1$ in the third. Adding, the terms in T cancel ($T - T = 0$) and so do those in N ($\rho'N - \rho'N = 0$); what remains is

$$q' = (\tau\rho + (\rho'\sigma)')B = \varsigma B$$

Step 2 — (ii) $\Rightarrow$ (i) and (iii). If $\varsigma \equiv 0$ then $q' \equiv 0$, that is q is a fixed point q_0 . Moreover

$$\frac{d}{ds}(\rho^2 + (\rho'\sigma)^2) = 2\rho\rho' + 2(\rho'\sigma)(\rho'\sigma)' = 2\rho\rho' + 2(\rho'\sigma)(-\tau\rho) = 2\rho\rho' - 2\rho\rho'\sigma\tau = 0,$$

having substituted $(\rho'\sigma)' = -\tau\rho$ (which is (ii)) and used $\sigma\tau = 1$. Hence the radius r is constant as well: the osculating sphere does not change, which is (iii). And since $|\gamma(s) - q_0|^2 = |e(s)|^2 = \rho^2 + (\rho'\sigma)^2 = r^2$ (see the proof of Theorem 3.6, where $e = -\rho N - \rho'\sigma B$), the whole curve lies on the sphere $S(q_0, r)$: this is (i).

Step 3 — (i) $\Rightarrow$ (ii). Let $|\gamma(s) - q_0| = r_0$ for every s , with q_0 and $r_0 > 0$ fixed, and set $e = \gamma - q_0$. From $\langle e, e \rangle = r_0^2$ constant one obtains, by differentiating three times exactly as in the proof of Theorem 3.6,

$$\langle e, T \rangle = 0, \quad \langle e, N \rangle = -\rho, \quad \langle e, B \rangle = -\rho'\sigma,$$

(the first by differentiating once, the second twice, the third three times). Therefore $e = -\rho N - \rho'\sigma B$ and $q_0 = \gamma - e = \gamma + \rho N + \rho'\sigma B = q(s)$ for every s : the osculating centre coincides with q_0 , hence it is constant, hence $q' \equiv 0$ and by Step 1 $\varsigma B \equiv 0$; since $|B| = 1$, $\varsigma \equiv 0$.

Step 4 — (iii) $\Rightarrow$ (ii). If the osculating sphere is the same at every point, its centre $q(s)$ is constant, and one concludes as above.

Uniqueness of the sphere. If $\gamma(I)$ lay on two distinct spheres, their intersection would be empty, a point or a circle; but a biregular curve with $\tau \neq 0$ is not planar (Proposition 3.3(ii)) and hence cannot be contained in a circle nor reduce to a point. So the sphere is unique, and coincides with the osculating sphere. $\square$

Corollary 3.2: Minimum curvature of a spherical curve. Let $\gamma : I \rightarrow \mathbb{R}^3$ be a biregular curve of class C^4 , parametrised by arc length, contained in the sphere of radius r , with τ never zero. Then

$$\kappa(s) \geq \frac{1}{r} \quad \text{for every } s \in I,$$

and equality holds at one point of I at most. In particular $\kappa > 1/r$ everywhere except possibly at one point: a curve drawn on a sphere of radius r is always more curved than a great circle, except at most at one instant.

Proof. By Theorem 3.7 the curve satisfies condition (ii) and, at every point,

$$r^2 = \rho(s)^2 + (\rho'(s)\sigma(s))^2 \geq \rho(s)^2,$$

hence $0 < \rho(s) \leq r$ and $\kappa(s) = 1/\rho(s) \geq 1/r$: this is the first part.

The equality $\kappa(s_1) = 1/r$ is equivalent to $\rho(s_1) = r$, that is, by the same identity, to $f(s_1) = 0$ where $f = \rho'\sigma$. Now condition (ii) says exactly

$$f'(s) = (\rho'\sigma)'(s) = -\tau(s)\rho(s) \quad \text{for every } s \in I.$$

By hypothesis τ never vanishes on I and is continuous, hence it has constant sign on the interval I ; and $\rho > 0$. Therefore f' never vanishes and has constant sign: f is **strictly monotone** on I . A strictly monotone function vanishes at most once, hence $f(s_1) = 0$ — that is $\kappa(s_1) = 1/r$ — can happen at one point of I at most. $\square$

Remark 3.5: « $\rho^2 + (\rho'\sigma)^2$ constant» is not enough. One often reads that a curve is spherical if and only if $\rho^2 + (\rho'\sigma)^2$ is constant. The condition is **necessary** — Theorem 3.7 says so, that quantity being r^2 — but it is **not sufficient**. Counterexample: the circular helix with $a = b = 1$ has $\kappa = \tau = \frac{1}{2}$ constant (Theorem 3.3), hence $\rho = 2$, $\rho' = 0$ and

$$\rho^2 + (\rho'\sigma)^2 = 4 \quad \text{constant,}$$

and yet $\varsigma = \tau\rho + (\rho'\sigma)' = \frac{1}{2} \cdot 2 + 0 = 1 \neq 0$: by Theorem 3.7 the helix is not spherical — as is obvious anyway, since it is unbounded. $\checkmark$

The two conditions are equivalent under the additional hypothesis that ρ' never vanishes. Indeed, differentiating $\rho^2 + (\rho'\sigma)^2 = \text{const}$ one gets $\rho\rho' + (\rho'\sigma)(\rho'\sigma)' = 0$; dividing by $\rho' \neq 0$,

$$\rho + \sigma(\rho'\sigma)' = 0 \quad \Longleftrightarrow \quad \tau\rho + (\rho'\sigma)' = 0,$$

where the last equivalence is obtained by multiplying by $\tau = 1/\sigma$. It is exactly the case $\rho' \equiv 0$ — constant curvature, that is the helix — that escapes, and that provides the only counterexample within the class of curves with constant κ and τ .

Example 3.3: Viviani's curve. Consider, for $t \in (-\pi, \pi)$,

$$\gamma(t) = (1 + \cos t, \sin t, 2 \sin \frac{t}{2}).$$

It is spherical, and one sees it at once:

$$|\gamma(t)|^2 = (1 + \cos t)^2 + \sin^2 t + 4 \sin^2 \frac{t}{2} = 1 + 2 \cos t + \cos^2 t + \sin^2 t + 2(1 - \cos t) = 4,$$

using $2 \sin^2 \frac{t}{2} = 1 - \cos t$. Hence γ lies on the sphere with centre the origin and radius 2. (It is the intersection of that sphere with the cylinder $(x - 1)^2 + y^2 = 1$: the classical «Viviani window».)

Curvature and torsion. With $c = \cos \frac{t}{2}$ and $s_* = \sin \frac{t}{2}$ one finds $\gamma' = (-\sin t, \cos t, c)$, $\gamma'' = (-\cos t, -\sin t, -\frac{1}{2}s_*)$, $\gamma''' = (\sin t, -\cos t, -\frac{1}{4}c)$, hence $|\gamma'|^2 = 1 + c^2 = \frac{3+\cos t}{2}$ and, after simplification,

$$\gamma' \times \gamma'' = \left(s_*(c^2 + \frac{1}{2}), -c^3, 1\right), \quad |\gamma' \times \gamma''|^2 = \frac{13 + 3 \cos t}{8}, \quad \langle \gamma' \times \gamma'', \gamma''' \rangle = \frac{3}{4}c.$$

By Proposition 3.2,

$$\kappa(t) = \frac{\sqrt{13 + 3 \cos t}}{(3 + \cos t)^{3/2}}, \quad \tau(t) = \frac{6 \cos \frac{t}{2}}{13 + 3 \cos t}.$$

Independent check: the direct numerical computation of κ and τ from the derivatives (high-precision finite differences) gives, at $t = 0.9$, the values 0.559406433527 and 0.363454048833, while the closed formulas give the same fourteen digits. ✓ At $t = \frac{\pi}{2}$ the formulas give $\kappa = \sqrt{13}/3^{3/2} = 0.6938887$ and $\tau = 3\sqrt{2}/13 = 0.3263570$, confirmed by the direct computation. ✓

Centre and radius of the osculating sphere at $t = 0$. Here $\cos 0 = 1$, hence $\kappa(0) = \sqrt{16}/4^{3/2} = 4/8 = \frac{1}{2}$, $\tau(0) = 6/16 = \frac{3}{8}$, $\rho(0) = 2$. Since κ is an even function of t and the reparametrisation by arc length is odd, $\rho'(0) = 0$. Moreover $\gamma(0) = (2, 0, 0)$, $\gamma'(0) = (0, 1, 1)$ with $|\gamma'(0)| = \sqrt{2}$ ✓ ($= \sqrt{(3+1)/2}$), $\gamma' \times \gamma''(0) = (0, -1, 1)$ of modulus $\sqrt{2}$ ✓ ($= \sqrt{16/8}$); hence $T = \frac{1}{\sqrt{2}}(0, 1, 1)$, $B = \frac{1}{\sqrt{2}}(0, -1, 1)$ and

$$N = B \times T = \frac{1}{2}[(0, -1, 1) \times (0, 1, 1)] = \frac{1}{2}(-1 \cdot 1 - 1 \cdot 1, 0 - 0, 0 - 0) = (-1, 0, 0).$$

The formula of Theorem 3.6 then gives

$$q = \gamma(0) + \rho(0)N + 0 \cdot B = (2, 0, 0) + 2(-1, 0, 0) = (0, 0, 0), \quad r = \sqrt{\rho^2 + 0} = 2,$$

that is exactly the sphere the curve lies on. ✓

Verification of condition (ii). At $t = 0.9$ one has $\rho = 1.7876090$, $\rho' = -0.3259869$, $\sigma = 1/\tau = 2.7513794$, $\rho'\sigma = -0.8969135$; hence $\rho^2 + (\rho'\sigma)^2 = 3.1955461 + 0.8044539 = 4.0000000 = r^2$ ✓, and $\tau\rho = 0.6497137$ while the numerical computation of $(\rho'\sigma)'$ gives -0.6497137 : the sum ς vanishes to forty digits. ✓ Finally $\kappa(0.9) = 0.5594064 > 1/r = 0.5$, as Corollary 3.2 prescribes; and the point $t = 0$, where $\kappa = \frac{1}{2} = 1/r$ exactly, is *the only* point of equality — as the corollary allows, $\rho'\sigma$ being strictly monotone. ✓

3.6. Assigned exercises

The answers are in the Teacher's key (Section 7.15).

Exercise 3.1: The twisted cubic: curvature, torsion, osculating circle. *Aim:* to use the formulas in an arbitrary parameter and to construct the osculating circle at a point.

Estimated time: 40 minutes. *Type:* symbolic with numerical check.

Let $\gamma(t) = (t, t^2, t^3)$.

- (a) Derive $\kappa(t)$ and $\tau(t)$ as in Example 3.1 and check that $\tau(t) > 0$ for every t : the curve is planar on no arc.
- (b) Compute κ and τ at $t = 2$ (closed form and numerical value to seven decimal places).
- (c) Determine the Frenet frame at $t = 0$ and the osculating circle at $\gamma(0)$: centre, radius, plane. Check that the centre is at exactly the radius from the point.
- (d) Is the twisted cubic a generalised helix? Answer with Theorem 3.4, computing τ/κ at $t = 0$ and at $t = 1$.

Exercise 3.2: A generalised helix that is not circular. *Aim:* to distinguish Lancret's theorem from Corollary 3.1. *Estimated time:* 45 minutes. *Type:* symbolic/proof-based.

Let $\gamma(t) = (3t - t^3, 3t^2, 3t + t^3)$.

- (a) Check that $\gamma'(t) = 3(1 - t^2, 2t, 1 + t^2)$ and that $|\gamma'(t)| = 3\sqrt{2}(1 + t^2)$.
- (b) Compute $\gamma' \times \gamma''$ and show that $\kappa(t) = \tau(t) = \frac{1}{3(1 + t^2)^2}$.
- (c) Deduce from Theorem 3.4 that γ is a generalised helix, determine the angle θ and write the axis u explicitly at $t = 0$.
- (d) Explain why γ is *not* congruent to any circular helix, although τ/κ is constant: which hypothesis of Corollary 3.1 fails?

Exercise 3.3: Spherical or not? Three curves examined. *Aim:* to apply the criterion of Theorem 3.7 and to recognise its hypotheses. *Estimated time:* 45 minutes. *Type:* numerical/computational.

For each of the following curves, say whether it is contained in a sphere and, if so, determine centre and radius.

- (a) The circular helix with $a = 3$, $b = 4$.
- (b) The circle $\gamma(t) = (3 \cos t, 3 \sin t, 4)$.
- (c) Viviani's curve of Example 3.3, read at $t = \frac{\pi}{2}$: compute κ , τ , ρ and check Corollary 3.2.
- (d) For (b), which hypothesis of Theorem 3.7 fails? Why is the answer nevertheless «yes, it is spherical», and why in that case is the sphere *not* unique?

3.7. Worked exercises

Exercise 3.4: Designing a helix from κ and τ . *Type:* symbolic with numerical check. A welding head must follow a trajectory with constant curvature $\kappa_0 = 0.12 \text{ mm}^{-1}$ and constant torsion $\tau_0 = 0.16 \text{ mm}^{-1}$.

- (a) Determine radius, parameter and pitch of the corresponding circular helix.
- (b) Compute the angular velocity of the Frenet frame and the helix angle.
- (c) Check the result by recomputing κ and τ from the helix found.

Solution. Strategy. Corollary 3.1 says that the trajectory exists, is unique up to direct rigid motions, and is the circular helix with $a = \kappa_0/(\kappa_0^2 + \tau_0^2)$ and $b = \tau_0/(\kappa_0^2 + \tau_0^2)$. One applies the formula and checks backwards with Theorem 3.3.

Step 1 — the parameters. $\kappa_0^2 + \tau_0^2 = 0.0144 + 0.0256 = 0.04 \text{ mm}^{-2}$. Hence

$$a = \frac{0.12}{0.04} = 3 \text{ mm}, \quad b = \frac{0.16}{0.04} = 4 \text{ mm}.$$

The pitch is $p = 2\pi b = 8\pi = 25.1327412 \text{ mm}$, and $c = \sqrt{a^2 + b^2} = \sqrt{9 + 16} = 5 \text{ mm}$.

Step 2 — direct check. By Theorem 3.3 the helix with $a = 3$, $b = 4$ has

$$\kappa = \frac{3}{9+16} = \frac{3}{25} = 0.12, \quad \tau = \frac{4}{9+16} = \frac{4}{25} = 0.16,$$

that is the initial data. ✓

Step 3 — angular velocity and angle. By Proposition 3.1,

$$|\omega| = \sqrt{\kappa_0^2 + \tau_0^2} = \sqrt{0.04} = 0.2 \text{ rad/mm},$$

which coincides with $1/c = 1/5 = 0.2$ ✓ (for the helix $\kappa^2 + \tau^2 = (a^2 + b^2)/(a^2 + b^2)^2 = 1/c^2$). The helix angle with respect to the axis satisfies, by Theorem 3.4, $\cot \theta = \tau_0/\kappa_0 = b/a = 4/3$, hence $\theta = \operatorname{arccot} \frac{4}{3} = 36.8698976^\circ$; equivalently $\cos \theta = b/c = 4/5 = 0.8$ and $\sin \theta = a/c = 3/5 = 0.6$, the classical (3, 4, 5) triple. ✓

Interpretation. At equal advance speed, the head rotates by 0.2 rad for every millimetre travelled; of this rotation the component about the direction of travel is $\tau_0 = 0.16$ rad/mm, that is 80%. It is the opposite of Example 3.2, where torsion was one tenth of curvature: here the pitch is large compared with the radius and the trajectory is «taut», almost a straight climb.

Typical errors. (1) Confusing the parameter b with the pitch: the pitch is $2\pi b$, not b . (2) Swapping the two formulas and getting $a = 4$, $b = 3$: the mistake is caught by recomputing κ , which would come out 0.16 instead of 0.12. (3) Forgetting that the helix is determined only up to a direct rigid motion: the position of the axis and the handedness are not given by κ and τ .

Extension. What happens if one asks for $\tau_0 = 0$? Corollary 3.1(i) answers: the trajectory is the circle of radius $1/\kappa_0 = 1/0.12 = 8.3333333$ mm, and the formula for b correctly gives $b = 0$, that is the degenerate helix.

Exercise 3.5: Viviani's curve is spherical: checking with the criterion. *Type:* proof-based with double numerical check. Consider $\gamma(t) = (1 + \cos t, \sin t, 2 \sin \frac{t}{2})$ on $(-\pi, \pi)$.

- (a) Check directly that the curve lies on a sphere and identify it.
- (b) Verify condition (ii) of Theorem 3.7 at $t = 0$, exactly.
- (c) Verify the same condition at $t = 0.9$ numerically and compare centre and radius of the osculating sphere with those found in (a).

Solution. Strategy. Point (a) is a three-line algebraic computation; (b) and (c) are the verification that the *criterion* returns what (a) has already established — this is how one checks a criterion: by applying it where the answer is known.

Step 1 — lying on the sphere. Using $2 \sin^2 \frac{t}{2} = 1 - \cos t$,

$$|\gamma|^2 = (1 + \cos t)^2 + \sin^2 t + 4 \sin^2 \frac{t}{2} = 1 + 2 \cos t + 1 + 2 - 2 \cos t = 4.$$

The curve lies on the sphere with centre $O = (0, 0, 0)$ and radius $r = 2$.

Step 2 — hypotheses of the theorem. $|\gamma'|^2 = 1 + \cos^2 \frac{t}{2} = \frac{3+\cos t}{2} \geq 1 > 0$: regular. $|\gamma' \times \gamma''|^2 = \frac{13+3 \cos t}{8} \geq \frac{10}{8} > 0$: biregular. $\tau(t) = \frac{6 \cos(t/2)}{13+3 \cos t}$ vanishes only for $\cos \frac{t}{2} = 0$, that is $t = \pm\pi$, excluded from the interval: $\tau \neq 0$ on $(-\pi, \pi)$. ✓ All the hypotheses of Theorem 3.7 hold.

Step 3 — exact verification at $t = 0$. As in Example 3.3: $\kappa(0) = \frac{1}{2}$, $\tau(0) = \frac{3}{8}$, $\rho(0) = 2$, and $\rho'(0) = 0$ because κ is even in t and the reparametrisation $s(t)$ is odd, so that $\rho(s)$ is even in s and its derivative vanishes at $s = 0$. Hence $\rho'\sigma$ vanishes at $t = 0$, and the centre

of the osculating sphere is

$$q = \gamma(0) + \rho(0)N(0) = (2, 0, 0) + 2(-1, 0, 0) = (0, 0, 0) = O,$$

with $r = \sqrt{\rho(0)^2 + 0} = 2$: it coincides with the sphere of Step 1. ✓ As for condition (ii), at $t = 0$ it forces $(\rho'\sigma)'(0) = -\tau(0)\rho(0) = -\frac{3}{8} \cdot 2 = -0.75$: the numerical computation of $(\rho'\sigma)'$ at $t = 0$ gives exactly -0.75 . ✓

Step 4 — numerical verification at $t = 0.9$. From the closed forms:

$$\kappa = 0.5594064, \quad \tau = 0.3634540, \quad \rho = 1.7876090, \quad \sigma = 2.7513794, \quad |\gamma'| = 1.3456615.$$

The derivative with respect to s is obtained by dividing the one with respect to t by $|\gamma'|$: $\rho' = -0.3259869$, hence $\rho'\sigma = -0.8969135$. Then

$$\rho^2 + (\rho'\sigma)^2 = 3.1955461 + 0.8044539 = 4.0000000 = r^2 \quad \checkmark$$

and

$$\tau\rho = 0.6497137, \quad (\rho'\sigma)' = -0.6497137, \quad \varsigma = 0 \quad \checkmark$$

(the sum vanishes to forty decimal places in the computation performed). The centre of the osculating sphere, computed with $q = \gamma + \rho N + \rho'\sigma B$, comes out $(0, 0, 0)$ to forty digits, and the radius 2: the osculating sphere *does not change*, as condition (iii) of Theorem 3.7 requires. ✓

Interpretation. Viviani's curve is the intersection of the sphere $x^2 + y^2 + z^2 = 4$ with the cylinder $(x - 1)^2 + y^2 = 1$, that is with the cylinder whose diameter is the radius of the sphere. It is the first historical example of a non-planar spherical curve studied analytically, and it shows concretely that «lying on a sphere» is a *differential* condition on κ and τ : one does not need the equation of the sphere to notice it.

Typical errors. (1) Differentiating ρ with respect to t instead of s : condition (ii) is written in arc length, and one is off by a factor $|\gamma'|$. (2) Using the form « $\rho^2 + (\rho'\sigma)^2$ constant» as a criterion: that would be a mistake, as Remark 3.5 shows. (3) Extending the curve to $t = \pm\pi$, where $\tau = 0$ and the hypotheses fail (it is the double point of the curve).

Extension. Check that at the point $t = 0$ the radius of curvature attains its maximum $\rho = 2 = r$: it is the only point at which, by Corollary 3.2, the equality $\kappa = 1/r$ can hold. Geometrically it is the point where the curve is as «straight» as possible on that sphere: there it osculates a great circle.

3.8. Self-assessment quiz

- (Definition) With the convention of this chapter, the torsion of a biregular curve is defined by
A) $T' = \tau N$ B) $B' = -\tau N$ C) $N' = \tau B$ only D) $\tau = |B'|$
- (Hypothesis) In Theorem 3.2 the hypothesis $\kappa(s) > 0$ for *every* s serves to
A) make the curve bounded B) guarantee that N , B and hence the Frenet system are defined at every point C) make τ positive D) ensure that the curve is simple
- (Symbolic computation) For the circular helix of radius a and parameter b the ratio τ/κ equals
A) a/b B) b/a C) ab D) $b/(a^2 + b^2)$

-
4. (Numerical computation) The circular helix with $a = 3$ and $b = 4$ has Darboux vector of modulus
 A) 0.12 B) 0.16 C) 0.20 D) 0.28
 5. (Proof step) In the proof of Theorem 3.2 orthonormality of the frame is preserved because
 A) the coefficient matrix is skew-symmetric, so that $G \equiv I_3$ solves $G' = AG + GA^\top$ with the same initial datum B) the solution is bounded C) $\kappa > 0$ D) the integral of a unit vector is a unit vector
 6. (Error diagnosis) A student writes: «The curve has $\rho^2 + (\rho'\sigma)^2$ constant, hence it lies on a sphere.» The mistake is
 A) the right quantity is $\rho^2 - (\rho'\sigma)^2$ B) that condition is only necessary: one needs $\tau\rho + (\rho'\sigma)' = 0$, and the circular helix is a counterexample C) the hypothesis $\kappa > 0$ is missing D) the formula holds only for plane curves
 7. (Transfer) A biregular curve of class C^3 with τ/κ constant and κ non-constant is
 A) necessarily a circular helix B) necessarily planar C) a generalised helix but not a circular helix D) necessarily spherical
 8. (Source and metacognition) The complete proof of existence in the fundamental theorem of space curves, reduced to the existence and uniqueness theorem for ordinary differential equations, is found in
 A) do Carmo, *Differential Geometry of Curves and Surfaces*, Section 1-5 for the statement and the appendix to Chapter 4 for existence B) do Carmo, Section 2-4 C) do Carmo, Chapter 5 D) do Carmo, appendix to Chapter 1

3.9. Teacher's key

BEST PRACTICE

Quiz — answers, rationales and diagnosis.

- 1) **B.** *Rationale:* this is Definition 3.3, made legitimate by Lemma 3.2 ($B' \parallel N$). *Distractors:* A is the first Frenet formula with κ replaced by τ ; C is true but incomplete (it is part of the second formula, and by itself it does not define τ because it does not say that N' has no other components); D is false because $|B'| = |\tau|$: the modulus loses the sign, which is precisely the information distinguishing right-handed from left-handed helices (Proposition 3.4). *Error diagnosed:* confusing an oriented quantity with its modulus. *Source:* Powell, M435, Definition 2.32 (with the opposite sign convention). *Prerequisite:* derivative of a unit vector. *Remedial work:* recompute B' for the right-handed helix and for its mirror image.
- 2) **B.** *Rationale:* if $\kappa(s_1) = 0$ the normal $N = T'/\kappa$ is not defined at s_1 , and with it neither are B , τ and the system of Step 1. *Distractors:* A is false (the helix has $\kappa > 0$ and is unbounded); C is false, τ has arbitrary sign; D is false, the theorem says nothing about self-intersections (Remark 3.2(c)). *Error diagnosed:* attributing to a hypothesis a conclusion that does not belong to it. *Source:* Gallier, ch. 19, §19.8, warning on the role of $c(s) > 0$. *Prerequisite:* definition of N . *Remedial work:* reread Remark 3.2(a).
- 3) **B.** *Rationale:* from Theorem 3.3, $\tau/\kappa = \frac{b/(a^2+b^2)}{a/(a^2+b^2)} = b/a$; the common denominator cancels. *Distractors:* A inverts the ratio; C is dimensionally wrong (τ/κ is dimensionless, ab is an area); D is τ , not the ratio. *Error diagnosed:* failing to cancel the common factor, or swapping numerator and denominator. *Source:* Theorem 3.3; Gallier, Problem 19.20. *Prerequisite:* algebra of fractions. *Remedial work:* check that $\tau/\kappa = \cot \theta$ is the reciprocal

of the slope, as Theorem 3.4 requires.

4) **C.** *Rationale:* $\kappa = 3/25 = 0.12$, $\tau = 4/25 = 0.16$ and $|\omega| = \sqrt{\kappa^2 + \tau^2} = \sqrt{0.0144 + 0.0256} = \sqrt{0.04} = 0.2$; equivalently $1/\sqrt{a^2 + b^2} = 1/5 = 0.2$. *Distractors:* A is κ ; B is τ ; D is the sum $\kappa + \tau$, that is the mistake of adding moduli instead of squares. *Error diagnosed:* adding orthogonal components without Pythagoras' theorem. *Source:* Proposition 3.1. *Prerequisite:* norm of a combination of orthogonal unit vectors. *Remedial work:* redo the computation with $a = b = 1$, where $|\omega| = \sqrt{2}/2 = 0.7071068$.

5) **A.** *Rationale:* this is Step 2 of the proof: the matrix A of the system satisfies $A + A^\top = 0$, hence the constant matrix $G \equiv I_3$ solves $G' = AG + GA^\top$; uniqueness for linear systems (Lemma 3.4) does the rest. *Distractors:* B is irrelevant (a bounded solution is not thereby orthonormal); C is needed elsewhere, to guarantee that the system exists; D is false (the integral of a unit vector is in general not a unit vector: $\int_0^1 T$ has modulus ≤ 1 , not $= 1$). *Error diagnosed:* accepting orthonormality as «obvious» instead of deducing it from skew-symmetry. *Source:* Wang, *Fundamental Theorem of the Local Theory of Curves*, §5; do Carmo, appendix to Chapter 4. *Prerequisite:* uniqueness for linear systems. *Remedial work:* write out the six equations for g_{ij} and check that $G \equiv I_3$ solves them.

6) **B.** *Rationale:* this is exactly Remark 3.5: the circular helix with $a = b = 1$ has $\rho = 2$ constant, hence $\rho^2 + (\rho'\sigma)^2 = 4$ constant, but $\varsigma = \tau\rho = 1 \neq 0$ and the curve is unbounded. *Distractors:* A invents a sign; C is false, $\kappa > 0$ is already among the hypotheses; D is false, for plane curves $\tau = 0$ and σ is not even defined. *Error diagnosed:* mistaking a necessary condition for a sufficient one. *Source:* Theorem 3.7; da Silva, Theorem 2.3.1. *Prerequisite:* distinguishing «only if» from «if». *Remedial work:* redo the computation on the helix with $a = b = 1$ and then on Viviani's curve.

7) **C.** *Rationale:* τ/κ constant gives a generalised helix by Theorem 3.4; but Corollary 3.1 requires κ and τ constant separately, and here κ is not. The example $\gamma(t) = (3t - t^3, 3t^2, 3t + t^3)$ of Remark 3.3 is precisely of this kind. *Distractors:* A confuses Lancret with the corollary; B is false (τ/κ constant and non-zero excludes $\tau \equiv 0$); D is unrelated: nothing links constant slope to lying on a sphere (and indeed helices are never spherical). *Error diagnosed:* confusing «constant ratio» with «both constant». *Source:* Theorem 3.4. *Prerequisite:* reading the hypotheses. *Remedial work:* compute κ and τ of the example at $t = 0$ and $t = 1$ and check that the ratio stays 1 while the values change.

8) **A.** *Rationale:* do Carmo states the theorem in Section 1-5 and defers the proof of existence to the appendix to Chapter 4, where the existence and uniqueness theorem for ordinary differential equations is proved. *Distractors:* B, C and D point to sections dealing with surfaces (Chapter 2), intrinsic geometry (Chapter 4) or the appendix to Chapter 1, which concerns continuity and differentiability. *Error diagnosed:* citing a text «from memory» without checking where the proof is. *Source:* do Carmo, Section 1-5; Powell, M435, Theorem 2.39, which refers explicitly to the pages of do Carmo. *Prerequisite:* none. *Remedial work:* compare the structure of that proof with the one of Theorem 3.2 and of the appendix to this chapter, which instead carries it out in full.

BEST PRACTICE

Assigned exercise 3.1 — answers. (a) As in Example 3.1: $\gamma' \times \gamma'' = (6t^2, -6t, 2)$, $\langle \gamma' \times \gamma'', \gamma''' \rangle = 12$ and

$$\kappa(t) = \frac{2\sqrt{9t^4 + 9t^2 + 1}}{(1 + 4t^2 + 9t^4)^{3/2}}, \quad \tau(t) = \frac{3}{9t^4 + 9t^2 + 1}.$$

The denominator of τ is $9t^4 + 9t^2 + 1 \geq 1 > 0$, hence $\tau(t) = 3/(9t^4 + 9t^2 + 1) > 0$ for every t : by Proposition 3.3(ii) no arc is planar.

(b) At $t = 2$: $9 \cdot 16 + 9 \cdot 4 + 1 = 144 + 36 + 1 = 181$ and $1 + 16 + 144 = 161$, hence

$$\kappa(2) = \frac{2\sqrt{181}}{161^{3/2}} = 0.0131714, \quad \tau(2) = \frac{3}{181} = 0.0165746.$$

Direct numerical check (high-precision derivatives): 0.013171355 and 0.016574586. ✓

(c) At $t = 0$: $\gamma'(0) = (1, 0, 0)$ of modulus 1 (the parameter is arc length at that point), $\gamma''(0) = (0, 2, 0)$, hence $T = (1, 0, 0)$, $\kappa(0) = 2$, $N = (0, 1, 0)$, $B = T \times N = (0, 0, 1)$. The osculating circle (Definition 3.7) has radius $\rho = 1/2 = 0.5$ and centre

$$q = \gamma(0) + \rho N = (0, 0, 0) + \frac{1}{2}(0, 1, 0) = (0, \frac{1}{2}, 0),$$

and lies in the osculating plane, spanned by $T = (1, 0, 0)$ and $N = (0, 1, 0)$, that is the plane $z = 0$. Check: $|q - \gamma(0)| = |(0, \frac{1}{2}, 0)| = \frac{1}{2} = \rho$. ✓

(d) τ/κ at $t = 0$ equals $3/2 = 1.5$; at $t = 1$ it equals $0.1578947/0.1664235 = 0.9487525$. It is not constant, hence by Theorem 3.4 the twisted cubic is *not* a generalised helix.

BEST PRACTICE

Assigned exercise 3.2 — answers. (a) $\gamma' = (3 - 3t^2, 6t, 3 + 3t^2) = 3(1 - t^2, 2t, 1 + t^2)$ and

$$|\gamma'|^2 = 9[(1 - t^2)^2 + 4t^2 + (1 + t^2)^2] = 9[2 + 4t^2 + 2t^4] = 18(1 + t^2)^2,$$

hence $|\gamma'| = 3\sqrt{2}(1 + t^2)$.

(b) $\gamma'' = 6(-t, 1, t)$ and $\gamma''' = 6(-1, 0, 1)$. Then

$$\gamma' \times \gamma'' = 18[(1 - t^2, 2t, 1 + t^2) \times (-t, 1, t)] = 18(t^2 - 1, -2t, 1 + t^2),$$

of modulus $18\sqrt{(t^2 - 1)^2 + 4t^2 + (1 + t^2)^2} = 18\sqrt{2}(1 + t^2)$. Hence

$$\kappa = \frac{18\sqrt{2}(1 + t^2)}{(3\sqrt{2}(1 + t^2))^3} = \frac{18\sqrt{2}(1 + t^2)}{54\sqrt{2}(1 + t^2)^3} = \frac{1}{3(1 + t^2)^2}.$$

Moreover $\langle \gamma' \times \gamma'', \gamma''' \rangle = 18 \cdot 6[-(t^2 - 1) + 0 + (1 + t^2)] = 108 \cdot 2 = 216$ and $|\gamma' \times \gamma''|^2 = 648(1 + t^2)^2$, hence $\tau = 216/(648(1 + t^2)^2) = 1/(3(1 + t^2)^2) = \kappa$. Numerical check at $t = 0.7$: both equal 0.150143386935. ✓

(c) $\tau/\kappa \equiv 1 = \cot \theta$ gives $\theta = \frac{\pi}{4} = 45^\circ$. At $t = 0$: $\gamma'(0) = 3(1, 0, 1)$, $|\gamma'(0)| = 3\sqrt{2}$, hence $T(0) = \frac{1}{\sqrt{2}}(1, 0, 1)$; $\gamma' \times \gamma''(0) = 18(-1, 0, 1)$, hence $B(0) = \frac{1}{\sqrt{2}}(-1, 0, 1)$. The axis is

$$u = \cos \frac{\pi}{4} T + \sin \frac{\pi}{4} B = \frac{1}{\sqrt{2}} \cdot \frac{1}{\sqrt{2}}[(1, 0, 1) + (-1, 0, 1)] = \frac{1}{2}(0, 0, 2) = (0, 0, 1),$$

that is the z axis. Check: $\langle T(t), (0, 0, 1) \rangle = \frac{3(1+t^2)}{3\sqrt{2}(1+t^2)} = \frac{1}{\sqrt{2}} = \cos 45^\circ$ for every t . ✓

(d) The hypothesis that κ and τ be *constant* fails: here $\kappa(0) = \frac{1}{3} = 0.3333333$ and $\kappa(1) = \frac{1}{12} = 0.0833333$. Theorem 3.4 requires only the ratio to be constant, Corollary 3.1 requires both functions to be constant; and by Theorem 3.2 two congruent curves have the *same* κ and τ , which for the circular helix are constant: hence no circular helix can be congruent to this curve.

BEST PRACTICE

Assigned exercise 3.3 — answers. (a) *No*. For the helix with $a = 3$, $b = 4$ one has

$\kappa = 0.12$, $\tau = 0.16$, $\rho = 1/0.12 = 8.3333333$ constant, hence $\rho' = 0$ and

$$\varsigma = \tau\rho + (\rho'\sigma)' = 0.16 \cdot 8.3333333 + 0 = 1.3333333 = \frac{4}{3} \neq 0 :$$

by Theorem 3.7 the curve is not spherical. (Note that $\varsigma = \tau\rho = b/a = 4/3$, in agreement with Remark 3.5.) Besides, the helix is unbounded.

(b) *Yes*. The circle $\gamma(t) = (3 \cos t, 3 \sin t, 4)$ has $|\gamma(t)|^2 = 9 + 16 = 25$: it lies on the sphere with centre the origin and radius 5. But it also lies on every sphere with centre $(0, 0, 4 + h)$ and radius $\sqrt{9 + h^2}$, for every $h \in \mathbb{R}$.

(c) At $t = \frac{\pi}{2}$: $\cos t = 0$ and $\cos \frac{t}{2} = \frac{\sqrt{2}}{2}$, hence

$$\kappa = \frac{\sqrt{13}}{3^{3/2}} = 0.6938887, \quad \tau = \frac{6 \cdot \frac{\sqrt{2}}{2}}{13} = \frac{3\sqrt{2}}{13} = 0.3263570, \quad \rho = 1.4411534.$$

Since $\rho = 1.4411534 < 2 = r$, one has $\kappa = 0.6938887 > 1/r = 0.5$: Corollary 3.2 is verified. ✓

(d) In case (b) the hypothesis $\tau \neq 0$ fails: the circle is planar, $\tau \equiv 0$, and $\sigma = 1/\tau$ is not even defined, so the criterion of Theorem 3.7 does not apply. The answer is still «yes» because lying on a sphere is checked directly; and the sphere is not unique precisely because the curve is planar: the spheres containing the circle are exactly those whose centre lies on the *axis* of the circle — the line through the centre $(0, 0, 4)$ orthogonal to the plane $z = 4$ — with radius fixed by Pythagoras' theorem, that is the one-parameter family described in (b). This is exactly the case excluded at the end of the proof of Theorem 3.7, where uniqueness is obtained by observing that a curve with $\tau \neq 0$ cannot lie on a circle.

3.10. Chapter formulary

Frenet frame and Frenet–Serret formulas (arc length, $\kappa > 0$).

$$T = \gamma', \quad \kappa = |\gamma''|, \quad N = \frac{\gamma''}{\kappa}, \quad B = T \times N, \quad N = B \times T, \quad T = N \times B.$$

$$T' = \kappa N, \quad N' = -\kappa T + \tau B, \quad B' = -\tau N; \quad \frac{d}{ds} \begin{pmatrix} T \\ N \\ B \end{pmatrix} = \begin{pmatrix} 0 & \kappa & 0 \\ -\kappa & 0 & \tau \\ 0 & -\tau & 0 \end{pmatrix} \begin{pmatrix} T \\ N \\ B \end{pmatrix}.$$

Darboux vector: $\omega = \tau T + \kappa B$, $X' = \omega \times X$, $|\omega| = \sqrt{\kappa^2 + \tau^2}$.

Arbitrary parameter ($v = |\gamma'|$).

$$\gamma' = vT, \quad \gamma'' = v'T + v^2\kappa N, \quad \gamma' \times \gamma'' = v^3\kappa B,$$

$$\kappa = \frac{|\gamma' \times \gamma''|}{|\gamma'|^3}, \quad \tau = \frac{\det(\gamma', \gamma'', \gamma''')}{|\gamma' \times \gamma''|^2}, \quad B = \frac{\gamma' \times \gamma''}{|\gamma' \times \gamma''|}.$$

Mind the sign: do Carmo, Gallier and Powell define $B' = +\tau N$ and hence have the formula with a minus sign.

Notable cases.

$$\kappa \equiv 0 \iff \text{straight line}; \quad \tau \equiv 0 \iff \text{plane curve};$$

$\kappa \equiv \kappa_0 > 0$ and $\tau \equiv 0 \iff$ circle of radius $1/\kappa_0$.

Circular helix $\gamma(t) = (a \cos t, a \sin t, bt)$, $c = \sqrt{a^2 + b^2}$, pitch $p = 2\pi b$:

$$|\gamma'| = c, \quad \kappa = \frac{a}{a^2 + b^2}, \quad \tau = \frac{b}{a^2 + b^2}, \quad |\omega| = \frac{1}{c};$$

$$\text{from constant } (\kappa_0, \tau_0): \quad a = \frac{\kappa_0}{\kappa_0^2 + \tau_0^2}, \quad b = \frac{\tau_0}{\kappa_0^2 + \tau_0^2}.$$

Lancret: generalised helix $\iff \frac{\tau}{\kappa} = \cot \theta$ constant; axis $u = \cos \theta T + \sin \theta B$.

Osculating circle and sphere ($\rho = 1/\kappa$, $\sigma = 1/\tau$, $\rho' = d\rho/ds$).

osculating circle: centre $\gamma + \rho N$, radius ρ , in the osculating plane;

osculating sphere: centre $q = \gamma + \rho N + \rho' \sigma B$, radius $r = \sqrt{\rho^2 + (\rho' \sigma)^2} \geq \rho$.

Spherical curves: with $\kappa > 0$ and τ never zero,

$$\gamma \text{ lies on a sphere } \iff \varsigma := \tau \rho + (\rho' \sigma)' \equiv 0 \iff q' \equiv 0,$$

and then centre q and radius r are the ones written above, both constant. The condition $\rho^2 + (\rho' \sigma)^2 = \text{const}$ alone is **necessary and not sufficient** (counterexample: the circular helix); it becomes sufficient if ρ' never vanishes. On a sphere of radius r : $\kappa \geq 1/r$, with equality at one point at most.

3.11. Appendix: existence and uniqueness for linear systems

Theorem 3.2 rests on a single analytic fact: the Cauchy problem $X' = \mathcal{A}(s)X$, $X(s_0) = X_0$, with $\mathcal{A}$ continuous, has exactly one solution on the whole interval. It is the *linear* case of the Picard–Lindelöf theorem, and in this form the proof closes without needing anything that is not elementary: we give it in full, so that no link is missing in the chapter. The strategy is the classical one: the problem is rewritten as the search for a fixed point of an integral operator, and the contraction mapping theorem is applied.

Lemma 3.3: Contraction mapping theorem (Banach–Caccioppoli). *Let (X, d) be a non-empty complete metric space and let $\Phi : X \rightarrow X$ satisfy $d(\Phi x, \Phi y) \leq \lambda d(x, y)$ for all $x, y \in X$, with a fixed $\lambda \in (0, 1)$. Then Φ has exactly one fixed point. Moreover, if for some $m \geq 1$ the iterate Φ^m is a contraction (without Φ being one), Φ still has exactly one fixed point.*

Proof. Existence. Choose $x_0 \in X$ and set $x_{n+1} = \Phi x_n$. By induction $d(x_{n+1}, x_n) \leq \lambda^n d(x_1, x_0)$. For $m > n$, the triangle inequality and the sum of the geometric series give

$$d(x_m, x_n) \leq \sum_{k=n}^{m-1} d(x_{k+1}, x_k) \leq d(x_1, x_0) \sum_{k=n}^{\infty} \lambda^k = \frac{\lambda^n}{1-\lambda} d(x_1, x_0) \xrightarrow{n \rightarrow \infty} 0.$$

The sequence is Cauchy, and by completeness it converges to some $x_* \in X$. Since Φ is Lipschitz, hence continuous, $\Phi x_* = \lim_n \Phi x_n = \lim_n x_{n+1} = x_*$.

Uniqueness. If $\Phi x = x$ and $\Phi y = y$, then $d(x, y) = d(\Phi x, \Phi y) \leq \lambda d(x, y)$, that is $(1-\lambda)d(x, y) \leq 0$; since $1-\lambda > 0$ and $d \geq 0$, we get $d(x, y) = 0$ and $x = y$.

Case Φ^m a contraction. By what has already been proved Φ^m has a unique fixed point x_* . Then $\Phi^m(\Phi x_*) = \Phi(\Phi^m x_*) = \Phi x_*$, that is Φx_* is a fixed point of Φ^m ; by uniqueness, $\Phi x_* = x_*$.

Conversely every fixed point of Φ is a fixed point of Φ^m , hence equal to x_* . $\square$

Lemma 3.4: Linear Cauchy problem. Let $I \subseteq \mathbb{R}$ be an interval, $\mathcal{A} : I \rightarrow M_n(\mathbb{R})$ continuous, $s_0 \in I$ and $X_0 \in \mathbb{R}^n$. Then there exists exactly one function $X \in C^1(I, \mathbb{R}^n)$ such that

$$X'(s) = \mathcal{A}(s)X(s) \quad \text{for every } s \in I, \quad X(s_0) = X_0.$$

Proof. Step 1 — reduction to a compact interval. Let $[\alpha, \beta] \subseteq I$ be a compact interval with $s_0 \in [\alpha, \beta]$. Since $\mathcal{A}$ is continuous and $[\alpha, \beta]$ compact, the function $s \mapsto \|\mathcal{A}(s)\|$ (operator norm associated with the Euclidean norm) is continuous and bounded: let $L = \max_{s \in [\alpha, \beta]} \|\mathcal{A}(s)\| < +\infty$, so that $|\mathcal{A}(s)v| \leq L|v|$ for every $v \in \mathbb{R}^n$ and every $s \in [\alpha, \beta]$.

Step 2 — the Picard operator. Let $E = C([\alpha, \beta], \mathbb{R}^n)$ with the norm $\|X\|_\infty = \max_{s \in [\alpha, \beta]} |X(s)|$; $(E, \|\cdot\|_\infty)$ is a Banach space (Remark 3.6). Define $\Phi : E \rightarrow E$ by

$$(\Phi X)(s) = X_0 + \int_{s_0}^s \mathcal{A}(u)X(u) du.$$

The integrand is continuous, hence ΦX is well defined, of class C^1 , and in particular continuous: Φ maps E into itself. By the fundamental theorem of calculus, $X \in E$ satisfies $\Phi X = X$ if and only if X is of class C^1 , satisfies $X' = \mathcal{A}X$ on $[\alpha, \beta]$ and $X(s_0) = X_0$: solving the Cauchy problem is the same as finding a fixed point of Φ .

Step 3 — the iterated estimate. We prove by induction on $m \geq 1$ that for all $X, Y \in E$ and every $s \in [\alpha, \beta]$

$$|(\Phi^m X)(s) - (\Phi^m Y)(s)| \leq \frac{L^m |s - s_0|^m}{m!} \|X - Y\|_\infty.$$

For $m = 1$:

$$|(\Phi X)(s) - (\Phi Y)(s)| = \left| \int_{s_0}^s \mathcal{A}(u)(X(u) - Y(u)) du \right| \leq \left| \int_{s_0}^s L |X(u) - Y(u)| du \right|,$$

and the last quantity is $\leq L |s - s_0| \|X - Y\|_\infty$. Assuming the estimate for m , one has

$$\begin{aligned} |(\Phi^{m+1} X)(s) - (\Phi^{m+1} Y)(s)| &\leq \left| \int_{s_0}^s L |(\Phi^m X)(u) - (\Phi^m Y)(u)| du \right| \\ &\leq \left| \int_{s_0}^s \frac{L^{m+1} |u - s_0|^m}{m!} du \right| \cdot \|X - Y\|_\infty = \frac{L^{m+1} |s - s_0|^{m+1}}{(m+1)!} \|X - Y\|_\infty, \end{aligned}$$

as required.

Step 4 — conclusion on $[\alpha, \beta]$. Setting $\ell = \beta - \alpha$, Step 3 gives

$$\|\Phi^m X - \Phi^m Y\|_\infty \leq \frac{(L\ell)^m}{m!} \|X - Y\|_\infty.$$

Since $\sum_m (L\ell)^m / m! = e^{L\ell}$ converges, the general term tends to zero: there is an m with $(L\ell)^m / m! < 1$, and for that m the iterate Φ^m is a contraction. By Lemma 3.3, Φ has exactly one fixed point in E : the Cauchy problem has exactly one solution on $[\alpha, \beta]$.

Step 5 — from $[\alpha, \beta]$ to I . Write I as the union of an increasing sequence of compact intervals $[\alpha_k, \beta_k]$ containing s_0 (for instance $[\alpha_k, \beta_k] = [a_k, b_k]$ with $a_k \downarrow \inf I$, $b_k \uparrow \sup I$ inside I). By Step 4 on each of them there is a unique solution X_k ; by uniqueness, X_{k+1} restricted to $[\alpha_k, \beta_k]$ coincides with X_k . The function X defined on I by $X(s) = X_k(s)$ for $s \in [\alpha_k, \beta_k]$ is therefore well posed, is of class C^1 , solves the problem, and is unique: two solutions on I agree on every compact set and hence on I . $\square$

Remark 3.6: What we import. In the whole chapter exactly one fact is **imported**, that is, used without proof: the completeness of the space $(C([\alpha, \beta], \mathbb{R}^n), \|\cdot\|_\infty)$, namely the fact that a sequence of continuous functions on a compact set, Cauchy for the maximum norm, converges uniformly to a continuous function. It is the classical theorem on uniform convergence from a first analysis course; a complete proof, in exactly the form used here, is in Wang, *Fundamental Theorem of the Local Theory of Curves*, Theorem 3.4 (University of Chicago REU 2018), verified and read in full.

What is missing, exactly: that step alone. The contraction mapping theorem is proved (Lemma 3.3), the iterated estimate is proved (Lemma 3.4, Step 3), the extension to the whole interval is proved (Step 5), and the fundamental theorem of curves is deduced from these (Theorem 3.2). No other result of the chapter is imported: in particular the non-linear case of the Picard–Lindelöf theorem is neither needed nor invoked.

B. da Silva, *Differential Geometry of Rotation Minimizing Frames, Spherical Curves, and Quantum Mechanics of a Constrained Particle*, thesis, arXiv:1806.08830 (22 June 2018), doi.org/10.48550/arXiv.1806.08830. Text read for the parts used: §2.2 «Frenet frame and Frenet equations for a space curve», which adopts *our* convention $b' = -\tau n$ (equation 2.17); §2.3 «Spherical curves and osculating spheres», where formula (2.24) gives centre and radius of the osculating sphere, $P_S = \alpha + \rho n + \frac{1}{\tau} \frac{d\rho}{ds} b$ and $R_S = \sqrt{\rho^2 + \frac{1}{\tau^2} (\rho')^2}$, and Theorem 2.3.1 — attributed to Kreyszig (1991) and Kühnel (2010) — states that a regular C^4 curve with non-zero torsion lies on a sphere of radius r if and only if $\varsigma(s) = \tau \rho + \frac{d}{ds}(\frac{\rho'}{\tau}) = 0$: this is Theorem 3.7 of this chapter, proved here in both directions. §3.2 also reports the equivalent characterisation of Bishop (1975) by means of *rotation minimizing frames* (Theorem 3.2.1) — verified on 5 September 2026.

CHAPTER 4

Global theorems on plane curves

Chapter 2 studied curvature *locally*, point by point. Here we collect the *global* theorems, which concern the curve as a whole and in which the circle systematically emerges as the extremal object: the rotation index, the support function and curves of constant width with the theorems of Barbier and Blaschke–Lebesgue, the isoperimetric inequality, the four-vertex theorem, and finally the global form of Gauss–Bonnet, which carries the same pattern of reasoning from curves to closed surfaces.

INFO

The idea in one line. Every theorem of this chapter has the form *an integral quantity of the curve is constrained*, and the circle is the equality case: the total curvature equals 2π , the perimeter of a convex body of constant width equals πw , the area at fixed perimeter is maximal, the points of stationary curvature are at least four.

Warning. Conventions of the chapter. The conventions of Chapter 2 apply: plane curves of class C^2 at least, regular ($\gamma' \neq 0$), *closed* when γ and all its derivatives agree at the endpoints, *simple* when γ is injective on $[a, b]$; positive orientation is counterclockwise; s is arc length, T and N are the unit tangent and normal, k is the signed curvature and $\rho = 1/|k|$ the radius of curvature. Decimal separators are points: 0.5.

INFO

Level and prerequisites. Level C–D. The whole chapter rests on Chapter 2: arc length and the Frenet formulas (Theorem 2.1), the curvature of the circle (Theorem 2.2), the characterisation of curves of constant curvature (Theorem 2.5), the evolute and its properties (Theorem 2.6). One also needs Fourier series with Parseval’s identity (Volume II, Chapter 4), used in Barbier’s and the isoperimetric theorem; the Jordan curve theorem (Appendix A), used only in the general case of the four-vertex theorem; and, for Section 4.6, the local form of Gauss–Bonnet on a geodesic triangle, proved for the sphere in Chapter 7.

4.1. The rotation index theorem

Definition 4.1: Rotation index. Let $\gamma : [0, L] \rightarrow \mathbb{R}^2$ be a closed regular curve parametrised by arc length, and let $\vartheta : [0, L] \rightarrow \mathbb{R}$ be a continuous determination of the angle of the unit tangent, i.e. a continuous function with $T(s) = (\cos \vartheta(s), \sin \vartheta(s))$. Since $T(L) = T(0)$, the difference $\vartheta(L) - \vartheta(0)$ is an integer multiple of 2π ; the number

$$\text{ind}(\gamma) = \frac{\vartheta(L) - \vartheta(0)}{2\pi} \in \mathbb{Z}$$

is the **rotation index** (or *turning number*) of γ .

Theorem 4.1: Rotation index theorem (Umlaufsatz, Hopf 1935). Let γ be a closed, regular and simple plane curve. Then $\text{ind}(\gamma) = \pm 1$, the sign being $+1$ if the curve is traversed counterclockwise. Consequently

$$\int_0^L k(s) ds = 2\pi \quad (\text{total curvature}).$$

Proof. Step 1 — reduction to the integral of the curvature. By Step 4 of the proof of Theorem 2.1, $k = \vartheta'$; hence

$$\int_0^L k(s) ds = \vartheta(L) - \vartheta(0) = 2\pi \text{ind}(\gamma),$$

and the claim about the integral follows from the one about the index.

Step 2 — choice of the starting point. Since γ is closed and continuous, its image is compact; let $p = \gamma(0)$ be a point of minimal ordinate (it exists by Weierstrass). Choose coordinates so that p is the origin and $T(0) = (1, 0)$: the whole curve then lies in the half-plane $y \geq 0$, and the line $y = 0$ is a *supporting line*.

Step 3 — the secant map. Let

$$\Delta = \{(s_1, s_2) : 0 \leq s_1 \leq s_2 \leq L\},$$

a closed triangle in the plane, and define $\psi : \Delta \rightarrow S^1$ by

$$\psi(s_1, s_2) = \frac{\gamma(s_2) - \gamma(s_1)}{\|\gamma(s_2) - \gamma(s_1)\|} \quad \text{if } s_1 < s_2 \text{ and } (s_1, s_2) \neq (0, L),$$

$$\psi(s, s) = T(s), \quad \psi(0, L) = -T(0).$$

This is well defined because γ is *simple*: the denominator vanishes only on the diagonal and at the vertex $(0, L)$. Continuity on the diagonal follows from the expansion $\gamma(s_2) - \gamma(s_1) = (s_2 - s_1)T(s_1) + o(s_2 - s_1)$; at the vertex $(0, L)$ one uses the same expansion with $\gamma(L) = \gamma(0)$ and $T(L) = T(0)$, which gives the unit vector $-T(0)$.

Step 4 — lifting. The triangle Δ is convex, hence simply connected; a continuous map into S^1 defined on a simply connected domain admits a continuous *lift* $\Psi : \Delta \rightarrow \mathbb{R}$ with $\psi = (\cos \Psi, \sin \Psi)$, unique up to an additive constant multiple of 2π (lifting theorem; see the bibliography). Fix $\Psi(0, 0) = 0$.

Step 5 — the index as the variation along the hypotenuse. On the diagonal $\psi(s, s) = T(s)$, so $\Psi(s, s)$ is a continuous determination of ϑ , and

$$2\pi \text{ind}(\gamma) = \Psi(L, L) - \Psi(0, 0) = \Psi(L, L).$$

Step 6 — computation along the two legs. By continuity of the lift, $\Psi(L, L)$ can be computed by travelling around the boundary of Δ along the legs instead of the hypotenuse.

First leg $s_1 = 0$, s_2 from 0 to L : here $\psi(0, s_2)$ is the unit vector from $p = \gamma(0)$ to $\gamma(s_2)$. Since the whole curve lies in the half-plane $y \geq 0$ and p has $y = 0$, this vector always has non-negative second component: it never enters the lower half-plane. Starting from $\Psi(0, 0) = 0$ (the vector $T(0) = (1, 0)$) and ending at $\psi(0, L) = -T(0) = (-1, 0)$, the continuous determination must equal π at the end (the only alternative, $-\pi$, would require crossing the lower half-plane). Hence $\Psi(0, L) = \pi$.

Second leg $s_2 = L$, s_1 from 0 to L : now $\psi(s_1, L)$ is the unit vector from $\gamma(s_1)$ to $\gamma(L) = p$, the opposite kind of vector; it always has non-positive second component, and goes from $-T(0)$ to $\psi(L, L) = T(L) = T(0)$. Passing through the lower half-plane, the continuous determination goes from π to 2π .

Step 7 — conclusion. $\Psi(L, L) = 2\pi$, hence $\text{ind}(\gamma) = 1$. If the curve is traversed clockwise one gets -1 by symmetry (apply the result to the reflected curve).

Step 8 — check on the circle. For the counterclockwise circle of radius r , $k = 1/r$ is constant and $L = 2\pi r$, so

$$\int_0^L k \, ds = \frac{2\pi r}{r} = 2\pi. \quad \checkmark$$

And for an ellipse, for any convex curve, for a non-convex but simple curve, the result is the same: the total curvature does not depend on the shape. It is a *topological invariant*.

Step 9 — necessity of simplicity. The lemniscate traversed once is closed and regular but not simple, and has index 0; the curve traversing a circle twice has index 2. Simplicity is therefore essential, and it is exactly the hypothesis that makes ψ well defined in Step 3. $\square$

Corollary 4.1: Total curvature and mean radius. For a simple closed curve of length L , the mean curvature is $\bar{k} = 2\pi/L$, the reciprocal of the radius of the circle of equal perimeter. In particular there is at least one point where $k(s) \geq 2\pi/L$ and at least one where $k(s) \leq 2\pi/L$.

Proof. The integral mean of k is $\frac{1}{L} \int_0^L k \, ds = 2\pi/L$ by Theorem 4.1. A circle of perimeter L has radius $L/2\pi$ and curvature $2\pi/L$: the mean therefore coincides with the value for the isoperimetric circle. The last assertion is the elementary property that a continuous function attains values both $\geq$ and $\leq$ its own mean. $\square$

Exercise 4.1. Verify the theorem for the circle of radius r traversed counterclockwise.

Solution. On the circle $\kappa \equiv 1/r$ and the length is $L = 2\pi r$, hence $\oint \kappa \, ds = \frac{1}{r} \cdot 2\pi r = 2\pi$: index $i = +1$. The tangent makes exactly one full turn, consistently with the counterclockwise orientation.

4.2. The support function

The previous sections described a curve through its points. For *convex* curves there is a dual description, in which the primary object is not the point but the *tangent line*: this is the support function, and with it the theorems of this and the next sections are proved by turning geometric problems into problems about Fourier series — that is, by referring them back to Chapter 4.

Definition 4.2: Support function. Let $K \subset \mathbb{R}^2$ be a compact convex set containing the origin in its interior. The **support function** of K is

$$h(\theta) = \max_{x \in K} \langle x, u(\theta) \rangle, \quad u(\theta) = (\cos \theta, \sin \theta).$$

Geometrically, $h(\theta)$ is the signed distance from the origin to the supporting line of K orthogonal to $u(\theta)$.

Theorem 4.2: Reconstruction of the curve from the support function. Let K be convex with boundary ∂K of class C^2 and everywhere positive curvature. Then h is of class C^2 and:

(i) the point of ∂K whose outer normal is $u(\theta)$ is

$$\gamma(\theta) = h(\theta) u(\theta) + h'(\theta) u'(\theta), \quad u'(\theta) = (-\sin \theta, \cos \theta);$$

(ii) the radius of curvature there is

$$\rho(\theta) = h(\theta) + h''(\theta) > 0;$$

(iii) (Cauchy's formula) the perimeter of K is

$$L = \int_0^{2\pi} h(\theta) d\theta;$$

(iv) the area of K is

$$A = \frac{1}{2} \int_0^{2\pi} (h(\theta)^2 - h'(\theta)^2) d\theta.$$

Proof. (i) The point $\gamma(\theta)$ is characterised by two conditions: it lies on the supporting line, i.e. $\langle \gamma(\theta), u(\theta) \rangle = h(\theta)$; and its tangent is orthogonal to $u(\theta)$, i.e. $\gamma'(\theta) \parallel u'(\theta)$.

Write $\gamma = \alpha u + \beta u'$ in the moving orthonormal basis $\{u, u'\}$ (orthonormal since u and u' are orthogonal unit vectors). The first condition gives $\alpha = h$. Differentiating, and using $u'' = -u$:

$$\gamma' = h'u + hu' + \beta'u' - \beta u = (h' - \beta)u + (h + \beta')u'.$$

The second condition forces the component along u to vanish: $\beta = h'$. Substituting gives the formula.

(ii) With $\beta = h'$, the previous computation gives

$$\gamma'(\theta) = (h + h'') u'(\theta).$$

On the other hand $u'(\theta)$ is the unit tangent (up to sign) and θ is the angle of the normal, hence also the angle of the tangent up to $\pi/2$: by Step 4 of the proof of Theorem 2.1, $k = d\vartheta/ds = d\theta/ds$, so

$$\rho = \frac{1}{k} = \frac{ds}{d\theta} = \|\gamma'(\theta)\| = h + h'',$$

positive by the hypothesis of positive curvature.

(iii) Integrating $ds = \rho d\theta$ over a full turn,

$$L = \int_0^{2\pi} (h + h'') d\theta = \int_0^{2\pi} h d\theta + [h']_0^{2\pi} = \int_0^{2\pi} h d\theta,$$

since h' is 2π -periodic and the boundary term vanishes.

(iv) The area enclosed by a simple closed curve is, by Green's theorem,

$$A = \frac{1}{2} \oint (x dy - y dx) = \frac{1}{2} \int_0^{2\pi} \det(\gamma(\theta), \gamma'(\theta)) d\theta.$$

With $\gamma = hu + h'u'$ and $\gamma' = (h + h'')u'$, and using $\det(u, u') = 1$, $\det(u', u') = 0$:

$$\det(\gamma, \gamma') = h(h + h'').$$

Hence

$$A = \frac{1}{2} \int_0^{2\pi} (h^2 + hh'') d\theta = \frac{1}{2} \int_0^{2\pi} (h^2 - h'^2) d\theta,$$

having integrated by parts $\int hh'' = [hh'] - \int h'^2 = -\int h'^2$ (boundary term zero by periodicity).

Step 5 — check on the circle. For the circle of radius r centred at the origin, $h \equiv r$: then $\gamma(\theta) = r u(\theta)$ (the circle itself), $\rho = r + 0 = r \checkmark$, $L = 2\pi r \checkmark$ and $A = \frac{1}{2} \int_0^{2\pi} r^2 d\theta = \pi r^2 \checkmark$.

Step 6 — check on a translated circle. For the circle of radius r centred at $c = (c_1, c_2)$ one has $h(\theta) = r + c_1 \cos \theta + c_2 \sin \theta$. Then $h'' = -c_1 \cos \theta - c_2 \sin \theta$ and $\rho = h + h'' = r \checkmark$; moreover $L = 2\pi r$ (the cosine and sine terms integrate to zero) $\checkmark$. For the area, $\int h^2 = 2\pi r^2 + \pi(c_1^2 + c_2^2)$ and $\int h'^2 = \pi(c_1^2 + c_2^2)$, hence $A = \pi r^2 \checkmark$, independent of the translation, as it must be. $\square$

Remark 4.1: Why the support function simplifies everything. The formula $\rho = h + h''$ is the heart of the method. It turns a geometric quantity — the radius of curvature — into a linear differential operator applied to h ; and since h is 2π -periodic, it can be expanded in a Fourier series (Chapter 4), where the operator $1 + \frac{d^2}{d\theta^2}$ becomes multiplication by $1 - n^2$. All the theorems that follow are, in essence, the computation of that multiplication. Note the special value $n = 1$, for which $1 - n^2 = 0$: the first harmonics contribute nothing to the curvature — indeed they correspond to mere translations of the convex body, as Step 6 shows.

Figure 4.1: The support function of a convex body. For every direction θ one takes the supporting line ℓ_θ orthogonal to $(\cos \theta, \sin \theta)$ that leaves the body entirely on one side; $h(\theta)$ is its signed distance from the origin, and $P(\theta)$ the contact point. The function h determines the convex body completely, and turns geometric problems into Fourier analysis: the perimeter is $L = \int_0^{2\pi} h$ (Cauchy's formula), the area is $A = \frac{1}{2} \int_0^{2\pi} (h^2 - h'^2)$, the width in direction θ is $w(\theta) = h(\theta) + h(\theta + \pi)$ and the radius of curvature is $\rho = h + h''$. For the ellipse drawn here $h(\theta) = \sqrt{a^2 \cos^2 \theta + b^2 \sin^2 \theta}$.

4.3. Curves of constant width and Barbier's theorem

Definition 4.3: Width. The **width** of a convex body K in direction θ is the distance between the two supporting lines orthogonal to $u(\theta)$:

$$w(\theta) = h(\theta) + h(\theta + \pi).$$

K has **constant width** w if $w(\theta) = w$ for every θ .

Example 4.1: The Reuleaux triangle. Take an equilateral triangle of side w and, for each vertex, draw the arc of circle of radius w centred at that vertex and lying between the other two. The figure bounded by the three arcs is the **Reuleaux triangle**.

Constant width. Every supporting line touches the figure either at a vertex or along an arc. If it touches the arc opposite the vertex V , the parallel supporting line on the other side passes through V , and the distance between the two is the radius of the arc, namely w . Since every direction falls into one of these cases, the width is constantly w .

Perimeter. Each arc subtends an angle of $60^\circ = \pi/3$ at its centre and has radius w , hence length $w\pi/3$; the three arcs give

$$L = 3 \cdot \frac{\pi w}{3} = \pi w,$$

exactly the perimeter of the circle of diameter w . This is no coincidence: it is Theorem 4.3.

Area. The area is that of the equilateral triangle plus three circular segments:

$$A = \frac{\sqrt{3}}{4}w^2 + 3 \left(\frac{\pi w^2}{6} - \frac{\sqrt{3}}{4}w^2 \right) = \frac{\pi w^2}{2} - \frac{\sqrt{3}}{2}w^2 = \frac{\pi - \sqrt{3}}{2}w^2.$$

Numerically, $\frac{3.141593-1.732051}{2} = 0.704771$, against $\pi w^2/4 = 0.785398 w^2$ for the circle of diameter w : the Reuleaux triangle has 89.73% of the area of the circle of the same width.

Applications. Curves of constant width appear in the design of polygonal coins (which must pass the selectors of vending machines in every orientation: the British 20p and 50p coins are Reuleaux heptagons), in cam mechanisms, and in dimensional inspection: *measuring a constant-width body with a calliper always gives the same value, so it is not enough to guarantee that a part is cylindrical*. This last is a recurrent error in quality control, and is why geometrical tolerancing standards prescribe measuring *roundness* (ISO 1101) and not merely width.

Theorem 4.3: Barbier's theorem. *Every convex curve of constant width w has perimeter*

$$L = \pi w,$$

independently of its shape. In particular all curves of constant width w have the same perimeter as the circle of diameter w .

Proof. First proof (Cauchy's formula). By Theorem 4.2(iii),

$$L = \int_0^{2\pi} h(\theta) d\theta.$$

Substituting $\theta \rightarrow \theta + \pi$ in the integral (a change of variable which, by periodicity, does not alter the value),

$$L = \int_0^{2\pi} h(\theta + \pi) d\theta.$$

Adding the two expressions and dividing by two,

$$L = \frac{1}{2} \int_0^{2\pi} (h(\theta) + h(\theta + \pi)) d\theta = \frac{1}{2} \int_0^{2\pi} w(\theta) d\theta = \frac{1}{2} \cdot 2\pi w = \pi w.$$

Second proof (Fourier series). Expand h in a Fourier series (Chapter 4):

$$h(\theta) = a_0 + \sum_{n \geq 1} (a_n \cos n\theta + b_n \sin n\theta).$$

Then

$$w(\theta) = h(\theta) + h(\theta + \pi) = 2a_0 + 2 \sum_{n \text{ even}, n \geq 2} (a_n \cos n\theta + b_n \sin n\theta),$$

because $\cos n(\theta + \pi) = (-1)^n \cos n\theta$ and similarly for the sine: the odd harmonics cancel, the even ones double. The width is therefore constant if and only if $a_n = b_n = 0$ for every even $n \geq 2$, and then $w = 2a_0$. By Cauchy's formula, $L = 2\pi a_0 = \pi w$.

Third proof (via curvature). From Theorem 4.2(ii), $\rho(\theta) = h(\theta) + h''(\theta)$. Then

$$\rho(\theta) + \rho(\theta + \pi) = (h(\theta) + h(\theta + \pi)) + (h''(\theta) + h''(\theta + \pi)) = w(\theta) + w''(\theta) = w,$$

w being constant. Integrating over half a turn,

$$L = \int_0^{2\pi} \rho \, d\theta = \int_0^\pi (\rho(\theta) + \rho(\theta + \pi)) \, d\theta = \int_0^\pi w \, d\theta = \pi w.$$

Step 4 — check on the Reuleaux triangle. Example 4.1 gave $L = \pi w$ by an independent computation. ✓

Step 5 — reading. Barbier's theorem is the first of a series of results in which the circle is *not* characterised: the perimeter does not distinguish the circle from the other curves of constant width. What does distinguish them is the area, as the next theorem says. □

Theorem 4.4: Extremes of area at constant width. Among all convex bodies of constant width w :

- (i) the maximum area is attained by the circle of diameter w , with $A = \pi w^2/4$;
- (ii) the minimum is attained by the Reuleaux triangle, with $A = \frac{\pi - \sqrt{3}}{2} w^2$ (Blaschke–Lebesgue theorem).

Proof. [of part (i) only] By Theorem 4.3 all convex bodies of constant width w have the same perimeter $L = \pi w$. By the isoperimetric inequality (Theorem 4.5, proved in the next section), among all closed curves of given perimeter the area is maximal for the circle and equals $L^2/4\pi$. Here

$$A \leq \frac{L^2}{4\pi} = \frac{\pi^2 w^2}{4\pi} = \frac{\pi w^2}{4},$$

with equality only for the circle, which indeed has constant width w (its diameter).

On part (ii). The Blaschke–Lebesgue theorem was proved independently by Wilhelm Blaschke (1915) and Henri Lebesgue (1914). The original proof goes through compactness of the space of convex bodies in the Hausdorff metric and an analysis of the minimisers; Section 4.3.1 gives a shorter and complete one, using only Minkowski's mixed areas and Pál's hexagon theorem. The minimum is 89.73% of the maximum, as checked in Example 4.1. □

4.3.1 Part (ii): the Blaschke–Lebesgue theorem, proved

The original proof of Blaschke and Lebesgue goes through compactness of the space of convex bodies and an analysis of the minimisers. There is, however, a markedly shorter route, due essentially to Chakerian, which uses only two tools: Minkowski's *mixed areas* and a theorem of Pál from 1920 on the existence of a circumscribed regular hexagon. We prove Pál's theorem in full, because it is elementary and instructive; of the mixed areas we import only two standard properties, which we state explicitly.

Lemma 4.1: Pál's hexagon theorem (1920). Let K be a convex body of constant width w . Then there exists a regular hexagon of width w (that is, of inradius $w/2$) containing K .

Proof. Let h be the support function of K (Definition 4.2), which is continuous, and let $u(\theta) = (\cos \theta, \sin \theta)$.

Step 1 — the circumscribed equiangular hexagon. Fix θ and consider the six directions $u_k = u(\theta + k\pi/3)$, $k = 0, \dots, 5$, and the six supporting half-planes

$$\Pi_k = \{x \in \mathbb{R}^2 : \langle x, u_k \rangle \leq h_k\}, \quad h_k = h\left(\theta + \frac{k\pi}{3}\right).$$

Since each Π_k contains K , so does $H(\theta) = \bigcap_{k=0}^5 \Pi_k$; it is a hexagon with all angles equal to 120° (the side normals are equally spaced), whose opposite sides are at distance

$$h_k + h_{k+3} = h\left(\theta + \frac{k\pi}{3}\right) + h\left(\theta + \frac{k\pi}{3} + \pi\right) = w$$

by constant width. It remains to choose θ so that $H(\theta)$ is *regular*.

Step 2 — when the hexagon is regular. The hexagon $H(\theta)$ is regular if and only if some translation brings all six side distances from the origin to the common value $w/2$: that is, if and only if there exists $t \in \mathbb{R}^2$ with

$$h_k - \langle t, u_k \rangle = \frac{w}{2} \quad \text{for every } k = 0, \dots, 5.$$

The equations with $k = 3, 4, 5$ follow from those with $k = 0, 1, 2$: indeed $u_{k+3} = -u_k$ and $h_{k+3} = w - h_k$, hence

$$h_{k+3} - \langle t, u_{k+3} \rangle = w - h_k + \langle t, u_k \rangle = w - (h_k - \langle t, u_k \rangle) = w - \frac{w}{2} = \frac{w}{2}.$$

Three equations in two unknowns remain. The three vectors u_0, u_1, u_2 satisfy the single linear relation

$$u_0 - u_1 + u_2 = 0,$$

as one checks at once by setting $\theta = 0$: $u_0 = (1, 0)$, $u_1 = (\frac{1}{2}, \frac{\sqrt{3}}{2})$, $u_2 = (-\frac{1}{2}, \frac{\sqrt{3}}{2})$, and $u_0 + u_2 = u_1$ (for general θ one merely rotates). Since u_0 and u_1 are independent, the system of the first two equations has exactly one solution t ; it satisfies the third as well if and only if the right-hand sides obey the same linear relation, that is if and only if

$$\left(h_0 - \frac{w}{2}\right) - \left(h_1 - \frac{w}{2}\right) + \left(h_2 - \frac{w}{2}\right) = 0, \quad \text{i.e.} \quad h_0 - h_1 + h_2 = \frac{w}{2}.$$

Step 3 — existence of θ . Put

$$F(\theta) = h(\theta) - h\left(\theta + \frac{\pi}{3}\right) + h\left(\theta + \frac{2\pi}{3}\right) - \frac{w}{2},$$

a continuous function on $\mathbb{R}$. Compute F one sixth of a turn later, using $h(\theta + \pi) = w - h(\theta)$:

$$F\left(\theta + \frac{\pi}{3}\right) = h\left(\theta + \frac{\pi}{3}\right) - h\left(\theta + \frac{2\pi}{3}\right) + h(\theta + \pi) - \frac{w}{2} = h_1 - h_2 + w - h_0 - \frac{w}{2} = -F(\theta).$$

So F changes sign (weakly) between θ and $\theta + \pi/3$: if $F(0) > 0$ then $F(\pi/3) < 0$, and by the intermediate value theorem there is $\theta^* \in (0, \pi/3)$ with $F(\theta^*) = 0$; if $F(0) < 0$ one argues the same way; if $F(0) = 0$ take $\theta^* = 0$.

Step 4 — conclusion. For $\theta = \theta^*$ the condition of Step 2 holds, hence there is t such that the hexagon $H(\theta^*)$ translated by $-t$ has all six sides at distance $w/2$ from the origin: it is a regular hexagon of inradius $w/2$, that is of width w , and it contains K . $\square$

*Remark 4.2: What we import from the theory of convex bodies. The final step needs two standard facts about Minkowski's **mixed area**, which we do not prove and cite explicitly (Schneider, *Convex Bodies: The Brunn–Minkowski Theory*, §5.1):*

(M1) (Minkowski) *for two convex bodies K, L in the plane and $\lambda \geq 0$ the area of the Minkowski sum is a quadratic polynomial*

$$A(K + \lambda L) = A(K) + 2\lambda A(K, L) + \lambda^2 A(L),$$

which defines the mixed area $A(K, L)$; it is symmetric, invariant under translations

of either argument, and satisfies $A(K, K) = A(K)$;
(M2) (monotonicity) if $K_1 \subseteq K_2$ then $A(K_1, L) \leq A(K_2, L)$, for every L .
Both are elementary results within the theory, but proving them requires the machinery of convex bodies which we have not built here. Everything else in the proof that follows is complete.

Lemma 4.2: *The sum $K + (-K)$ is a disc. Let K be a convex body of constant width w . Then*

$$K + (-K) = D(0, w),$$

the disc of centre the origin and radius w .

Proof. The support function of a Minkowski sum is the sum of the support functions, $h_{K+L} = h_K + h_L$: indeed

$$h_{K+L}(u) = \max_{x \in K, y \in L} \langle x + y, u \rangle = \max_{x \in K} \langle x, u \rangle + \max_{y \in L} \langle y, u \rangle.$$

Moreover $h_{-K}(u) = \max_{x \in K} \langle -x, u \rangle = h_K(-u)$. Hence, for every direction u ,

$$h_{K+(-K)}(u) = h_K(u) + h_K(-u) = w$$

by constant width. But the constant w is exactly the support function of the disc $D(0, w)$. Since a convex body is determined by its support function (Theorem 4.2), the two bodies coincide. $\square$

Proof. Proof of part (ii) of Theorem 4.4.

Step 1 — the starting identity. Applying (M1) with $L = -K$ and $\lambda = 1$, and using $A(-K) = A(K)$ (central symmetry preserves area),

$$A(K + (-K)) = A(K) + 2A(K, -K) + A(-K) = 2A(K) + 2A(K, -K).$$

By Lemma 4.2 the left-hand side equals πw^2 , hence

$$\pi w^2 = 2A(K) + 2A(K, -K).$$

Step 2 — bounding the mixed area. By Lemma 4.1 there is a regular hexagon H of width w with $K \subseteq H$. Passing to opposites, $-K \subseteq -H$. A regular hexagon is centrally symmetric, so $-H$ is a translate of H ; by translation invariance and monotonicity (M2), applied twice,

$$A(K, -K) \leq A(H, -K) \leq A(H, -H) = A(H, H) = A(H).$$

Step 3 — the area of the hexagon. A regular hexagon of inradius ρ has perimeter $6 \cdot 2\rho/\sqrt{3}$ and area $\frac{1}{2}p\rho = 2\sqrt{3}\rho^2$. With $\rho = w/2$,

$$A(H) = 2\sqrt{3} \cdot \frac{w^2}{4} = \frac{\sqrt{3}}{2} w^2.$$

Step 4 — conclusion. Substituting into Step 1,

$$\pi w^2 = 2A(K) + 2A(K, -K) \leq 2A(K) + \sqrt{3} w^2,$$

whence

$$A(K) \geq \frac{\pi - \sqrt{3}}{2} w^2.$$

Step 5 — the minimum is attained. The Reuleaux triangle has constant width w (Example 4.1) and area exactly $\frac{\pi - \sqrt{3}}{2} w^2 = 0.704771 w^2$: the inequality is therefore an equality for it, and the minimum is attained. Numerically the ratio to the maximum is

$$\frac{(\pi - \sqrt{3})/2}{\pi/4} = \frac{0.704771}{0.785398} = 0.897342,$$

that is 89.73%, in agreement with the figure recorded earlier. $\square$

Remark 4.3: What is left out: uniqueness. The proof above establishes the inequality and the fact that the Reuleaux triangle attains it. It does not establish that this is the only minimiser up to isometry: that requires a further analysis of the equality case, which means tracing back the conditions under which (M2) is an equality. Uniqueness is true and is proved in the sources cited; here we record it as a statement, keeping it clearly distinct from what we have proved.

It is worth noticing how little was needed: constant width enters exactly twice, in Lemma 4.1 and in Lemma 4.2, and in both cases only through the identity $h(\theta) + h(\theta + \pi) = w$. All the rest is algebra of mixed areas.

Figure 4.2: The Reuleaux triangle: the simplest curve of constant width after the circle. It is made of three circular arcs of radius w , each centred at the opposite vertex. In every direction the distance between the two supporting lines is always w , because one passes through a vertex and the other is tangent to the arc centred at that vertex: the shape therefore rotates inside a square of side w while always touching all four sides. By Barbier's theorem the perimeter is πw , exactly as for the circle of diameter w ; but the area is $\frac{1}{2}(\pi - \sqrt{3})w^2 \simeq 0.7048 w^2$, smaller than the circle's, and by the Blaschke–Lebesgue theorem it is the smallest possible.

4.4. The isoperimetric inequality

Theorem 4.5: Isoperimetric inequality. Let γ be a closed, simple plane curve of class C^1 , of length L , enclosing an area A . Then

$$4\pi A \leq L^2,$$

with equality if and only if γ is a circle.

Proof. [for convex curves, via the support function (Hurwitz)] **Step 1 — series expansion.** Let h be the support function, expanded in a Fourier series as in the second proof of Theorem 4.3:

$$h(\theta) = a_0 + \sum_{n \geq 1} (a_n \cos n\theta + b_n \sin n\theta).$$

Step 2 — perimeter. By Theorem 4.2(iii) and orthogonality of the trigonometric functions (Theorem (Volume II, Chapter 4) of Chapter 4),

$$L = \int_0^{2\pi} h \, d\theta = 2\pi a_0.$$

Step 3 — area. By Parseval's identity (Theorem (Volume II, Chapter 4) of Chapter 4) in real form,

$$\int_0^{2\pi} h^2 \, d\theta = 2\pi a_0^2 + \pi \sum_{n \geq 1} (a_n^2 + b_n^2),$$

and since $h'(\theta) = \sum_{n \geq 1} n(-a_n \sin n\theta + b_n \cos n\theta)$,

$$\int_0^{2\pi} h'^2 \, d\theta = \pi \sum_{n \geq 1} n^2 (a_n^2 + b_n^2).$$

Hence, by Theorem 4.2(iv),

$$A = \frac{1}{2} \left[2\pi a_0^2 + \pi \sum_{n \geq 1} (1 - n^2)(a_n^2 + b_n^2) \right] = \pi a_0^2 - \frac{\pi}{2} \sum_{n \geq 2} (n^2 - 1)(a_n^2 + b_n^2),$$

the $n = 1$ term having disappeared because $1 - n^2 = 0$.

Step 4 — the inequality. From $L = 2\pi a_0$ we get $L^2/(4\pi) = \pi a_0^2$, hence

$$\frac{L^2}{4\pi} - A = \frac{\pi}{2} \sum_{n \geq 2} (n^2 - 1)(a_n^2 + b_n^2) \geq 0,$$

since $n^2 - 1 > 0$ for $n \geq 2$. This is the claim.

Step 5 — equality case. Equality holds iff $a_n = b_n = 0$ for every $n \geq 2$, i.e.

$$h(\theta) = a_0 + a_1 \cos \theta + b_1 \sin \theta,$$

which by Step 6 of the proof of Theorem 4.2 is the support function of the circle of radius a_0 centred at (a_1, b_1) . So equality characterises the circle.

Step 6 — the non-convex case. If γ is not convex, consider its *convex hull*: it has greater or equal area and smaller or equal perimeter (replacing a concave arc by its chord shortens the boundary and adds area). Hence $4\pi A \leq 4\pi A_{\text{conv}} \leq L_{\text{conv}}^2 \leq L^2$, and the inequality extends. The equalities require γ to equal its convex hull, i.e. to be convex, and then the circle by Step 5.

Step 7 — the isoperimetric deficit. The quantity $\frac{L^2}{4\pi} - A$ measures “how far the curve is from being a circle”, and Step 4 expresses it as a sum of squares of the higher harmonics of the support function. It is the same pattern as Wirtinger's inequality, and the same pattern by which, in Chapter 4, Parseval's identity quantified the approximation error: the energy of the neglected harmonics.

Step 8 — check on the ellipse. For the ellipse with semi-axes $a = 3$, $b = 2$, $A = \pi ab = 18.8496$ and the perimeter (an elliptic integral, numerically $L = 15.8654$) give

$$\frac{L^2}{4\pi} = \frac{251.711}{12.5664} = 20.0305 > 18.8496 = A. \quad \checkmark$$

The isoperimetric ratio $4\pi A/L^2 = 0.94104 < 1$: the ellipse encloses 94.1% of the area a circle of the same perimeter would enclose. $\square$

Hurwitz: Fourier series of the curve itself. Up to scaling, let $L = 2\pi$ and parametrize by arc length $s \in [0, 2\pi]$, with $x'^2 + y'^2 = 1$; translating, assume $\int_0^{2\pi} x \, ds = 0$. Expand in Fourier series $x = \sum_n (a_n \cos ns + b_n \sin ns)$ and $y = \sum_n (c_n \cos ns + d_n \sin ns)$. By Parseval's identity,

$$\int_0^{2\pi} (x'^2 + y'^2) \, ds = \pi \sum_{n \geq 1} n^2 (a_n^2 + b_n^2 + c_n^2 + d_n^2) = 2\pi,$$

while the area (Green's formula) is $A = \int_0^{2\pi} xy' \, ds = \pi \sum_{n \geq 1} n(a_n d_n - b_n c_n)$. Hence

$$\frac{L^2}{4\pi} - A = \pi - A = \frac{\pi}{2} \sum_{n \geq 1} [n^2 (a_n^2 + b_n^2 + c_n^2 + d_n^2) - 2n(a_n d_n - b_n c_n)].$$

Each term is bounded below using $n \geq 1$: $n^2(a_n^2 + d_n^2) - 2na_n d_n \geq n(a_n^2 + d_n^2) - 2na_n d_n = n(a_n - d_n)^2 \geq 0$ (and similarly for b_n, c_n), so the sum is ≥ 0 : $L^2 \geq 4\pi A$. Equality. Requires every term to be zero: possible only if $a_n = b_n = c_n = d_n = 0$ for $n \geq 2$ and, for $n = 1$, $a_1 = d_1$, $b_1 = -c_1$. Then $x = a_1 \cos s + b_1 \sin s$, $y = -b_1 \cos s + a_1 \sin s$, which satisfies $x^2 + y^2 = a_1^2 + b_1^2$: a circle. $\square$

Remark 4.4: History and scope. The isoperimetric problem is very old — the legend of Dido, who obtained as much land as she could enclose with an ox hide, is its narrative statement — and the answer “the circle” was already held to be obvious by Zenodorus (2nd century BC). The first correct modern proof is due to Karl Weierstrass, by the calculus of variations; Jakob Steiner's proof (1838), by symmetrisation, showed that if a maximum exists then it is the circle, but not its existence — a gap filled precisely by Weierstrass. The proof given here is due to Adolf Hurwitz (1901) and is the shortest: it replaces all the geometry by Parseval's identity.

Remark 4.5: The circle as maximum enclosure. Equivalently: among all curves of given length, the circle encloses the maximum area. It is the reason why soap bubbles and pressurized pipe sections tend to the circle, and a guiding principle in shape optimization (minimize perimeter for given area).

Exercise 4.2. How much “less efficient” is the square than the circle at enclosing area?

Solution. For the circle $L^2/(4\pi A) = 1$. For a square of side ℓ : $L = 4\ell$, $A = \ell^2$, hence $L^2/(4\pi A) = 16\ell^2/(4\pi\ell^2) = 4/\pi \approx 1.273$. The isoperimetric ratio exceeds 1 by 27%: for the same perimeter the square encloses $\pi/4 \approx 78.5\%$ of the circle's area.

4.5. The four-vertex theorem

Definition 4.4: Vertex of a curve. A **vertex** of a plane C^3 curve is a point where the curvature is stationary, i.e. $k'(s) = 0$.

Theorem 4.6: Four-vertex theorem. Every closed, simple plane curve of class C^3 that is convex has at least four vertices.

Proof. Step 1 — at least two vertices always exist. The function k is continuous on the compact $[0, L]$ and periodic, hence attains a maximum and a minimum; at those points $k' = 0$. If maximum and minimum coincide, k is constant and by Theorem 2.5 the curve is a circle, which has $k' \equiv 0$: every point is a vertex and the claim is trivially true. So assume k is not constant and let A and B be the points of maximum and minimum.

Step 2 — hypothesis for contradiction. Suppose A and B are the *only* vertices. Then k' vanishes only at A and B , hence has constant sign on each of the two arcs into which A and B divide the curve: positive on the arc along which k increases from B to A , negative on the other.

Step 3 — choice of coordinates. Let r be the line through A and B . Since the curve is convex, a line meets it in at most two points (or in a segment, excluded here by the strict convexity implied by $k > 0$; for general convex curves one argues on the hull). So r meets the curve only at A and B , and the two arcs lie in the two opposite half-planes determined by r . Choose coordinates with r the x -axis: then $y(s)$ has constant sign on each arc, opposite on the two, and vanishes only at A and B .

Step 4 — the product has constant sign. By construction $k'(s)$ and $y(s)$ have constant sign on each arc. Reversing the y -axis if necessary, we may assume they have the *same* sign on both arcs, so

$$k'(s)y(s) \geq 0 \quad \text{for every } s,$$

with equality only at A and B . Hence

$$\int_0^L k'(s)y(s) ds > 0.$$

Step 5 — but the integral vanishes. Integrate by parts; the boundary term vanishes because the curve is closed and k, y are periodic:

$$\int_0^L k'(s)y(s) ds = - \int_0^L k(s)y'(s) ds.$$

Now $y' = T_2$, the second component of the unit tangent; and by the Frenet formulas (Theorem 2.1), with $T = (T_1, T_2)$ and $N = (-T_2, T_1)$,

$$T' = kN \implies T'_1 = -kT_2 \implies ky' = kT_2 = -T'_1.$$

Hence

$$- \int_0^L ky' ds = \int_0^L T'_1(s) ds = [T_1(s)]_0^L = 0,$$

because $T(L) = T(0)$.

Step 6 — contradiction and conclusion. Steps 4 and 5 are incompatible: the integral is simultaneously positive and zero. So the hypothesis of Step 2 is false and there are more than two vertices. But the vertices of a non-constant periodic function come in even number, because between two consecutive maxima there is a minimum: hence there are at least four.

Step 7 — the general case. Convexity was used only in Step 3, to guarantee that the line AB separates the two arcs. The theorem in fact holds for *every* simple closed curve, convex or not: it was stated for convex curves by Syamadas Mukhopadhyaya (1909) and proved in general by Adolf Kneser (1912); an elementary proof of the general case is due to Robert Osserman (1985). Section 4.5.1 proves the general case in full, importing only the Jordan curve theorem.

Step 8 — check on the ellipse. For a non-circular ellipse, from Example 2.2,

$$k(t) = \frac{ab}{(a^2 \sin^2 t + b^2 \cos^2 t)^{3/2}},$$

and the derivative vanishes where that of the denominator does, i.e. where $(a^2 - b^2) \sin t \cos t = 0$: at $t = 0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}$. Exactly four vertices, the ends of the axes — and, by Theorem 2.6(ii), the four cusps of the astroid evolute of Example 2.4. ✓

Step 9 — why it is a theorem about the circle. The equality case — infinitely many vertices — occurs only for the circle, as Step 1 shows. The theorem therefore says that *every* closed curve is “at least four times like a circle”: at four points at least its curvature is stationary, i.e. the curve is locally indistinguishable from a circle to third order. □

4.5.1 The general case: non-convex curves

Step 7 of the previous proof declared the convexity hypothesis superfluous, referring to the literature. We close that reference here with a complete proof, along Osserman’s minimal enclosing circle route (1985): the only imported statement is the Jordan curve theorem, which does not concern the circle. First two local tools on the osculating circle, useful elsewhere as well; then the proof.

Lemma 4.3: The osculating circle crosses the curve where $k' \neq 0$. Let γ be a plane curve of class C^3 parametrised by arc length, with $k(s_0) > 0$, and let σ be its osculating circle at $p = \gamma(s_0)$ (Definition 2.4). If $k'(s_0) \neq 0$, then γ crosses σ at p : every neighbourhood of s_0 contains points of the curve inside the osculating disc and points outside it.

Proof. Set $s_0 = 0$, $\rho = 1/k(0)$, and let $C = \gamma(0) + \rho N(0)$ be the centre of the osculating circle. Consider the C^3 function

$$f(s) = |\gamma(s) - C|^2 - \rho^2,$$

which is negative where the curve is inside the osculating disc, positive where it is outside, zero where it meets it. We compute the first three derivatives using the Frenet formulas (Theorem 2.1), $T' = kN$ and $N' = -kT$.

Order 0. $f(0) = |\gamma(0) - C|^2 - \rho^2 = |-\rho N(0)|^2 - \rho^2 = 0$.

Order 1. $f'(s) = 2\langle T, \gamma - C \rangle$, and at 0

$$f'(0) = 2\langle T(0), -\rho N(0) \rangle = 0,$$

because $T \perp N$: the osculating circle is tangent to the curve.

Order 2. $f''(s) = 2\langle T', \gamma - C \rangle + 2\langle T, T \rangle = 2k\langle N, \gamma - C \rangle + 2$, and at 0

$$f''(0) = 2k(0)\langle N(0), -\rho N(0) \rangle + 2 = -2k(0)\rho + 2 = -2 + 2 = 0,$$

because $\rho = 1/k(0)$: this is the second-order contact condition that *defines* the osculating circle (Theorem 2.4).

Order 3. Differentiating once more,

$$f'''(s) = 2k'\langle N, \gamma - C \rangle + 2k\langle N', \gamma - C \rangle + 2k\langle N, T \rangle = 2k'\langle N, \gamma - C \rangle - 2k^2\langle T, \gamma - C \rangle,$$

and at 0 the second term vanishes (as at first order), while the first gives

$$f'''(0) = 2k'(0)\langle N(0), -\rho N(0) \rangle = -2\rho k'(0) = -\frac{2k'(0)}{k(0)}.$$

Conclusion. By Taylor’s formula with Peano remainder,

$$f(s) = -\frac{k'(0)}{3k(0)} s^3 + o(s^3) \quad (s \rightarrow 0).$$

If $k'(0) \neq 0$ the coefficient of s^3 is nonzero, hence f has the same sign as $-k'(0)s^3/(3k(0))$ in a punctured neighbourhood of 0: opposite signs on the left and on the right. The curve therefore passes from one side of the osculating circle to the other. □

Corollary 4.2: *Where the osculating circle supports, there is a vertex.* Let $p = \gamma(s_0)$ be a point at which the osculating circle σ supports the curve, that is, at which there is a neighbourhood of s_0 whose points all lie on the same (weak) side of σ : all in the closed osculating disc, or all in its closed complement. Then p is a vertex.

Proof. If $k'(s_0) \neq 0$, then by Lemma 4.3 every neighbourhood of s_0 would contain points on both sides of σ , against the support hypothesis. Hence $k'(s_0) = 0$, that is p is a vertex by Definition 4.4. (If $k(s_0) = 0$ the osculating circle degenerates into a line, and the same computation applies to the signed distance from the tangent line, whose expansion starts with the term $\frac{1}{6}k'(s_0)s^3$ as soon as $k(s_0) = 0$.) $\square$

Definition 4.5: Vertex as a local extremum. For a regular curve of class C^2 , parametrised by arc length with signed curvature k , a parameter s_0 (or the point $\gamma(s_0)$) is a **vertex** if k has a local maximum or a local minimum at s_0 , that is, if there is $\eta > 0$ such that $k(s_0) \geq k(s)$ for every $|s - s_0| < \eta$, or $k(s_0) \leq k(s)$ for every $|s - s_0| < \eta$. If the curve is of class C^3 , then k is C^1 and $k'(s_0) = 0$ at every vertex (Fermat's theorem): one recovers Definition 4.4. For C^3 curves the two notions are used interchangeably in what follows.

What we import. A single statement, which does not concern the circle and is a prerequisite from the topology of the plane.

INFO

(J) Jordan curve theorem. *If $J \subset \mathbb{R}^2$ is a Jordan curve (a homeomorphic image of a circle), then $\mathbb{R}^2 \setminus J$ has exactly two connected components, one bounded, $\text{int } J$, and one unbounded, $\text{ext } J$, and J is the boundary of each of the two: every point of J is a limit of points of both.* Sources: J. R. Munkres, *Topology*, 2nd ed., Prentice Hall, 2000, §63; C. Thomassen, *The Jordan–Schönflies theorem and the classification of surfaces*, American Mathematical Monthly 99 (1992), no. 2, pp. 116–130. For the curve $\alpha = \gamma(\mathbb{R})$ we set $F = \alpha \cup \text{int } \alpha$, the closed region enclosed. Everything else in this subsection is proved.

Local structure and orientation.

Lemma 4.4: *Two sides of a Jordan curve at a smooth point.* Let J be a Jordan curve with a parametrisation $\varphi : \mathbb{R}/\ell\mathbb{Z} \rightarrow J$ (a homeomorphism), let $p = \varphi(u_0)$, and suppose φ is of class C^1 with $\varphi' \neq 0$ on an open interval containing u_0 . Fix $\eta > 0$ such that $\delta(u) = \varphi(u_0 + u)$ is C^1 and regular on $[-\eta, \eta]$; the rest of J , that is $J \setminus \delta((-\eta, \eta))$, is compact and does not contain p , hence it has positive distance from p , and the same holds for $\delta([- \eta, \eta] \setminus (-u_1, u_1))$ for every $0 < u_1 < \eta$. Let n be a unit vector normal to $\delta'(0)$. Then there is an open rectangle $\mathcal{R}$ centred at p such that:

- (i) $\mathcal{R} \setminus J$ has exactly two connected components, $\mathcal{R}^+$ and $\mathcal{R}^-$; $\mathcal{R}^+$ contains the points $p + tn$ and $\mathcal{R}^-$ the points $p - tn$, for small $t > 0$;
- (ii) one of the two components is contained in $\text{int } J$ and the other in $\text{ext } J$;
- (iii) (continuity of the side) if J is a regular C^1 arc also near the points $\delta(u)$, $|u|$ small, and $n(u)$ is the normal that varies continuously with $n(0) = n$, then the component of $\mathbb{R}^2 \setminus J$ that contains $\delta(u) + tn(u)$ (small $t > 0$) is the same for all u near 0.

Proof. (i) Coordinates with $p = 0$, $\delta'(0)$ parallel to e_1 and $n = e_2$. Since $x'(0) \neq 0$, by the inverse function theorem the first coordinate $x = x(u)$ is a C^1 diffeomorphism of a neighbourhood of 0 onto an interval $(-a, a)$, and the arc is the graph $y = \varphi_0(x)$ of some $\varphi_0 \in C^1(-a, a)$ with $\varphi_0(0) = 0$, $\varphi_0'(0) = 0$. Taking $0 < a' < a$ and $b > c_0 := \max_{|x| \leq a'} |\varphi_0(x)|$, let $\mathcal{R} =$

$(-a', a') \times (-b, b)$; shrinking a' and b we may assume that $\mathcal{R}$ contains no other point of J (the rest of J and the points $\delta(u)$ with $|u|$ not small are at positive distance from p). Then $\mathcal{R} \setminus J = \mathcal{R}^+ \cup \mathcal{R}^-$ with $\mathcal{R}^\pm = \{(x, y) \in \mathcal{R} : \pm(y - \varphi_0(x)) > 0\}$. Each of them is connected: the strip $\{c_0 < y < b\} \cap \mathcal{R}$ is a rectangle contained in $\mathcal{R}^+$, and every point of $\mathcal{R}^+$ is joined to it by a vertical segment that stays above the graph; similarly for $\mathcal{R}^-$. The two sets are open and disjoint, hence they are the components; $(0, t) \in \mathcal{R}^+$ for $0 < t < b$.

(ii) $\mathcal{R}^+$ is connected and does not meet J , hence it lies in $\text{int } J$ or in $\text{ext } J$; the same for $\mathcal{R}^-$. By (J), p is a limit both of points of $\text{int } J$ and of points of $\text{ext } J$, and those close enough to p lie in $\mathcal{R}^+ \cup \mathcal{R}^-$: if both components lay in $\text{int } J$, no point of $\text{ext } J$ would be near p , absurd; symmetrically for $\text{ext } J$.

(iii) In the coordinates of (i), for small $|u|$ we have $\delta(u) = (x(u), \varphi_0(x(u)))$ and $n(u) \rightarrow (0, 1)$. Since $|\varphi'_0| \leq \frac{1}{2}$ near 0, for small u we have $n_2(u) > \frac{1}{2}|n_1(u)|$ and, for small $t > 0$, the point $\delta(u) + tn(u)$ has ordinate $\varphi_0(x(u)) + tn_2(u) > \varphi_0(x(u)) + \frac{1}{2}t|n_1(u)| \geq \varphi_0(x(u) + tn_1(u))$: it lies above the graph, that is in $\mathcal{R}^+$. The local component “on the side of $n(u)$ ” at $\delta(u)$ and $\mathcal{R}^+$ therefore have a point in common, and lie in the same component of $\mathbb{R}^2 \setminus J$. $\square$

Corollary 4.3: Positive orientation. *For the curve $\alpha = \gamma(\mathbb{R})$ exactly one of the two alternatives holds: $N(s)$ points towards $\text{int } \alpha$ for every s , or $-N(s)$ points towards $\text{int } \alpha$ for every s . Replacing $\gamma(s)$ by $\gamma(-s)$ if necessary, one obtains that N is the **inward normal** at every point: $\mathcal{R}^+ \subset \text{int } \alpha$ on the side of N and $\mathcal{R}^- \subset \text{ext } \alpha$ on the side of $-N$. This is the positive orientation, for which a circle traversed counterclockwise has $k \equiv 1/r > 0$.*

Proof. Let A be the set of parameters $s \in \mathbb{R}/L\mathbb{Z}$ such that $\gamma(s) + tN(s) \in \text{int } \alpha$ for small $t > 0$. By Lemma 4.4(ii) every parameter lies in A or in the analogous set A' with $\text{ext } \alpha$; by Lemma 4.4(iii) both sets are open. A and A' are complementary and open in the connected space $\mathbb{R}/L\mathbb{Z}$: one of the two is empty. $\square$

Lemma 4.5: Cusp. *Let J be a Jordan curve with parametrisation $\varphi : \mathbb{R}/\ell\mathbb{Z} \rightarrow J$, $p = \varphi(u_0)$, and suppose φ is of class C^1 and regular, with one-sided derivatives at u_0 , on $[u_0, u_0 + \eta]$ and on $[u_0 - \eta, u_0]$. Put $\delta_1(x) = \varphi(u_0 + x)$ and $\delta_2(x) = \varphi(u_0 - x)$ for $x \in [0, \eta]$: two regular injective C^1 arcs issuing from p . Suppose they have the same initial direction $\delta'_1(0) \parallel \delta'_2(0) \parallel e_1$ (same sense) and that in the local graphs $y = \varphi_1(x)$, $y = \varphi_2(x)$ ($0 \leq x < a$) one has $\varphi_1(x) > \varphi_2(x)$ for $0 < x < a$. Then there is a rectangle $\mathcal{R}$ centred at p such that $\mathcal{R} \setminus J$ has exactly two components: the **cusp** $\{(x, y) \in \mathcal{R} : 0 < x, \varphi_2(x) < y < \varphi_1(x)\}$ and the **rest**, which contains $\{x < 0\} \cap \mathcal{R}$, $\{y > \varphi_1(x), x \geq 0\}$ and $\{y < \varphi_2(x), x \geq 0\}$.*

Proof. The rest of J , that is $J \setminus \varphi((u_0 - \eta, u_0 + \eta))$, is compact and does not contain p : it has positive distance from p , even when it passes close to p . As in Lemma 4.4 one constructs $\mathcal{R} = (-a', a') \times (-b, b)$, smaller than that distance, with $\mathcal{R} \cap J$ equal to the two graphs over $[0, a']$. The cusp is connected (vertical segments up to the curve $y = \frac{1}{2}(\varphi_1 + \varphi_2)$, which is connected). The rest is connected: the part $\{x < 0\}$ is a rectangle; every point with $x \geq 0$ above φ_1 is joined vertically to a high horizontal strip and from there to the part $x < 0$; similarly below φ_2 . The two parts are open and disjoint. $\square$

The enclosing circle and the contact points. From now on α is positively oriented, Γ is the circle of Lemma 4.6, with centre O and radius R , D is the open disc and $\bar{D}$ the closed one, $K = \alpha \cap \Gamma$ is the *contact set*. Arcs of Γ are traversed counterclockwise; for $p \in \Gamma$, τ_p is the counterclockwise unit tangent to Γ at p , and $i\tau_p = (O - p)/R$. A *gap* is a connected component of $\Gamma \setminus K$: a maximal open arc of Γ free of contact points, with endpoints in K .

Lemma 4.6: Minimal enclosing circle. *There is a closed disc $\bar{D}(O, R)$ of minimal radius among those containing α , with $R > 0$; and it is unique.*

Proof. The function $f(c) = \max_{x \in \alpha} |x - c|$ is well defined (α is compact), continuous (it is 1-Lipschitz) and $f(c) \geq |c| - \max_{x \in \alpha} |x| \rightarrow +\infty$ as $|c| \rightarrow \infty$: it has a global minimum at a point O ; put $R = f(O)$. By definition $\alpha \subset \bar{D}(O, R)$, and no closed disc of smaller radius contains α . $R > 0$ because α has more than one point. Uniqueness: if $O_1 \neq O_2$ were both minimal, with $O_m = \frac{1}{2}(O_1 + O_2)$ and $\delta = \frac{1}{2}|O_1 - O_2| > 0$, the parallelogram identity would give $|x - O_m|^2 = \frac{1}{2}(|x - O_1|^2 + |x - O_2|^2) - \delta^2 \leq R^2 - \delta^2$ for every $x \in \alpha$, and $f(O_m) < R$: absurd. $\square$

Lemma 4.7: The contact set does not lie in an open semicircle. *$K \neq \emptyset$ and K is not contained in any open semicircle of Γ . Consequently: (a) K has at least two points, and if it has exactly two they are antipodal; (b) every gap has angular width $\leq \pi$; (c) if $K \neq \Gamma$ then gaps exist, and if K contains no arc of Γ then every gap has distinct endpoints and there are at least two distinct gaps.*

Proof. If $K = \emptyset$, then $\max_{x \in \alpha} |x - O| < R$ and a smaller disc would contain α . Let u be a unit vector and suppose $K \subset \{p \in \Gamma : \langle p - O, u \rangle > 0\}$. Since K is compact there is $\delta > 0$ with $\langle p - O, u \rangle \geq \delta$ on K . The set $\alpha_{\text{far}} = \{x \in \alpha : \langle x - O, u \rangle \leq \delta/2\}$ is compact and does not meet Γ , hence, if it is non-empty, $\max_{\alpha_{\text{far}}} |x - O| = R - \eta$ with $\eta > 0$. Take $0 < \varepsilon < \min(\delta, \eta)$ and $O' = O + \varepsilon u$. For $x \in \alpha$ with $\langle x - O, u \rangle \geq \delta/2$: $|x - O'|^2 = |x - O|^2 - 2\varepsilon \langle x - O, u \rangle + \varepsilon^2 \leq R^2 - \varepsilon\delta + \varepsilon^2 < R^2$; for $x \in \alpha_{\text{far}}$: $|x - O'| \leq R - \eta + \varepsilon < R$. Hence $f(O') < R$: absurd. (a) A single point, or two non-antipodal points, lie in an open semicircle. (b) If a gap had width $> \pi$, its complement would be a closed arc of width $< \pi$ containing K , contained in an open semicircle. (c) $\Gamma \setminus K$ is open in Γ ; its components are open arcs with endpoints in K (the case “ Γ minus one point” is excluded by (a)). If K contains no arc, every gap (b, a) has $b \neq a$, and the complementary closed arc $[a, b]$ is not contained in K : it contains a point of $\Gamma \setminus K$ and with it a gap $G_2 \subset (a, b)$, distinct from $G_1 = (b, a)$. $\square$

Lemma 4.8: Comparison with a circle. *Let σ be the circle with centre c and radius $r > 0$, let $\gamma(s_0) \in \sigma$ and let $n = (c - \gamma(s_0))/r$ be the unit vector towards the centre. If in a neighbourhood of s_0 the curve lies in the closed disc $\bar{D}(c, r)$, then $\langle T(s_0), n \rangle = 0$ and $\langle \gamma''(s_0), n \rangle \geq 1/r$; if it lies in the closed complement of the open disc, then $\langle T(s_0), n \rangle = 0$ and $\langle \gamma''(s_0), n \rangle \leq 1/r$.*

Proof. $g(s) = |\gamma(s) - c|^2 - r^2$ is C^2 with $g(s_0) = 0$. In the first case $g \leq 0$ near s_0 : interior maximum, $g'(s_0) = 2\langle T, \gamma - c \rangle(s_0) = 0$ and $g''(s_0) = 2 + 2\langle \gamma''(s_0), -rn \rangle \leq 0$, that is $\langle \gamma''(s_0), n \rangle \geq 1/r$. In the second case $g \geq 0$, interior minimum, with the inequalities reversed. $\square$

Lemma 4.9: At the contact points. *Let $p = \gamma(s_p) \in K$. Then the curve is tangent to Γ at p , the inward normal points towards the centre, $N(s_p) = (O - p)/R$, hence $T(s_p) = \tau_p$, and $k(s_p) \geq 1/R$.*

Proof. Since $\alpha \subset \bar{D}$, Lemma 4.8 with $\sigma = \Gamma$ gives $T(s_p) \perp (O - p)$, that is $T(s_p) = \pm \tau_p$, and $\langle \gamma''(s_p), n \rangle \geq 1/R$ with $n = (O - p)/R$. It remains to show that $N(s_p) = n$. In the coordinates of Lemma 4.4 at p : $p = 0$, $T(s_p) = e_1$, $N(s_p) = e_2$, $O = \pm Re_2$. If $O = -Re_2$, the point $(0, t)$ with small $t > 0$, which lies in $\mathcal{R}^+ \subset \text{int } \alpha \subset \bar{D}$ (Corollary 4.3), would be at distance $R + t > R$ from O : absurd. Hence $O = Re_2$, $N(s_p) = n$, $k(s_p) = \langle \gamma''(s_p), N(s_p) \rangle \geq 1/R$, and from $i\tau_p = n = iT(s_p)$ it follows that $T(s_p) = \tau_p$. $\square$

The gaps. Let $G = (b, a)$ be a gap, the open counterclockwise arc from b to a , of width $\theta \leq \pi$, with $b \neq a$; let $s_b < s_a < s_b + L$ be the parameters of b and a . Let ℓ be the line ba , let ν be the unit normal to ℓ pointing towards G (the arc, of width $\leq \pi$, lies in a closed half-plane of ℓ) and $H_+ = \{x : \langle x - b, \nu \rangle > 0\}$.

Lemma 4.10: *From an endpoint of a gap the curve sets off counterclockwise and reaches the other endpoint without touching Γ . (a) $T(s_b) = \tau_b$ and $\langle \tau_b, \nu \rangle > 0$. (b) There is $\varepsilon > 0$ such that $\gamma(s) \in D \cap H_+$ for every $s \in (s_b, s_b + \varepsilon)$. (c) The first parameter $s > s_b$ with $\gamma(s) \in K$ is s_a : the arc $\alpha' = \gamma([s_b, s_a])$ satisfies $\alpha' \cap \Gamma = \{b, a\}$.*

Proof. (a) The first part is Lemma 4.9. The line ℓ is a secant through b , not the tangent: $\langle \tau_b, \nu \rangle \neq 0$. With $b = O + Re^{i\phi_b}$, the function $h(\phi) = \langle O + Re^{i(\phi_b + \phi)} - b, \nu \rangle$ vanishes at 0, is positive for $0 < \phi < \theta$, and $h'(0) = R\langle \tau_b, \nu \rangle$: were it negative, h would be negative just after 0. (b) Near s_b one has $\gamma(s) \neq O$; let $\psi(s)$ be the argument of $\gamma(s) - O$, a C^1 function with $\psi(s_b) = \phi_b$ and, by the formula $\frac{d}{ds} \arg z = \langle z', iz \rangle / |z|^2$ and the identity $i(b - O) = R\tau_b$, $\psi'(s_b) = \langle \tau_b, R\tau_b \rangle / R^2 = 1/R > 0$. Moreover $h_\gamma(s) = \langle \gamma(s) - b, \nu \rangle$ has $h_\gamma(s_b) = 0$ and $h'_\gamma(s_b) = \langle \tau_b, \nu \rangle > 0$. There is therefore $\varepsilon > 0$ such that for $s \in (s_b, s_b + \varepsilon)$: $\phi_b < \psi(s) < \phi_b + \theta$ and $\gamma(s) \in H_+$. If for such an s we had $\gamma(s) \in \Gamma$, then $\gamma(s) = O + Re^{i\psi(s)} \in G$; but $G \cap K = \emptyset$ and $\gamma(s) \in K$: absurd. Hence $\gamma(s) \in D$.

(c) The set $\Sigma = \{s \in [s_b + \varepsilon, s_b + L] : \gamma(s) \in K\}$ is closed and contains s_a : it has a minimum s' , which by (b) is the first parameter $> s_b$ with $\gamma(s') \in K$. Let $P' = \gamma(s')$ and suppose, for contradiction, that $P' \neq a$. Let $\beta_1 = \gamma([s_b, s'])$, $\beta_2 = \gamma([s', s_b + L])$ and let Γ_1 be the closed counterclockwise arc of Γ from b to P' . Since β_1 has no interior contacts, $\beta_1 \cap \Gamma_1 = \{b, P'\}$ and $J = \beta_1 \cup \Gamma_1$ is a Jordan curve, parametrised by running along β_1 from b to P' and then along Γ_1 from P' to b clockwise; at b the two arcs issuing from it are β_1 and Γ_1 traversed counterclockwise, both with initial direction τ_b . The arc Γ_1 contains G and, after G , the point a , interior to Γ_1 (because $P' \neq a$ and $P' \notin G$); and a is interior to β_2 .

Fact 1: the exterior of $\bar{D}$ lies in $\text{ext } J$, being connected, unbounded and disjoint from $J \subset \bar{D}$.

Fact 2: at every $x \in \beta_2^\circ \cap J$ the local side interior to D is $\text{int } J$. Such an x is a contact point on Γ_1 , distinct from b, P' , at positive distance from β_1 (the curve is simple): near x , J coincides with Γ . Lemma 4.4 at x gives two sides, one in $\text{int } J$ and one in $\text{ext } J$; the side exterior to D contains points outside $\bar{D}$, which lie in $\text{ext } J$ (Fact 1); hence the side interior to D is $\text{int } J$.

Fact 3: $\beta_2^\circ \setminus J$ lies entirely in $\text{int } J$ or entirely in $\text{ext } J$. Define $g(s)$, for $s \in (s', s_b + L)$, as the component of $\mathbb{R}^2 \setminus J$ containing $\gamma(s)$ if $\gamma(s) \notin J$, and $g(s) = \text{int}$ if $\gamma(s) \in J$. g is locally constant: at a parameter with $\gamma(s) \notin J$ the nearby points lie in the same open component; at a parameter s_x with $x = \gamma(s_x) \in J$ the nearby points $\gamma(s)$ lie in the rectangle of Lemma 4.4 at x and in $\bar{D}$: either on $\Gamma = J$ (and $g = \text{int}$ by definition) or on the side interior to D , which is $\text{int } J$ by Fact 2. A locally constant function on an interval is constant.

Fact 4: $g(s_a) = \text{int}$, because $a \in J$.

Fact 5: $g(s) = \text{ext}$ for $s < s_b + L$ near $s_b + L$. Near $b = \gamma(s_b + L)$ the curve J consists of the initial piece of β_1 and that of Γ_1 , both issuing from b with direction τ_b ; the rest of J is at positive distance from b . In the coordinates with $b = 0$, $\tau_b = e_1$, $O = Re_2$: Γ_1 is the graph of $\varphi_2(x) = R - \sqrt{R^2 - x^2}$ and β_1 the graph of some $\varphi_1 \geq \varphi_2$ (because $\beta_1 \subset \bar{D}$) with $\varphi_1 > \varphi_2$ for small $x > 0$ (because $\beta_1^\circ \cap \Gamma = \emptyset$). Lemma 4.5 applies: the rest contains points with $x > 0$, $y < \varphi_2(x)$, that is outside $\bar{D}$, hence $\text{rest} \subset \text{ext } J$ (Fact 1 and connectedness). The points $\gamma(s)$ with $s < s_b + L$ near $s_b + L$ have abscissa $x(s) = (s - s_b - L) + o(s - s_b - L) < 0$: they lie in the rest, that is in $\text{ext } J$.

Facts 3, 4, 5 are incompatible. Hence $P' = a$. □

Lemma 4.11: *Between two consecutive contacts the curvature drops below $1/R$. With the previous notation, let $\alpha' = \gamma([s_b, s_a])$, let $\bar{G}$ be the closed counterclockwise arc of Γ from b to a , let m be the midpoint of $\bar{ba}$ and $d = \frac{1}{2}|a - b| > 0$. There exists $s_1 \in (s_b, s_a)$ with $k(s_1) < 1/R$.*

Proof. *Step 1 — the pencil through b and a .* Every circle through b and a has centre $m + t\nu$ and radius $\sqrt{d^2 + t^2}$. For $x \in H_+$ put $t(x) = \frac{|x - m|^2 - d^2}{2\langle x - m, \nu \rangle}$: it is the parameter of the unique circle of the pencil through x , and for a circle of the pencil of parameter t_1

$$x \text{ is interior to it} \iff |x - m|^2 - 2t_1\langle x - m, \nu \rangle < d^2 \iff t(x) < t_1. \quad (*)$$

Γ belongs to the pencil: $O = m + t_0\nu$ with $t_0 \leq 0$, because $\bar{G}$ has width $\leq \pi$ and lies in $\bar{H}_+$, hence $O \notin H_+$. For the points $y \in G \subset H_+$ one has $t(y) = t_0$.

Step 2 — the point Q and the circle C' . By Lemma 4.10(b) the point $Q = \gamma(s_b + \varepsilon/2)$ lies in $D \cap H_+$ and is interior to α' . By (*) with $t_1 = t_0$: $t_Q := t(Q) < t_0 \leq 0$. Let C' be the circle of the pencil of parameter t_Q , centre $c' = m + t_Q\nu$, radius $R' = \sqrt{d^2 + t_Q^2}$: from $t_Q < t_0 \leq 0$ it follows that $t_Q^2 > t_0^2$ and $R' > R$. Let D' be its open disc.

Step 3 — translations towards $-\nu$. For $t \geq 0$ let $D'_t = D' - t\nu$ (centre $c' - t\nu$, radius R') and let C'_t be its boundary. (i) $D'_t \cap \bar{H}_+ \subset D'$: if $x + t\nu \in D'$ and $\langle x - m, \nu \rangle \geq 0$, then $\langle x - c', \nu \rangle = \langle x - m, \nu \rangle - t_Q > 0$ and $|x - c'|^2 = |(x + t\nu) - c'|^2 - 2t\langle x - c', \nu \rangle - t^2 \leq |(x + t\nu) - c'|^2 < R'^2$. (ii) $D'_t \cap \bar{G} = \emptyset$ for every $t \geq 0$: a $y \in G$ has $t(y) = t_0 > t_Q$, hence $y \notin D'$ by (*) and $y \notin D'_t$ by (i); and $|b - c'| = |a - c'| = R'$. (iii) $b, a \notin \bar{D}'_t$ for $t > 0$: $|b - c' + t\nu|^2 = R'^2 + 2t\langle b - c', \nu \rangle + t^2 = R'^2 - 2t t_Q + t^2 > R'^2$ (we used $\langle b - m, \nu \rangle = 0$); likewise for a .

Step 4 — the last contact. Let $\mathcal{T} = \{t \geq 0 : \bar{D}'_t \cap \alpha' \neq \emptyset\}$. We have $0 \in \mathcal{T}$ ($Q \in C'$); $\mathcal{T}$ is bounded ($\alpha' \subset \bar{D}(O, R)$ and $\bar{D}'_t$ moves away from it) and closed (by compactness of α' and continuity). Let $t^* = \max \mathcal{T}$: $\bar{D}'_{t^*} \cap \alpha' \neq \emptyset$ and $D'_{t^*} \cap \alpha' = \emptyset$ (if some $x \in \alpha'$ had $|x - c' + t^*\nu| < R'$, by continuity the same would hold for t slightly larger than t^*). Let $Q_1 = \gamma(s_1) \in \alpha' \cap C'_{t^*}$.

Step 5 — Q_1 is interior to α' . If $t^* > 0$, by (iii) $Q_1 \neq b, a$; if $t^* = 0$ take $Q_1 = Q$. In either case $s_1 \in (s_b, s_a)$ and $\gamma(s_1) \notin \Gamma$ (Lemma 4.10(c)).

Step 6 — the disc lies on the side of the inward normal. Let $J_1 = \alpha' \cup \bar{G}$, a Jordan curve ($\alpha' \cap \bar{G} = \{b, a\}$), parametrised by running along α' from b to a and then along $\bar{G}$ from a to b clockwise; let $\mathcal{L} = \text{int } J_1$. (α) $\mathcal{L} \subset \bar{D}$: the exterior of $\bar{D}$ is connected, unbounded and disjoint from J_1 , hence contained in $\text{ext } J_1$. (β) *The cusp at b lies in $\mathcal{L}$.* In the coordinates of Fact 5 (with α' and $\bar{G}$ in place of β_1 and Γ_1) Lemma 4.5 gives the cusp $\{0 < x, \varphi_2 < y < \varphi_1\}$, connected and disjoint from J_1 . Let $y_0 \in G$ be near b : near y_0 , J_1 coincides with Γ (the arc α' is at positive distance from y_0); Lemma 4.4 at y_0 gives two sides, and the one exterior to D contains points outside $\bar{D}$, that is of $\text{ext } J_1$ by (α): the side interior to D at y_0 is $\mathcal{L}$. The cusp contains points of that side, hence cusp $\subset \mathcal{L}$. (γ) *At every $s \in (s_b, s_a)$ the local side of α' on the side of $-N(s)$ is $\mathcal{L}$.* By Lemma 4.4 applied to J_1 at $\gamma(s)$ (where J_1 coincides with the C^2 arc α' , and $\bar{G}$ is far away because $\gamma(s) \notin \Gamma$) the two sides are $\mathcal{L}$ and $\text{ext } J_1$. For s slightly larger than s_b the point $\gamma(s) - tN(s)$ (small $t > 0$) lies in the cusp (in the coordinates of Fact 5, $\gamma(s) = (x(s), \varphi_1(x(s)))$ and $N(s) \rightarrow e_2$): the side of $-N(s)$ is $\mathcal{L}$ near s_b , and by the continuity of the side (Lemma 4.4(iii)) it is so on the whole of (s_b, s_a) . (δ) $D'_{t^*} \cap \mathcal{L} = \emptyset$. D'_{t^*} is connected and does not meet J_1 (Step 4 for α' , Step 3(ii) for $\bar{G}$): if it met $\mathcal{L}$ it would be contained in it; but it has radius $R' > R$ and does not lie in $\bar{D} \supset \mathcal{L}$. (ε) Let n_c be the unit vector from Q_1 towards the centre $c'' = c' - t^*\nu$ of C'_{t^*} . The points $Q_1 + tn_c$, $0 < t < R'$, lie in D'_{t^*} , hence neither in J_1 nor in $\mathcal{L}$; for small t they lie in the rectangle of Lemma 4.4 at Q_1 , and therefore in the side $\text{ext } J_1$, which by (γ) is the side of $+N(s_1)$. Since α' lies in the closed

complement of D'_{t*} and touches C'_{t*} at Q_1 , Lemma 4.8 gives $T(s_1) \perp n_c$, that is $n_c = \pm N(s_1)$; the position just found gives $n_c = N(s_1)$.

Step 7 — the inequality. Again by Lemma 4.8, $\langle \gamma''(s_1), n_c \rangle \leq 1/R'$, that is $k(s_1) = \langle \gamma''(s_1), N(s_1) \rangle \leq 1/R' < 1/R$. $\square$

Theorem 4.7: Four-vertex theorem, general case. *Every closed, simple, regular plane curve of class C^2 — convex or not — has at least four vertices, that is at least four distinct points at which the signed curvature has a local extremum. If the curve is of class C^3 , the curvature has at least four distinct stationary points.*

Proof. Case I: K contains an arc of Γ . On such an arc the curve coincides with Γ , traversed counterclockwise (Lemma 4.9): $k \equiv 1/R$ on an open interval of parameters, and every point of it is a vertex (a local maximum and a local minimum at once). There are infinitely many vertices.

Case II: K contains no arc. By Lemma 4.7(c) there are two distinct gaps $G_1 = (b_1, a_2)$ and $G_2 = (b_2, a_3)$, with distinct endpoints and width $\leq \pi$. By Lemma 4.10(c) the arcs $\alpha'_1 = \gamma([s_{b_1}, s_{a_2}])$ and $\alpha'_2 = \gamma([s_{b_2}, s_{a_3}])$ (with $s_{b_i} < s_{a_{i+1}} < s_{b_i} + L$) contain no interior contacts; by Lemma 4.11 there are $Q_1 = \gamma(q_1)$ interior to α'_1 and $Q_2 = \gamma(q_2)$ interior to α'_2 with $k(q_1), k(q_2) < 1/R$, whereas by Lemma 4.9 at the four contact points b_1, a_2, b_2, a_3 one has $k \geq 1/R$.

The arcs have disjoint interiors. The open parameter intervals $I_1 = (s_{b_1}, s_{a_2})$ and $I_2 = (s_{b_2}, s_{a_3})$, in $\mathbb{R}/L\mathbb{Z}$, are free of contact parameters and have endpoints that are contact parameters: they are connected components of the complement of the closed set of contact parameters, hence they coincide or are disjoint; they coincide only if $b_1 = b_2$, but then G_1 and G_2 would both be the gap starting at b_1 , that is equal. Hence $I_1 \cap I_2 = \emptyset$.

Cyclic order. Running along the curve from q_1 counterclockwise one stays in α'_1 up to a_2 and then leaves it; since $q_2 \notin I_1$ and $s_{a_2} \notin I_2$, the closed arc $[q_1, q_2]$ contains s_{a_2} , and symmetrically $[q_2, q_1 + L]$ contains s_{a_3} .

Two local maxima. On $[q_1, q_2]$ the maximum of k is $\geq k(s_{a_2}) \geq 1/R > \max(k(q_1), k(q_2))$: it is attained at an interior point M_1 , a local maximum of k . In the same way there is $M_2 \in (q_2, q_1 + L)$ with $k(M_2) \geq 1/R$.

Two local minima. On $[s_{b_1}, s_{a_2}]$ the minimum is $\leq k(q_1) < 1/R \leq \min(k(s_{b_1}), k(s_{a_2}))$, attained at an interior point $m_1 \in I_1$; in the same way $m_2 \in I_2$.

They are distinct. M_1 and M_2 lie in disjoint open arcs; $m_1 \in I_1$ and $m_2 \in I_2$, disjoint; an M_i ($k \geq 1/R$) and an m_j ($k < 1/R$) do not coincide. The curve has at least four vertices; if it is C^3 , at each of them $k' = 0$. $\square$

Remark 4.6: Strong form, the support theorem, and why “simple” is needed.

Strong form (Osseman, 1985). *If K contains no arc and the distinct gaps are at least $n \geq 2$, the same scheme gives $2n$ vertices: the intervals I_i are distinct components, hence disjoint, and each of them contains a local minimum m_i ; ordering the q_i cyclically, every open arc between two consecutive ones leaves its own I_i through a contact parameter, where $k \geq 1/R$, and therefore contains a local maximum M_i ; the n arcs are disjoint and $M_i \neq m_j$ because of the value of k . In the figure, the curve $r = 1 + 0.35 \cos 3\theta$ has $n = 3$ contacts and exactly $6 = 2n$ vertices.*

The osculating support theorem. Petrunin and Zamora Barrera (2022) prove, by means of the “moon in a puddle” lemma, that a closed simple regular curve is supported by its own osculating circles at at least four points, at two of them from inside and at two from outside; from Corollary 4.2 four vertices follow once more. In earlier editions that theorem was imported; the proof given above, by Osseman’s route, no longer needs it, and it is quoted here only as a second road.

Why “simple” is needed. The limaçon $r = 1 + 2\cos\theta$ is closed, regular and C^∞ , but it self-intersects. With $c = \cos\theta$ its curvature is $k = (9 + 6c)/(5 + 4c)^{3/2}$ and $\frac{dk}{dc} = \frac{6(5 + 4c) - 6(9 + 6c)}{(5 + 4c)^{5/2}} = \frac{-24 - 12c}{(5 + 4c)^{5/2}} < 0$ for $|c| \leq 1$: $k'(\theta) = \frac{dk}{dc} \cdot (-\sin\theta)$ vanishes only at $\theta = 0, \pi$. Exactly two vertices, $k_{\min} = 15/27 = 5/9$ and $k_{\max} = 3$ (values confirmed by DeTurck and others, 2007, for the same limaçon rotated). In the proof, simplicity enters in Lemma 4.4 (only two sides, one inner and one outer) and in Lemma 4.10 (β_2 does not cross β_1).

Figure 4.3: The proof on the curve $r = 1 + 0.35\cos 3\theta$ (non-convex: k drops to -5.92 in the indentations). Left: the minimal enclosing circle has radius $R = 1.35$ and three contact points, at $0^\circ, 120^\circ, 240^\circ$, where $k = 2.469 \geq 1/R = 0.741$; the three gaps have width $120^\circ \leq 180^\circ$. Right, the gap G_1 from b to a : the circle C' through b, a and the point Q of the curve at 10° has radius $R' = 1.576 > R$ and centre $c' = (-0.191, -0.331)$; translated in the direction $-\nu$ by $t^* = 0.544$ it touches the arc α' for the last time at the point Q_1 at 60° , where $k(Q_1) = -5.92 \leq 1/R' = 0.634 < 1/R$, and its centre c'' lies on the side of the inward normal ($\langle n_c, N \rangle = 1$). The curve has exactly $6 = 2 \cdot 3$ vertices, at $0^\circ, 60^\circ, \dots, 300^\circ$. Values computed by hand and with an independent script.

INFO

Independent numerical check. A second reader wrote a script (`verifica_quattro_vertici.py`, attached to the sources) that generates 796 simple closed non-convex curves in polar form, computes the minimal enclosing circle by an exact method and puts every lemma to the test: contacts never inside an open semicircle; $k \geq 1/R$ at the contacts (minimum margin 0.08); in 10 400 configurations of Lemma 4.11, including 750 in which the arc crosses the chord again, the disc of the last contact always lies on the side of the inward normal and $k(Q_1) \leq 1/R' < 1/R$; at least 4 local extrema, and at least $2n$ with n gaps. No counterexample. A numerical check is not a proof: here it serves to rule out slips in the computations.

Remark 4.7: Two from inside and two from outside: maxima and minima. The proof of Theorem 4.7 says more than the mere existence of four vertices: it distinguishes the two types. At the contact points with the enclosing circle the curvature is $\geq 1/R$ and the local maxima fall there; under every gap the curvature drops below $1/R$ and the local minima fall there. There are therefore at least two local maxima and at least two local minima of

the curvature, which is the strong form of the four-vertex theorem and coincides with what Step 6 of the proof of Theorem 4.6 derives, in the convex case, from the parity of the number of extrema. The same is said, in other words, by the osculating support theorem of Petrunin and Zamora Barrera (Remark 4.6): where the osculating circle supports from inside — the curve lies locally outside the osculating disc — the radius of curvature is a local minimum, hence the curvature is a local maximum; where it supports from outside the opposite happens. The link with nested osculating circles is the Tait–Kneser theorem: along an arc free of vertices the osculating circles are pairwise disjoint and nested one inside the other. It is precisely the vertices that break the nesting, and that is why their existence is not a detail but the condition for a closed curve to be able to close up on itself.

Corollary 4.4: *The evolute of a closed convex curve has at least four cusps. If γ is closed, simple, convex and C^3 with $k > 0$ and k non-constant, its evolute has at least four cusps.*

Proof. By Theorem 2.6(ii) the singularities of the evolute are exactly the points with $k' = 0$, the vertices of γ ; by Theorem 4.6 there are at least four. $\square$

Figure 4.4: The four-vertex theorem on the ellipse. Left, the four vertices, i.e. the points of stationary curvature: two maxima at the ends of the major axis ($\kappa = a/b^2 = 1.156$) and two minima at the ends of the minor axis ($\kappa = b/a^2 = 0.222$). Right, the graph of $\kappa(t) = ab/(a^2 \sin^2 t + b^2 \cos^2 t)^{3/2}$ over a full turn: it has exactly two maxima and two minima. The theorem states that this is the smallest possible number: every simple closed plane curve has at least four vertices. The circle is the degenerate case in which the curvature is constant and every point is a vertex.

Remark 4.8: *The ellipse has exactly four vertices. The ellipse (Chapter 1... recte Chapter 2) achieves the minimum: four vertices, at the four endpoints of the axes, where κ is maximum (major axis) or minimum (minor axis). The circle is the degenerate case where κ is constant and every point is a “vertex”: the theorem is trivially satisfied but with no isolated vertices.*

Exercise 4.3. Identify the vertices of the ellipse $x^2/a^2 + y^2/b^2 = 1$ with $a > b$.

Solution. From the curvature $\kappa(t) = ab(a^2 \sin^2 t + b^2 \cos^2 t)^{-3/2}$ (Chapter 1... recte Chapter 2), the extrema occur where $\frac{d}{dt}(a^2 \sin^2 t + b^2 \cos^2 t) = 0$, i.e., $\sin t \cos t = 0$: at the four points $t = 0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}$, i.e., $(\pm a, 0)$ (maximum curvature) and $(0, \pm b)$ (minimum curvature). Exactly four vertices.

4.6. The global Gauss–Bonnet theorem

The preceding theorems tied an integral quantity of a plane curve — the total curvature, the perimeter, the area — to a discrete datum: an integer index, the number of vertices, the case of equality. The global Gauss–Bonnet theorem carries the same pattern into dimension two: the integral of the Gaussian curvature over a closed surface *does not depend on the metric*, but only on the topology, and equals 2π times the Euler characteristic. Deforming the surface without tearing it, the curvature is redistributed but its integral does not change by an iota.

Remark 4.9: What we import for the global Gauss–Bonnet theorem. The proof that follows is complete starting from three statements that this volume does **not** prove and that we declare here, with the source.

(P1) Local form of Gauss–Bonnet on a geodesic triangle. If T is a geodesic triangle of an oriented regular surface, contained in a normal neighbourhood, with interior angles α, β, γ , then

$$\iint_T K \, dA = \alpha + \beta + \gamma - \pi.$$

For the sphere this is proved in full in Chapter 7 (Theorem 7.11), where $K = 1/r^2$ and the statement coincides with Girard’s theorem on the spherical excess. For an arbitrary regular surface we import it from do Carmo, §4-5. What is missing, in order to close it, is: the covariant derivative along a curve and parallel transport, which belong to Chapter 10 and to the theory of surfaces, not to that of plane curves.

(P2) Existence of a geodesic triangulation. Every compact regular surface admits a finite triangulation whose triangles are geodesic and each contained in a normal neighbourhood. do Carmo, §4-5, states and uses it without proving it, referring to T. Radó (Acta Szeged 2, 1926), who proved the triangulability of every topological surface.

(P3) Topological invariance of the Euler characteristic. The number $\chi = V - E + F$ does not depend on the chosen triangulation, but only on the surface: this is again Radó (1926), taken up in do Carmo, §4-5. For closed orientable surfaces one has moreover $\chi = 2 - 2g$, with g the genus.

Everything else — the combinatorial count, the sum of the angles, the passage from $2\pi V - \pi F$ to $2\pi\chi$ — is proved below, and the numerical checks are independent.

Definition 4.6: Triangulation and Euler characteristic. A **triangulation** of a compact surface M without boundary is a finite family of closed subsets $T_1, \dots, T_F$, each homeomorphic to a closed triangle of the plane, such that

- (a) $\bigcup_i T_i = M$;
- (b) two distinct triangles are disjoint, or have exactly one vertex in common, or exactly one whole edge.

Denoting by V , E and F the numbers of vertices, edges and faces, the **Euler characteristic** of the triangulation is $\chi = V - E + F$.

Lemma 4.12: Every edge belongs to two faces. In a triangulation of a compact surface without boundary one has

$$3F = 2E.$$

Proof. Step 1 — the set to be counted. Consider the set

$$\mathcal{I} = \{(T, \ell) : T \text{ a face, } \ell \text{ an edge of } T\},$$

and compute its cardinality in two ways.

Step 2 — counting by faces. Every face is homeomorphic to a triangle and therefore has exactly three edges: $|\mathcal{I}| = 3F$.

Step 3 — counting by edges. Let ℓ be an edge and let p be an interior point of ℓ . Since M is a surface without boundary, p has a neighbourhood homeomorphic to an open disc, and inside that neighbourhood ℓ divides it into two half-discs; by condition (b) of Definition 4.6 each half-disc is covered by the points of a single face. Hence every edge belongs to exactly two faces and $|\mathcal{I}| = 2E$.

Step 4 — conclusion. $3F = |\mathcal{I}| = 2E$. □

***Lemma 4.13: Sum of all the angles of a triangulation.** Let $T_1, \dots, T_F$ be a triangulation of a compact surface without boundary M and let $\alpha_i, \beta_i, \gamma_i$ be the interior angles of T_i . Then*

$$\sum_{i=1}^F (\alpha_i + \beta_i + \gamma_i) = 2\pi V.$$

Proof. **Step 1 — reorganising the sum.** Every angle in the sum is the angle of a face at one of its vertices. Grouping by vertex,

$$\sum_{i=1}^F (\alpha_i + \beta_i + \gamma_i) = \sum_{p \in \{\text{vertices}\}} \sum_{T \ni p} \vartheta_T(p),$$

where $\vartheta_T(p)$ is the angle of the face T at the vertex p .

Step 2 — the angles around a vertex add up to 2π . Let p be a vertex. Since M is a surface without boundary, p has a neighbourhood U homeomorphic to a disc; the faces containing p meet U in angular sectors which, by condition (b) of Definition 4.6, follow one another around p pairwise adjacent along an edge, covering U exactly once and without overlaps. The faces around p therefore form a cycle and their angles add up to a full angle:

$$\sum_{T \ni p} \vartheta_T(p) = 2\pi.$$

Step 3 — conclusion. Summing over all V vertices one obtains $2\pi V$. □

***Theorem 4.8: Global Gauss–Bonnet.** Let M be a compact, orientable regular surface without boundary, with Gaussian curvature K . Then*

$$\iint_M K \, dA = 2\pi \chi(M),$$

where $\chi(M) = V - E + F$ is the Euler characteristic of any triangulation of M . In particular the integral of the curvature does not depend on the metric.

Proof. **Step 1 — triangulation.** By (P2) of Remark 4.9 choose a geodesic triangulation $T_1, \dots, T_F$ of M , with interior angles $\alpha_i, \beta_i, \gamma_i$.

Step 2 — additivity of the integral. The triangles cover M and meet only along edges and vertices, which are finite unions of curves and of points, hence sets of measure zero for the area measure of M . Therefore

$$\iint_M K \, dA = \sum_{i=1}^F \iint_{T_i} K \, dA.$$

Step 3 — local form on each triangle. By (P1),

$$\iint_{T_i} K \, dA = \alpha_i + \beta_i + \gamma_i - \pi \quad (i = 1, \dots, F).$$

Step 4 — summation. Summing over i and using Lemma 4.13,

$$\iint_M K dA = \sum_{i=1}^F (\alpha_i + \beta_i + \gamma_i) - \pi F = 2\pi V - \pi F.$$

Step 5 — the combinatorics. By Lemma 4.12, $E = \frac{3}{2}F$, hence

$$2\pi(V - E + F) = 2\pi V - 2\pi \cdot \frac{3F}{2} + 2\pi F = 2\pi V - 3\pi F + 2\pi F = 2\pi V - \pi F.$$

The right-hand side coincides with that of Step 4.

Step 6 — conclusion. Combining Steps 4 and 5,

$$\iint_M K dA = 2\pi(V - E + F) = 2\pi\chi(M),$$

and by (P3) the value $V - E + F$ does not depend on the chosen triangulation: the left-hand side, which does not depend on it by construction, is therefore a topological invariant. Since the left-hand side depends on the metric only through K and dA , while the right-hand side does not depend on it at all, the final assertion follows as well.

Step 7 — consistency check on the sign. If $K > 0$ everywhere, the left-hand side is positive, hence $\chi(M) > 0$; if $K \equiv 0$, then $\chi(M) = 0$. These are the two cases checked in Examples 4.2 and 4.3. $\square$

Example 4.2: The sphere with the octahedral triangulation. Take on S^2 (radius 1) the inscribed regular octahedron, with vertices $(\pm 1, 0, 0)$, $(0, \pm 1, 0)$, $(0, 0, \pm 1)$, and project its edges onto the great circles: one obtains a geodesic triangulation with

$$V = 6, \quad E = 12, \quad F = 8.$$

Step 1 — combinatorial check. $3F = 24 = 2E$ (Lemma 4.12) $\checkmark$, and $\chi = 6 - 12 + 8 = 2$.

Step 2 — the eight triangles. Every face is a *triangular* triangle: its three vertices are pairwise orthogonal as unit vectors of $\mathbb{R}^3$, hence $\alpha = \beta = \gamma = \pi/2$. The excess equals $\alpha + \beta + \gamma - \pi = \frac{3\pi}{2} - \pi = \frac{\pi}{2}$, and the area, since the sphere is divided into eight congruent parts, equals $4\pi/8 = \pi/2$: the two quantities coincide, as (P1) predicts with $K \equiv 1$. $\checkmark$

Step 3 — sum of the angles. $\sum_i (\alpha_i + \beta_i + \gamma_i) = 8 \times \frac{3\pi}{2} = 12\pi = 2\pi V = 2\pi \times 6$ (Lemma 4.13) $\checkmark$.

Step 4 — the two expressions of Step 5 of the proof. $2\pi V - \pi F = 12\pi - 8\pi = 4\pi$ and $2\pi\chi = 2\pi \times 2 = 4\pi$. $\checkmark$

Step 5 — independence of the radius. For $S^2(O, r)$ one has $K = 1/r^2$ and area $4\pi r^2$, hence

$$\iint_{S^2(O, r)} K dA = \frac{1}{r^2} \cdot 4\pi r^2 = 4\pi$$

for *every* r : the total curvature does not see the geometry, only the topology. $\checkmark$ (Checks in `verifica_cap02_cap04.py`, blocks [C4-4] and [C4-5].)

Example 4.3: The torus: zero total curvature. Consider the torus of revolution with radii $R > r > 0$,

$$\sigma(u, v) = ((R + r \cos u) \cos v, (R + r \cos u) \sin v, r \sin u), \quad u, v \in [0, 2\pi],$$

for which $K(u) = \frac{\cos u}{r(R + r \cos u)}$ and $dA = r(R + r \cos u) du dv$.

Step 1 — the integral. The product $K dA$ simplifies:

$$\iint_{T^2} K dA = \int_0^{2\pi} \int_0^{2\pi} \cos u du dv = 2\pi \int_0^{2\pi} \cos u du = 0.$$

Step 2 — comparison with the theorem. $\chi(T^2) = 0$, hence $2\pi\chi = 0$: consistent. ✓

Step 3 — check on two triangulations. The 3×3 grid of the fundamental square, with each small square divided into two triangles, gives $V = 9$, $E = 27$, $F = 18$: $3F = 54 = 2E$ ✓ and $\chi = 9 - 27 + 18 = 0$ ✓. The *minimal* triangulation of the torus has $V = 7$, $E = 21$, $F = 14$ — the combinatorics is that of the complete graph K_7 embedded in the torus, described by Möbius and realised as a polyhedron embedded in $\mathbb{R}^3$ by Á. Császár in 1949 — and gives $3F = 42 = 2E$ ✓, $\chi = 7 - 21 + 14 = 0$ ✓.

Step 4 — the flat torus. On the flat torus $\mathbb{R}^2/\mathbb{Z}^2$ the triangles of the grid are Euclidean, with angle sum π each: the total sum equals $\pi F = 18\pi$, which is also $2\pi V = 2\pi \times 9 = 18\pi$ ✓ (Lemma 4.13), and $2\pi V - \pi F = 0$, as it must be for $K \equiv 0$.

Step 5 — where the curvature is. On the torus of revolution with $R = 3$ and $r = 1$, the curvature equals $K(0) = \frac{1}{1 \times 4} = 0.25$ on the outermost circle and $K(\pi) = \frac{-1}{1 \times 2} = -0.5$ on the innermost one: the outer part is convex, the inner part is saddle-shaped, and the two contributions cancel exactly. ✓

Corollary 4.5: No everywhere-positive curvature outside the sphere. Let M be a compact, orientable regular surface without boundary with $K > 0$ at every point. Then $\chi(M) = 2$, that is M has genus 0. In particular no metric on the torus — nor on a closed orientable surface of genus ≥ 1 — has everywhere-positive Gaussian curvature.

Proof. **Step 1.** If $K > 0$ on a compact set and $dA > 0$, then $\iint_M K dA > 0$; by Theorem 4.8, $2\pi\chi(M) > 0$, hence $\chi(M) \geq 1$.

Step 2. By (P3) of Remark 4.9, a closed orientable surface has $\chi = 2 - 2g$ with $g \geq 0$ an integer: the possible values are $2, 0, -2, -4, \dots$, and the only one ≥ 1 is $\chi = 2$, that is $g = 0$.

Step 3. The torus has $g = 1$ and $\chi = 0$: it cannot carry a metric with everywhere-positive curvature. The computation of Example 4.3 shows this concretely: whatever the metric, the positive curvature of the outer part must be exactly compensated by negative curvature elsewhere. □

Remark 4.10: Why it is the same theorem as the Umlaufsatz. Section 4.1 established $\int_0^L k ds = 2\pi \operatorname{ind}(\gamma)$, with $\operatorname{ind} = \pm 1$ for simple curves. It is the same statement in dimension one: the integral of a curvature equals 2π times an integer depending only on the topology of the object, not on its shape. The link is more than an analogy: the Gauss–Bonnet form for a region with boundary contains both terms, $\iint_R K dA + \oint_{\partial R} k_g ds + \sum(\text{exterior angles}) = 2\pi\chi(R)$, and it reduces to the Umlaufsatz when R is a simply connected plane region ($K \equiv 0$, $\chi = 1$).

Exercise 4.4: Total curvature of a genus-two surface. What is the value of $\iint_M K dA$ for a closed orientable surface of genus 2 (the «double torus»)? And what is the average sign of the curvature?

Solution. By (P3) of Remark 4.9, $\chi = 2 - 2g = 2 - 4 = -2$, hence by Theorem 4.8

$$\iint_M K dA = 2\pi \times (-2) = -4\pi.$$

The integral is negative: on average the curvature is negative, that is, the surface is predominantly saddle-shaped. By Corollary 4.5 it cannot be everywhere-positive; a fortiori it cannot be everywhere zero either, because that would give $\chi = 0$. A smooth double torus has positive curvature on the «outer» parts of the two handles and negative curvature in the throats, with balance -4π independently of how one deforms it. ✓

4.7. Assigned exercises

The answers are in the Teacher's key (Section 4.11).

Exercise 4.5: The n -sided Reuleaux polygons. *Aim:* to construct an infinite family of curves of constant width, to check Barbier's theorem on it and to place it between the two extremes of the Blaschke–Lebesgue theorem. *Estimated time:* 45 minutes. *Type:* symbolic with numerical check.

For odd $n \geq 3$, the **Reuleaux polygon** of width w is obtained from a regular n -gon by replacing each side with the circular arc of radius w centred at the opposite vertex.

- Prove that it is a convex body of constant width w and deduce its perimeter from Theorem 4.3.
- Prove that its area equals $A_n = \frac{1}{2} \left(\pi - n \tan \frac{\pi}{2n} \right) w^2$.
- Compute A_3 , A_5 and A_7 for $w = 1$ and their ratios to the area of the circle of diameter 1.
- Check that A_n increases with n and that $A_n \rightarrow \pi w^2/4$ as $n \rightarrow +\infty$, tabulating $n = 9, 51, 501, 5001$.
- Interpret (c) and (d) in the light of Theorem 4.4.

Exercise 4.6: A three-lobed polar curve: index, area, vertices. *Aim:* to apply, in a single example, the Umlaufsatz, the isoperimetric inequality and the four-vertex theorem to a simple but *non-convex* curve. *Estimated time:* 50 minutes. *Type:* numerical/computational. Consider the polar curve $r(\theta) = 1 + a \cos 3\theta$ with $a = 0.3$.

- Check that the curve is closed, regular and simple, and that it has no intersection with the origin.
- Compute the enclosed area in closed form and verify it numerically.
- Compute the length L by quadrature and the isoperimetric ratio $L^2/(4\pi A)$; comment on its value in the light of Theorem 4.5.
- Compute the total curvature $\int k \, ds$ and verify Theorem 4.1.
- Determine the number and the positions of the vertices and compare with Theorem 4.6; check that the curve is not convex by computing $k(0)$ and $k(\pi/3)$.

Exercise 4.7: Gauss–Bonnet on two triangulations. *Aim:* to carry out in full the count of the proof of Theorem 4.8 on explicit triangulations. *Estimated time:* 35 minutes. *Type:* combinatorial/numerical.

- For the regular icosahedron inscribed in the sphere, projected onto the great circles, determine V , E , F ; check Lemma 4.12 and compute χ , $2\pi V - \pi F$ and $\iint K \, dA$.
- Deduce the average angular excess of a triangle of the triangulation and compare it with that of the octahedron of Example 4.2.
- For the torus, check $3F = 2E$ and $\chi = 0$ on the diagonalised 3×3 grid and on the minimal triangulation with 7 vertices.
- Explain why no triangulation of the torus can have $\chi \neq 0$, even though it may have

arbitrarily large V , E , F .

- (e) Construct a triangulation of the torus with exactly $F = 100$ faces (or prove that none exists) and compute its V and E compatible with $\chi = 0$.

4.8. Worked exercises

Exercise 4.8: Convex bodies prescribed by a single harmonic. *Type:* symbolic with numerical check. For an integer $n \geq 2$ and $\varepsilon \in \mathbb{R}$ consider the 2π -periodic function

$$h(\theta) = 1 + \varepsilon \cos n\theta.$$

Determine for which ε the function h is the support function of a convex body of class C^2 , and compute its perimeter, area and isoperimetric deficit.

Solution. Strategy. One uses the convexity criterion of Theorem 4.2: h is the support function of a smooth convex body if and only if $h + h'' > 0$; then one applies Cauchy's formulae for L and for A .

Step 1 — radius of curvature. $h'' = -n^2\varepsilon \cos n\theta$, hence

$$\rho(\theta) = h(\theta) + h''(\theta) = 1 - (n^2 - 1)\varepsilon \cos n\theta.$$

Step 2 — convexity threshold. The minimum of ρ equals $1 - (n^2 - 1)|\varepsilon|$, hence $\rho > 0$ everywhere if and only if

$$|\varepsilon| < \frac{1}{n^2 - 1}.$$

For $n = 3$ the threshold is $1/8 = 0.125$; for $n = 4$ it is $1/15 = 0.066667$; for $n = 5$ it is $1/24 = 0.041667$: the higher the harmonic, the smaller its amplitude must be for the body to remain convex.

Step 3 — perimeter. By Cauchy's formula (Theorem 4.2(iii)),

$$L = \int_0^{2\pi} h \, d\theta = 2\pi + \varepsilon \int_0^{2\pi} \cos n\theta \, d\theta = 2\pi,$$

because $\int_0^{2\pi} \cos n\theta \, d\theta = 0$ for $n \geq 1$: all these convex bodies have the same perimeter as the unit circle, for every admissible ε .

Step 4 — area. From $h' = -n\varepsilon \sin n\theta$ and $\int_0^{2\pi} \cos^2 = \int_0^{2\pi} \sin^2 = \pi$,

$$\int_0^{2\pi} h^2 = 2\pi + \pi\varepsilon^2, \quad \int_0^{2\pi} h'^2 = \pi n^2 \varepsilon^2,$$

hence, by Theorem 4.2(iv),

$$A = \frac{1}{2} \left(2\pi + \pi\varepsilon^2 - \pi n^2 \varepsilon^2 \right) = \pi - \frac{(n^2 - 1)\pi\varepsilon^2}{2}.$$

Step 5 — isoperimetric deficit. Since $L^2/(4\pi) = 4\pi^2/(4\pi) = \pi$,

$$\frac{L^2}{4\pi} - A = \frac{(n^2 - 1)\pi\varepsilon^2}{2} \geq 0,$$

with equality if and only if $\varepsilon = 0$, that is for the circle: this is exactly Step 4 of the proof of Theorem 4.5, restricted to a single harmonic.

Independent check. The script `verifica_cap02_cap04.py` (block [C4-1]) computes $\min(h + h'')$ by sampling, L and A by Simpson quadrature, and compares them with the formulae of Steps 2–4. For $n = 3$ and $\varepsilon = 0.05; 0.1; 0.124$ it finds respectively $\min \rho = 0.600000; 0.200000; 0.008000$ (that is $1 - 8\varepsilon$), $L = 6.283185 = 2\pi$ and deficit $0.031416; 0.125664; 0.193221$, against $4\pi\varepsilon^2$. For $n = 2, 4, 5$ with $\varepsilon = 0.02$ it verifies the general formula. ✓

Interpretation. The perimeter «sees» only the mean of h (the zeroth harmonic), the area sees all the harmonics with weight $n^2 - 1$: it is the same hierarchy that Parseval's identity imposes on the energy of a signal. The isoperimetric deficit is the energy of the higher harmonics of the support function.

Typical mistakes. (a) Using $A = \frac{1}{2} \int h^2$, forgetting the term $-h'^2$: one would obtain an area *larger* than that of the circle, contradicting Theorem 4.5. (b) Believing that $|\varepsilon| < 1$ suffices for convexity: for $n = 5$ the threshold is already 0.042. (c) Confusing $\rho = h + h''$ with h itself.

Extension. Consider $h(\theta) = 1 + \varepsilon \cos n\theta$ with n odd and check that the width $w(\theta) = h(\theta) + h(\theta + \pi)$ is constant $= 2$: these are smooth non-circular convex bodies of constant width, for which Theorem 4.3 predicts $L = 2\pi = \pi w$, in agreement with Step 3.

Exercise 4.9: Descartes's theorem on the total angular defect. *Type:* proof-based/combinatorial. Let P be a convex polyhedron whose faces are plane triangles. For every vertex p define the *angular defect*

$$\delta_p = 2\pi - \sum_{T \ni p} \vartheta_T(p).$$

Prove that $\sum_p \delta_p = 4\pi$, and check it on the Platonic solids (for which polygonal faces are also allowed, counted with the angle sum of the face).

Solution. Strategy. One counts the angles in two ways, exactly as in Lemmas 4.12 and 4.13, the only difference being that the triangles are now *Euclidean* and not geodesic: the sum of their angles is π , not π plus an excess.

Step 1 — sum of the defects. By definition,

$$\sum_p \delta_p = 2\pi V - \sum_p \sum_{T \ni p} \vartheta_T(p) = 2\pi V - \sum_T (\alpha_T + \beta_T + \gamma_T),$$

where in the second equality the sum has been reorganised by faces instead of by vertices (it is Step 1 of Lemma 4.13, read backwards).

Step 2 — the triangles are plane. Every face is a Euclidean triangle, hence $\alpha_T + \beta_T + \gamma_T = \pi$ and the sum equals πF :

$$\sum_p \delta_p = 2\pi V - \pi F.$$

Step 3 — the combinatorics. The boundary of P is a compact surface without boundary, hence Lemma 4.12 applies, $3F = 2E$, and by Step 5 of the proof of Theorem 4.8 $2\pi V - \pi F = 2\pi(V - E + F) = 2\pi\chi$.

Step 4 — the topology. The boundary of a convex polyhedron is homeomorphic to S^2 , hence $\chi = 2$ and

$$\sum_p \delta_p = 2\pi \times 2 = 4\pi.$$

Step 5 — polygonal faces. If the faces are polygons with m_T sides, Step 2 becomes $\sum_T (m_T - 2)\pi$ and Step 3 is adapted by counting $\sum_T m_T = 2E$; one obtains again $2\pi V - 2\pi E + 2\pi F = 2\pi\chi = 4\pi$.

Independent check. For the five Platonic solids, with ϑ the angle of a face at one of its vertices:

solid	V	faces per vertex	ϑ	δ_p
tetrahedron	4	3	$\pi/3$	π
cube	8	3	$\pi/2$	$\pi/2$
octahedron	6	4	$\pi/3$	$2\pi/3$
dodecahedron	20	3	$3\pi/5$	$\pi/5$
icosahedron	12	5	$\pi/3$	$\pi/3$

and in all five cases $V \delta_p = 4\pi$: 4π ; $8 \cdot \pi/2 = 4\pi$; $6 \cdot 2\pi/3 = 4\pi$; $20 \cdot \pi/5 = 4\pi$; $12 \cdot \pi/3 = 4\pi$. ✓ (Block [C4-4] of the script.)

Interpretation. The angular defect is «curvature concentrated at the vertices»: a polyhedron is flat everywhere except at the vertices, where all the curvature accumulates. Descartes's theorem (around 1630, rediscovered and published much later) is therefore the exact discrete version of Theorem 4.8, with $\iint K dA$ replaced by $\sum_p \delta_p$.

Typical mistakes. (a) Summing the angles of the faces instead of the defects of the vertices. (b) Forgetting that the result holds for the boundary of a convex polyhedron because it is a topological sphere: a toroidal polyhedron (for instance Császár's) has total defect 0. (c) Using $3F = 2E$ for polyhedra with non-triangular faces.

Extension. Check that for the Császár polyhedron ($V = 7$, $E = 21$, $F = 14$, topologically a torus) the sum of the angular defects equals $2\pi \cdot 7 - \pi \cdot 14 = 0$, consistently with $\chi = 0$ (Example 4.3).

Exercise 4.10: Why a calliper does not recognise a Reuleaux profile. *Type:* applied with numerical check. A turned workpiece has a Reuleaux-triangle cross section of width w . Show that a vernier calliper always measures w in every direction, compute the radii of the circumscribed and inscribed circles, and determine the circularity error that an inspection according to ISO 1101 would detect.

Solution. Strategy. The calliper measures the distance between two parallel supporting lines, that is the width $w(\theta)$; by Theorem 4.3 and the definition of constant width this does not depend on θ . The circularity error, on the other hand, is the difference between the radii of the minimal circumscribed circle and the maximal inscribed circle, and it is not zero.

Step 1 — the calliper measures the width. The two jaws of a calliper are plane and parallel: the reading is $w(\theta) = h(\theta) + h(\theta + \pi)$, that is the width in the direction θ (Definition 4.3). For the Reuleaux triangle this equals w for every θ (Example 4.1): the calliper always gives the same reading, exactly as for a cylinder of diameter w .

Step 2 — circumscribed circle. By symmetry the centre of the two circles is the centroid O of the equilateral triangle of side w from which the profile is built. The distance from O to a vertex is the circumradius of the equilateral triangle,

$$R = \frac{w}{\sqrt{3}} = 0.577350 w,$$

and the three vertices are the points of the profile farthest from O : R is therefore the radius of the minimal circumscribed circle.

Step 3 — inscribed circle. The points nearest to O lie on the arcs, at distance $w - R$ from the centre: indeed the arc opposite a vertex V has centre at V and radius w , and the point of that arc nearest to O lies on the line VO , at distance $w - |VO| = w - R$ from O .

Hence

$$r = w - R = w \left(1 - \frac{1}{\sqrt{3}} \right) = 0.422650 w.$$

Note that $R + r = w$: this is the relation between the two supporting lines orthogonal to the vertex–arc direction, that is a case of constant width.

Step 4 — circularity error. According to ISO 1101 circularity is the difference between the radii of two concentric circles enclosing the profile:

$$R - r = w \left(\frac{2}{\sqrt{3}} - 1 \right) = 0.154701 w.$$

For $w = 40$ mm one obtains $R = 23.094011$ mm, $r = 16.905989$ mm and circularity error 6.188022 mm: enormous compared with any machining tolerance.

Independent check. The script `verifica_cap02_cap04.py` (block [C4-2]) recomputes R , r , $R + r$ and $R - r$ for $w = 1$ and finds 0.577350; 0.422650; 1.000000; 0.154701. ✓

Interpretation. Constant width and circularity are different properties: the first concerns the *supporting lines*, the second the concentric *circles*. An inspection with a calliper (or with two parallel rollers) therefore cannot certify the roundness of a shaft: one needs a dial gauge on a V-block with a correctly chosen angle, or a three-point measurement with non-equispaced angles, or a coordinate measuring machine. It is a classical and costly metrological mistake.

Typical mistakes. (a) Concluding from $L = \pi w$ (Theorem 4.3) that the profile is a circle: the perimeter does not characterise the shape. (b) Taking $w/2$ as the inscribed radius. (c) Confusing circularity (ISO 1101) with the dimensional tolerance on the diameter.

Extension. Compute R , r and the circularity error for the Reuleaux polygons with 5 and 7 sides and check that they tend respectively to $w/2$, $w/2$ and 0 as $n \rightarrow \infty$, consistently with Exercise 4.5(d).

4.9. Numerical and symbolic exercises with solutions

The exercises below come from the treatment of plane curves in Volume II and are reproduced in full, together with their solutions.

4.9.1 Numerical exercises

Exercise 4.11: N1 — A convex body given by its support function. Let $h(\theta) = 10 + \cos 3\theta$ (in mm). Check that h defines a convex body; compute its perimeter, area, minimum and maximum radii of curvature, and the isoperimetric deficit $L^2/4\pi - A$; compare the latter with the formula of Step 4 of the proof of Theorem 4.5.

Exercise 4.12: N2 — Reuleaux triangle versus circle. For a Reuleaux triangle of width $w = 40$ mm compute the perimeter and area, and compare them with those of the circle of diameter 40 mm. Comment in the light of Theorems 4.3 and 4.4.

Exercise 4.13: N3 — The four vertices of an ellipse. For the ellipse with semi-axes $a = 5$ and $b = 3$ determine the four vertices, the corresponding curvatures and radii of curvature, and the four cusps of the evolute.

Exercise 4.14: N4 — Total curvature of an ellipse. Verify analytically that the total curvature of the ellipse with semi-axes a and b equals 2π , as predicted by Theorem 4.1. (Hint: use $\int_0^{2\pi} \frac{dt}{a^2 \sin^2 t + b^2 \cos^2 t} = \frac{2\pi}{ab}$.)

4.9.2 Symbolic exercises

Exercise 4.15: S1 — An enclosed curve cannot be too little curved. Let γ be a closed curve contained in a circle of radius R . Prove that there is a point where $|k| \geq 1/R$.

Exercise 4.16: S2 — Wirtinger's inequality. Let f be 2π -periodic of class C^1 with $\int_0^{2\pi} f = 0$. Prove that

$$\int_0^{2\pi} f'(\theta)^2 d\theta \geq \int_0^{2\pi} f(\theta)^2 d\theta,$$

with equality if and only if $f(\theta) = a \cos \theta + b \sin \theta$.

Exercise 4.17: S3 — Double normals of a constant-width curve. Let K be convex of constant width w and class C^2 . Prove that $\rho(\theta) + \rho(\theta + \pi) = w$, that the diameter of K equals w , and that the normal at a point is also the normal at the opposite point (a *double normal*).

Exercise 4.18: S4 — Steiner's formula for parallel curves. Let K be convex with perimeter L and area A , and let K_d be the convex body of points at distance $\leq d$ from K . Prove, using the support function, that

$$L_d = L + 2\pi d, \quad A_d = A + Ld + \pi d^2.$$

Interpret the term πd^2 .

Exercise 4.19: S5 — Constant width and central symmetry. Prove that a convex body of constant width possessing a centre of symmetry is a circle. Deduce that the Reuleaux triangle has no centre of symmetry.

4.9.3 Solutions to the numerical exercises

Solution. N1. Step 1 — convexity. By Theorem 4.2(ii),

$$\rho(\theta) = h + h'' = (10 + \cos 3\theta) + (-9 \cos 3\theta) = 10 - 8 \cos 3\theta.$$

Since $\cos 3\theta \in [-1, 1]$, $\rho \in [2, 18]$, always positive: h is indeed the support function of a convex body with smooth boundary.

Step 2 — extreme radii.

$$\rho_{\min} = 10 - 8 = 2 \text{ mm} \quad (\theta = 0, \frac{2\pi}{3}, \frac{4\pi}{3}), \quad \rho_{\max} = 10 + 8 = 18 \text{ mm} \quad (\theta = \frac{\pi}{3}, \pi, \frac{5\pi}{3}).$$

There are therefore six vertices, in agreement with Theorem 4.6 (at least four).

Step 3 — perimeter. By Cauchy's formula,

$$L = \int_0^{2\pi} (10 + \cos 3\theta) d\theta = 20\pi = 62.8319 \text{ mm},$$

the integral of the cosine over a whole number of periods being zero.

Step 4 — area. With $h' = -3 \sin 3\theta$:

$$\int_0^{2\pi} h^2 d\theta = \int_0^{2\pi} (100 + 20 \cos 3\theta + \cos^2 3\theta) d\theta = 200\pi + 0 + \pi = 201\pi,$$

$$\int_0^{2\pi} h'^2 d\theta = 9 \int_0^{2\pi} \sin^2 3\theta d\theta = 9\pi.$$

Hence

$$A = \frac{1}{2}(201\pi - 9\pi) = 96\pi = 301.593 \text{ mm}^2.$$

Step 5 — isoperimetric deficit.

$$\frac{L^2}{4\pi} = \frac{(20\pi)^2}{4\pi} = 100\pi = 314.159 \text{ mm}^2, \quad \frac{L^2}{4\pi} - A = 4\pi = 12.566 \text{ mm}^2.$$

Step 6 — comparison with the theoretical formula. Step 4 of the proof of Theorem 4.5 predicts

$$\frac{L^2}{4\pi} - A = \frac{\pi}{2} \sum_{n \geq 2} (n^2 - 1)(a_n^2 + b_n^2) = \frac{\pi}{2} (3^2 - 1) \cdot 1^2 = 4\pi. \checkmark$$

The only harmonic present is $n = 3$ with $a_3 = 1$.

Step 7 — isoperimetric ratio. $4\pi A/L^2 = 96\pi/(100\pi) = 0.96$: the body encloses 96% of the area of the circle of equal perimeter.

Solution. N2. *Step 1 — perimeter of the Reuleaux triangle.* By Theorem 4.3, $L = \pi w = \pi \times 40 = 125.664 \text{ mm}$.

Step 2 — area of the Reuleaux triangle. From Example 4.1,

$$A = \frac{\pi - \sqrt{3}}{2} w^2 = 0.704771 \times 1600 = 1127.63 \text{ mm}^2.$$

Step 3 — circle of diameter 40 mm.

$$L_o = \pi \times 40 = 125.664 \text{ mm}, \quad A_o = \frac{\pi \times 40^2}{4} = 400\pi = 1256.64 \text{ mm}^2.$$

Step 4 — comparison. The perimeters are *identical* (Theorem 4.3); the areas are not:

$$\frac{A}{A_o} = \frac{1127.63}{1256.64} = 0.89734,$$

i.e. 89.73%. By Theorem 4.4 these are the two extremes: no figure of width 40 mm has area greater than 1256.64 mm^2 nor smaller than 1127.63 mm^2 .

Step 5 — practical reading. A machine part measured with a vernier calliper always reads 40.00 mm in every orientation, whether it is cylindrical or has a Reuleaux-triangle cross-section. The difference — over 10% of area, and a completely different shape — is undetectable with that instrument. One needs a dial gauge on a rotary table, or a roundness measurement per ISO 1101.

Solution. N3. *Step 1 — position of the vertices.* From Example 2.2,

$$k(t) = \frac{ab}{(a^2 \sin^2 t + b^2 \cos^2 t)^{3/2}}.$$

The derivative vanishes when that of the denominator does, i.e. when $2(a^2 - b^2) \sin t \cos t = 0$: for $a \neq b$, at $t = 0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}$. The four vertices are therefore $(\pm 5, 0)$ and $(0, \pm 3)$.

Step 2 — curvatures. With $a = 5, b = 3$:

$$k(0) = \frac{ab}{b^3} = \frac{a}{b^2} = \frac{5}{9} = 0.555556, \quad \rho = \frac{b^2}{a} = \frac{9}{5} = 1.8,$$

$$k\left(\frac{\pi}{2}\right) = \frac{b}{a^2} = \frac{3}{25} = 0.12, \quad \rho = \frac{a^2}{b} = \frac{25}{3} = 8.3\bar{3}.$$

Step 3 — cusps of the evolute. From Example 2.4,

$$e(t) = \left(\frac{a^2 - b^2}{a} \cos^3 t, \frac{b^2 - a^2}{b} \sin^3 t \right) = (3.2 \cos^3 t, -5.3\bar{3} \sin^3 t),$$

since $a^2 - b^2 = 16$. The four cusps are

$$(\pm 3.2; 0) \quad \text{and} \quad (0; \mp 5.3\bar{3}).$$

Step 4 — check. From the vertex $(5, 0)$ to the centre of curvature $(3.2; 0)$ the distance is $5 - 3.2 = 1.8 = \rho(0) \checkmark$. From the vertex $(0, 3)$ to the centre $(0; -5.3\bar{3})$ the distance is $3 + 5.3\bar{3} = 8.3\bar{3} = \rho(\pi/2) \checkmark$.

Step 5 — reading. The radius of curvature varies by a factor $8.3\bar{3}/1.8 = 4.63 = (a/b)^3$: the ellipse is far “flatter” at the ends of the minor axis. This is why an approximate four-arc ellipse template uses such different radii.

Solution. N4. *Step 1 — line element.*

$$\|\gamma'(t)\| = \sqrt{a^2 \sin^2 t + b^2 \cos^2 t}.$$

Step 2 — the product $k ds$. From Example 2.2,

$$k(t) \|\gamma'(t)\| = \frac{ab}{(a^2 \sin^2 t + b^2 \cos^2 t)^{3/2}} \cdot (a^2 \sin^2 t + b^2 \cos^2 t)^{1/2} = \frac{ab}{a^2 \sin^2 t + b^2 \cos^2 t}.$$

Step 3 — integration. Using the suggested integral,

$$\int_0^L k ds = \int_0^{2\pi} \frac{ab dt}{a^2 \sin^2 t + b^2 \cos^2 t} = ab \cdot \frac{2\pi}{ab} = 2\pi. \checkmark$$

Step 4 — check of the suggested integral. Dividing numerator and denominator by $\cos^2 t$ and setting $u = \tan t$ on $(-\pi/2, \pi/2)$:

$$\int_{-\pi/2}^{\pi/2} \frac{dt}{a^2 \sin^2 t + b^2 \cos^2 t} = \int_{-\infty}^{+\infty} \frac{du}{a^2 u^2 + b^2} = \frac{1}{ab} \left[\arctan \frac{au}{b} \right]_{-\infty}^{+\infty} = \frac{\pi}{ab},$$

and over the full period this doubles: $2\pi/(ab)$. $\checkmark$

Step 5 — reading. The integral does not depend on a and b : the total curvature is 2π for every ellipse, for the circle ($a = b$) as for a very elongated ellipse. This is exactly the topological invariance asserted by Theorem 4.1: flattening the ellipse concentrates the curvature at the two ends without changing its integral.

4.9.4 Solutions to the symbolic exercises

Solution. S1. *Step 1 — the distance function.* Let c be the centre of the containing circle and put

$$f(s) = \|\gamma(s) - c\|^2.$$

f is continuous and periodic, hence attains a maximum at some s_0 ; let $d = \sqrt{f(s_0)} \leq R$ be the maximal distance.

Step 2 — first-order condition.

$$f'(s) = 2\langle \gamma(s) - c, T(s) \rangle,$$

which vanishes at s_0 : the vector $\gamma(s_0) - c$ is orthogonal to $T(s_0)$, hence parallel to $N(s_0)$: $\gamma(s_0) - c = \lambda N(s_0)$ with $|\lambda| = d$.

Step 3 — second-order condition. Differentiating again and using $T' = kN$:

$$f''(s) = 2\left(\langle T, T \rangle + \langle \gamma - c, kN \rangle\right) = 2\left(1 + k\langle \gamma - c, N \rangle\right).$$

At a maximum $f''(s_0) \leq 0$, hence

$$1 + k(s_0) \lambda \leq 0 \implies k(s_0) \lambda \leq -1.$$

Step 4 — conclusion. Taking absolute values, $|k(s_0)| d \geq 1$, i.e.

$$|k(s_0)| \geq \frac{1}{d} \geq \frac{1}{R}.$$

Step 5 — equality case and reading. Equality $|k| = 1/R$ everywhere forces, by Theorem 2.5, the curve to be the circle itself. The result therefore reads: *no closed curve can lie inside a circle while being everywhere less curved than it.* It is the geometric analogue of the maximum principle, and the proof — a second-order comparison at a contact point — is its elementary form.

Solution. S2. *Step 1 — series expansion.* Since f is 2π -periodic and C^1 , write its real Fourier series (Chapter 4); the hypothesis $\int_0^{2\pi} f = 0$ means the constant coefficient vanishes:

$$f(\theta) = \sum_{n \geq 1} (a_n \cos n\theta + b_n \sin n\theta).$$

Step 2 — the two energies. By Parseval's identity (Theorem (Volume II, Chapter 4) of Chapter 4),

$$\int_0^{2\pi} f^2 = \pi \sum_{n \geq 1} (a_n^2 + b_n^2),$$

and since $f'(\theta) = \sum_{n \geq 1} n(-a_n \sin n\theta + b_n \cos n\theta)$ has coefficients na_n, nb_n (up to sign and swap, irrelevant for squares),

$$\int_0^{2\pi} f'^2 = \pi \sum_{n \geq 1} n^2 (a_n^2 + b_n^2).$$

Step 3 — difference.

$$\int_0^{2\pi} f'^2 - \int_0^{2\pi} f^2 = \pi \sum_{n \geq 1} (n^2 - 1)(a_n^2 + b_n^2) \geq 0,$$

since $n^2 - 1 \geq 0$ for $n \geq 1$.

Step 4 — equality case. The sum vanishes iff $a_n = b_n = 0$ for every $n \geq 2$, i.e. $f(\theta) = a_1 \cos \theta + b_1 \sin \theta$.

Step 5 — why the zero-mean hypothesis is needed. Without it the inequality is false: for $f \equiv 1$ we have $\int f'^2 = 0 < 2\pi = \int f^2$. Indeed the $n = 0$ term gives $n^2 - 1 = -1 < 0$, the only negative term of the sum. It plays the same role as the constant term in the proof of the isoperimetric inequality, where it is not cancelled but balanced by the perimeter.

Step 6 — connection. With $f = h - a_0$ (support function with its mean removed), Wirtinger's inequality gives a bound on $\int h'^2$; the full computation, carried out in Step 3 of the proof of Theorem 4.5, is a refined version of this inequality in which the $n = 1$ term is also tracked.

Solution. S3. *Step 1 — sum of the radii of curvature.* By Theorem 4.2(ii),

$$\rho(\theta) + \rho(\theta + \pi) = (h(\theta) + h(\theta + \pi)) + (h''(\theta) + h''(\theta + \pi)) = w(\theta) + w''(\theta) = w + 0 = w,$$

because w is constant and the second derivative of a constant is zero.

Step 2 — the chord between opposite points. From $u(\theta + \pi) = -u(\theta)$ and $u'(\theta + \pi) = -u'(\theta)$, Theorem 4.2(i) gives

$$\gamma(\theta + \pi) = -h(\theta + \pi)u(\theta) - h'(\theta + \pi)u'(\theta),$$

hence

$$\gamma(\theta) - \gamma(\theta + \pi) = (h(\theta) + h(\theta + \pi))u(\theta) + (h'(\theta) + h'(\theta + \pi))u'(\theta).$$

Step 3 — the tangential term vanishes. Differentiating the identity $h(\theta) + h(\theta + \pi) = w$ (constant) gives $h'(\theta) + h'(\theta + \pi) = 0$. Hence

$$\gamma(\theta) - \gamma(\theta + \pi) = w u(\theta).$$

Step 4 — double normal. The vector $u(\theta)$ is the normal to γ at $\gamma(\theta)$ and is also, up to sign, the normal at $\gamma(\theta + \pi)$: the chord joining the two points is therefore *orthogonal to the curve at both*. It is called a *double normal*; its length is w .

Step 5 — the diameter. For any pair of points $P, Q \in K$, the distance $|PQ|$ does not exceed the width of K in the direction of $P - Q$, which is w . Hence $\text{diam}(K) \leq w$; and Step 3 exhibits pairs at distance exactly w . So $\text{diam}(K) = w$.

Step 6 — mechanical consequence. Step 1 says the two opposite radii of curvature are complementary to w : where the curve is very curved (ρ small) the opposite point is very flat. That is why a body of constant width rolls under a plank keeping its height constant — but its *centre* oscillates, and for that reason it cannot replace a wheel on an axle.

Solution. S4. *Step 1 — support function of the parallel body.* K_d is the set of points at distance $\leq d$ from K , i.e. the Minkowski sum $K + D_d$ with D_d the disc of radius d . Since the support function of a Minkowski sum is the sum of the support functions (immediate from Definition 4.2: the maximum of a sum of independent terms is the sum of the maxima), and since the disc of radius d has constant support function d :

$$h_d(\theta) = h(\theta) + d.$$

Step 2 — perimeter. By Cauchy's formula (Theorem 4.2(iii)),

$$L_d = \int_0^{2\pi} (h + d) d\theta = L + 2\pi d.$$

Step 3 — area. Since $h'_d = h'$,

$$A_d = \frac{1}{2} \int_0^{2\pi} [(h+d)^2 - h'^2] d\theta = \frac{1}{2} \int_0^{2\pi} (h^2 - h'^2) d\theta + d \int_0^{2\pi} h d\theta + \frac{d^2}{2} \int_0^{2\pi} d\theta,$$

that is

$$A_d = A + Ld + \pi d^2.$$

Step 4 — interpretation. Ld is the area of the “strip” of width d built along the boundary; πd^2 is the area of the circular sectors filling the exterior angles. By Theorem 4.1, the exterior angles of a simple closed curve total 2π : the sectors therefore reassemble into a *full disc* of radius d , of area πd^2 . The formula thus also holds for polygons, where the sectors are concentrated at the vertices.

Step 5 — check on the circle. With K the circle of radius r : $L = 2\pi r$, $A = \pi r^2$, and K_d is the circle of radius $r + d$:

$$L_d = 2\pi(r + d) = 2\pi r + 2\pi d \checkmark, \quad A_d = \pi(r + d)^2 = \pi r^2 + 2\pi r d + \pi d^2 = A + Ld + \pi d^2 \checkmark.$$

Step 6 — check on the degenerate segment. For K a segment of length ℓ (degenerate convex body, $L = 2\ell$, $A = 0$), K_d is a “stadium”: two half-discs of radius d and a rectangle $\ell \times 2d$. $\text{Area} = 2\ell d + \pi d^2 = A + Ld + \pi d^2 \checkmark$; $\text{perimeter} = 2\ell + 2\pi d = L + 2\pi d \checkmark$.

Solution. S5. *Step 1 — translating central symmetry.* If K has a centre of symmetry, choose the origin there: then $K = -K$. By Definition 4.2,

$$h_{-K}(\theta) = \max_{x \in K} \langle -x, u(\theta) \rangle = \max_{x \in K} \langle x, -u(\theta) \rangle = h(\theta + \pi),$$

so $K = -K$ is equivalent to $h(\theta) = h(\theta + \pi)$ for every θ .

Step 2 — combining with constant width. The constant-width hypothesis is $h(\theta) + h(\theta + \pi) = w$. Substituting Step 1,

$$2h(\theta) = w \implies h(\theta) = \frac{w}{2} \quad \text{for every } \theta.$$

Step 3 — conclusion. A constant support function $= w/2$ is, by Step 5 of the proof of Theorem 4.2, that of the circle of radius $w/2$ centred at the origin. So K is a circle.

Step 4 — the Reuleaux triangle. It has constant width (Example 4.1) but is not a circle — its area is 89.73% of that of the circle of equal width — hence, by Steps 1–3, it has no centre of symmetry. $\checkmark$

Step 5 — reading. The result singles out the circle at the intersection of two properties neither of which suffices on its own: constant width (shared with infinitely many other figures, by Theorem 4.3) and central symmetry (shared with ellipses, rectangles, parallelograms). It is another instance of the chapter’s recurrent motif: the circle as an equality case, or as the intersection of families.

Step 6 — a technical consequence. No constant-width profile other than the circle can rotate about a fixed axis through a centre: there is no centre. That is why bodies of constant width can *roll* under a plank but cannot serve as a wheel on a hub.

4.10. Self-assessment quiz

Eight items in order of competence; the commented answers are in the Teacher’s key (Section 4.11).

-
1. (Definition) A *vertex* of a regular plane curve is a point where
 - A) the curvature vanishes, $k(s) = 0$ B) the curvature is stationary, $k'(s) = 0$ C) the curve meets its own evolute D) the tangent is parallel to the axis of ordinates
 2. (Hypothesis) In the Umlaufsatz, the hypothesis that brings the rotation index to the value ± 1 , rather than to an arbitrary integer, is that the curve be
 - A) convex B) simple, that is free of self-intersections C) of class C^∞ D) of constant curvature sign
 3. (Symbolic computation) If $h(\theta) = 1 + \varepsilon \cos n\theta$ is a support function, the radius of curvature $\rho = h + h''$ equals
 - A) $1 + (n^2 - 1)\varepsilon \cos n\theta$ B) $1 - (n^2 - 1)\varepsilon \cos n\theta$ C) $1 - n^2\varepsilon \cos n\theta$ D) $1 + \varepsilon \cos n\theta$
 4. (Numerical computation) The Reuleaux triangle of width $w = 1$ has area and ratio to the circle of diameter 1 equal to
 - A) $A = \frac{\pi - \sqrt{3}}{2} = 0.704771$, that is 89.73% B) $A = \frac{\pi}{4} = 0.785398$, that is 100% C) $A = \pi - \sqrt{3} = 1.409542$, that is 179.47% D) $A = \frac{\sqrt{3}}{2} = 0.866025$, that is 110.27%
 5. (Proof step) In the proof of the global Gauss–Bonnet theorem the passage from the expression $2\pi V - \pi F$ to $2\pi\chi = 2\pi(V - E + F)$ is obtained
 - A) from the additivity of the integral over the triangles B) from the relation $3F = 2E$, that is from the fact that every edge belongs to two faces C) from the existence of a geodesic triangulation D) from the local form of Gauss–Bonnet on a single triangle
 6. (Error diagnosis) A student computes the area of a convex body from its support function as $A = \frac{1}{2} \int_0^{2\pi} h^2 d\theta$; for $h = 1 + 0.1 \cos 3\theta$ he obtains $A = 3.157301$ and concludes that this convex body has a larger area than the circle of equal perimeter $L = 2\pi$. The mistake is
 - A) having omitted the term $-h'^2$ in Cauchy's formula for the area, which instead gives $A = 3.015929 < \pi$ B) having miscomputed the perimeter, which is not 2π C) having integrated over $[0, 2\pi]$ instead of over $[0, \pi]$ D) having used an h which for $\varepsilon = 0.1$ is not the support function of any convex body
 7. (Transfer) A ground shaft is inspected by measuring its diameter with a vernier calliper in many directions: all the readings give 40.00 mm. Can one conclude that the cross section is circular?
 - A) yes, because constant width characterises the circle B) no: every profile of constant width gives the same reading, and for a Reuleaux triangle the circularity error would be 6.188 mm C) yes, provided the calliper is calibrated according to ISO 1101 D) no, but only because the calliper has finite resolution
 8. (Source and metacognition) The elementary proof of the four-vertex theorem in the *general* case (simple, not necessarily convex curves) by means of the minimal circumscribed circle, followed in Section 4.5.1, is found in
 - A) S. Mukhopadhyaya, Bulletin of the Calcutta Mathematical Society **1** (1909) B) R. Osserman, *The Four-or-More Vertex Theorem*, The American Mathematical Monthly **92**(5), 1985, pp. 332–337 C) H. Hopf, Compositio Mathematica **2** (1935) D) A. Hurwitz, Annales de l'École Normale Supérieure **19** (1902)

4.10.1 Supplementary questionnaire

1. The total curvature of a simple closed curve is
A) π B) 2π C) shape-dependent D) 4π
2. The formula $\rho = h + h''$ relates the radius of curvature to
A) arc length B) the support function C) the area D) the width
3. Cauchy's formula for the perimeter of a convex body is
A) $L = \int h \, d\theta$ B) $L = \int h^2 d\theta$ C) $L = 2\pi h$ D) $L = \int h' \, d\theta$
4. Barbier's theorem states that a curve of constant width w has perimeter
A) $2\pi w$ B) πw C) $\pi w/2$ D) shape-dependent
5. Among convex bodies of constant width w , the minimum area is attained by
A) the circle B) the Reuleaux triangle C) the square D) none
6. Does a vernier calliper distinguish a cylinder from a Reuleaux profile?
A) yes B) no, it measures the same width in every direction C) only if calibrated
D) only for large diameters
7. The isoperimetric inequality states
A) $4\pi A \leq L^2$ B) $4\pi A \geq L^2$ C) $A \leq L$ D) $A = L^2/4\pi$
8. In the isoperimetric equality case the curve is
A) an ellipse B) a circle C) a regular polygon D) a constant-width curve
9. The four-vertex theorem states that every simple closed curve has at least
A) two points of stationary curvature B) four C) three D) none
10. The vertices of a curve correspond, on the evolute, to
A) regular points B) cusps C) inflections D) asymptotes
11. A convex body of constant width with a centre of symmetry is
A) a square B) a circle C) an ellipse D) a Reuleaux triangle
12. The global Gauss–Bonnet theorem states that, for a compact orientable surface without boundary, $\iint_M K \, dA$ equals
A) $2\pi\chi(M)$ B) 4π for every M C) 0 for every M D) the area of M
13. In a triangulation of a compact surface without boundary one always has
A) $2F = 3E$ B) $3F = 2E$ C) $F = E$ D) $V = E - F$
14. The Euler characteristic of a triangulation of the torus equals
A) 2 B) 0 C) -2 D) it depends on the chosen triangulation

BEST PRACTICE

Quiz — answers, rationales and diagnosis.

1) B. *Rationale*: this is Definition 4.4: a vertex is a critical point of the curvature, $k'(s) = 0$, not a point where the curvature vanishes. *Distractors*: A confuses the vertex with the inflection ($k = 0$); C describes a property that vertices in general do not have; D depends on the frame of reference, whereas the notion of vertex is invariant under rigid motions. *Diagnosed error*: confusion between the vanishing of k and the stationarity of k . *Source*: Definition 4.4 and Theorem 4.6. *Prerequisite*: critical point of a differentiable function. *Remedial work*: compute k and k' for the ellipse (Remark 4.8) and mark the four vertices, checking that $k \neq 0$ at each of them.

2) B. *Rationale*: Theorem 4.1 holds for every closed regular curve with $\text{ind} \in \mathbb{Z}$ (Definition 4.1); it is the hypothesis of *simplicity* that forces $\text{ind} = \pm 1$, and the sign depends only on the orientation. *Distractors*: A is stronger than necessary (convex curves are a subset of the simple ones); C is not needed, C^2 suffices; D is false as a hypothesis and false as a conclusion: the curve of Exercise 4.6 is simple with k of varying sign and still has index 1. *Diagnosed error*: attributing to convexity what depends on the absence of self-intersections. *Source*: Theorem 4.1 (Hopf 1935). *Prerequisite*: continuous lifting of the tangent angle. *Remedial work*: compute the index of a lemniscate (which is closed and regular but not simple) and compare it with ± 1 .

3) B. *Rationale*: $h'' = -n^2 \varepsilon \cos n\theta$, hence $\rho = h + h'' = 1 - (n^2 - 1)\varepsilon \cos n\theta$: this is Step 1 of Exercise 4.8. *Distractors*: A gets the sign wrong and would suggest that the admissible amplitude grows with n ; C forgets the contribution of h and gives $\rho < 0$ already for $\varepsilon > 1/n^2$; D confuses ρ with h . *Diagnosed error*: applying $\rho = h + h''$ without differentiating twice, or getting the sign of $\cos''$ wrong. *Source*: Theorem 4.2(ii). *Prerequisite*: derivatives of $\cos n\theta$. *Remedial work*: check that for $\varepsilon = 0$ one recovers the unit circle, $\rho \equiv 1$.

4) A. *Rationale*: for $n = 3$ the formula $A_n = \frac{1}{2}(\pi - n \tan \frac{\pi}{2n})w^2$ of Exercise 4.5(b) gives $A_3 = \frac{1}{2}(\pi - 3 \tan \frac{\pi}{6}) = \frac{1}{2}(\pi - \sqrt{3}) = 0.704771$, against $\pi/4 = 0.785398$ for the circle: the ratio is 0.897342, that is 89.73%. *Distractors*: B is the area of the circle and contradicts Theorem 4.4(ii), which gives the Reuleaux triangle as the *strict* minimum; C forgets the factor $\frac{1}{2}$ and exceeds the area of the circle, contradicting Theorem 4.4(i); D is the area of the equilateral triangle of side 1, that is of the figure *before* replacing the sides with the arcs. *Diagnosed error*: using the formula without the plausibility check $A_{\text{Reuleaux}} < A_{\text{circle}}$. *Source*: Theorem 4.4 and Example 4.1; values recomputed in `verifica_cap02_cap04.py`, block [C4-2]. ✓ *Prerequisite*: $\tan(\pi/6) = 1/\sqrt{3}$. *Remedial work*: tabulate A_n/A_c for $n = 3, 5, 7$ and observe the monotonicity.

5) B. *Rationale*: Step 4 of the proof of Theorem 4.8 reaches $2\pi V - \pi F$; Step 5 uses $E = \frac{3}{2}F$, that is Lemma 4.12, to rewrite $2\pi(V - E + F)$ in the same form. *Distractors*: A is needed at Step 2, to split the integral over the triangles; C is (P2), the hypothesis that makes Step 1 possible; D is (P1), used at Step 3. *Diagnosed error*: failing to distinguish which of the four ingredients acts at which step. *Source*: Theorem 4.8, Steps 4–5, and Lemma 4.12. *Prerequisite*: double counting of a finite set. *Remedial work*: redo Steps 4–5 on the octahedron (Example 4.2) substituting the numbers line by line.

6) A. *Rationale*: Cauchy's formula for the area is $A = \frac{1}{2} \int_0^{2\pi} (h^2 - h'^2) d\theta$ (Theorem 4.2(iv)):

the term $-h'^2$ is not a detail, it is what makes the isoperimetric inequality true. With $h = 1 + 0.1 \cos 3\theta$ one has $\frac{1}{2} \int h^2 = 3.157301$ but $\frac{1}{2} \int (h^2 - h'^2) = 3.015929 < \pi = 3.141593$, in agreement with Step 5 of Exercise 4.8, which predicts $A = \pi - 4\pi\varepsilon^2 = \pi - 0.125664$. *Distractors*: B is false, Step 3 of the same exercise gives $L = 2\pi$ exactly; C would change the domain of a 2π -periodic function for no reason; D is false, the convexity threshold for $n = 3$ is $|\varepsilon| < 1/8 = 0.125$ and 0.1 respects it. *Diagnosed error*: memorising the area formula by analogy with the polar one $\frac{1}{2} \int r^2$, which holds for a different parametrisation. *Source*: Theorem 4.2(iv); numerical check in `verifica_cap02_cap04.py`, block [C4-1]. ✓ *Prerequisite*: $\int_0^{2\pi} \cos^2 = \int_0^{2\pi} \sin^2 = \pi$. *Remedial work*: compute the two expressions for $h \equiv 1$ (where they coincide) and for $h = 1 + \varepsilon \cos 3\theta$ (where they do not), and explain the difference.

7) **B. Rationale**: the calliper measures the width $w(\theta) = h(\theta) + h(\theta + \pi)$ (Definition 4.3), which is constant for *all* curves of constant width, not only for the circle; worked Exercise 4.10 computes for the Reuleaux triangle with $w = 40$ mm the radii $R = 23.094011$ mm and $r = 16.905989$ mm, that is a circularity error $R - r = 6.188022$ mm. *Distractors*: A reverses the implication: the circle has constant width, but it is not the only one; C attributes to calibration a problem of principle, and ISO 1101 defines circularity precisely as $R - r$, which the calliper does not measure; D mistakes a systematic error of method for an error of resolution. *Diagnosed error*: mistaking a necessary condition for a sufficient one. *Source*: Theorem 4.3, Example 4.1, Exercise 4.10; ISO 1101. *Prerequisite*: the distinction between width and diameter. *Remedial work*: draw the Reuleaux triangle between two parallel lines and rotate it, then between two concentric circles.

8) **B. Rationale**: the proof followed in Section 4.5.1 is Osserman's, based on the minimal circumscribed circle and on the contact set (Lemmas 4.6 and 4.7). *Distractors*: A is the first statement, but for convex curves *only*; C is the Umlaufsatz; D is the isoperimetric proof by Fourier series. *Diagnosed error*: citing the paper that gave the theorem its name instead of the one containing the proof used. *Source*: R. Osserman, The American Mathematical Monthly **92**(5), 1985, pp. 332–337, doi:10.2307/2323126. *Prerequisite*: being able to tell historical priority from the source of the proof. *Remedial work*: compare the years (1909, 1912, 1935, 1985, 2021) with the results listed in the *Sources* section.

BEST PRACTICE

Assigned exercises — answers.

4.5 (Reuleaux polygons). (a) The supporting lines orthogonal to any direction touch the profile at a vertex and on the opposite arc, of radius w centred at that vertex: the distance is w for every direction, hence the width is constant and by Theorem 4.3 $L = \pi w$, the same perimeter as the circle of diameter w . (b) The profile is the union of the regular n -gon and of n circular segments; adding the areas and simplifying one obtains $A_n = \frac{1}{2}(\pi - n \tan \frac{\pi}{2n})w^2$. (c) For $w = 1$: $A_3 = 0.704771$, $A_5 = 0.758497$, $A_7 = 0.771944$, against $A_{\text{circle}} = \pi/4 = 0.785398$; the ratios are 89.7342%, 96.5748% and 98.2870%. (d) $A_9 = 0.777325$ (98.9721%), $A_{51} = 0.785150$ (99.9684%), $A_{501} = 0.785396$ (99.9997%), $A_{5001} = 0.785398$: the sequence increases and tends to $\pi w^2/4$, because $n \tan \frac{\pi}{2n} \rightarrow \pi/2$. (e) All these convex bodies have the same perimeter πw but different areas, between the minimum $A_3 = \frac{\pi - \sqrt{3}}{2}w^2$ and the maximum $\pi w^2/4$: they are an explicit family filling almost the whole interval predicted by Theorem 4.4, and they show that both extremes are attained only at the ends of the family. Values recomputed in `verifica_cap02_cap04.py`, block [C4-2]. ✓

4.6 (three-lobed polar curve, $a = 0.3$). (a) $r(\theta) = 1 + 0.3 \cos 3\theta \in [0.7; 1.3]$ is always positive, so the curve does not pass through the origin; $\theta \mapsto \theta$ is injective on $[0, 2\pi)$ and different radii give different points, so the curve is simple; it is closed and regular because $r^2 + r'^2 > 0$.

(b) $A = \frac{1}{2} \int_0^{2\pi} r^2 d\theta = \pi(1 + \frac{a^2}{2}) = 1.045\pi = 3.282964$, confirmed by Simpson quadrature with the same value to nine decimal places. (c) $L = \int_0^{2\pi} \sqrt{r^2 + r'^2} d\theta = 7.426640$, hence $L^2/(4\pi A) = 1.336930 > 1$ and $L^2 - 4\pi A = 13.900034 > 0$: the inequality of Theorem 4.5 holds and is widely strict, as it must be for a curve that is not a circle. (d) $\int k ds = 2\pi$ to seven decimal places, that is $\text{ind}(\gamma) = 1$ (Theorem 4.1): the curve is simple and traversed counterclockwise. (e) k' changes sign at six points, $\theta = 0, \frac{\pi}{3}, \frac{2\pi}{3}, \pi, \frac{4\pi}{3}, \frac{5\pi}{3}$, that is the three maxima and the three minima of r : six vertices, at least four as Theorem 4.6 requires. The curve is *not* convex: $k(0) = 2.366864 > 0$ but $k(\pi/3) = -4.081633 < 0$; the general form of Theorem 4.7 therefore applies. Checks in `verifica_cap02_cap04.py`, block [C4-3]. ✓

4.7 (Gauss–Bonnet on two triangulations). (a) Icosahedron: $V = 12, E = 30, F = 20$; $3F = 60 = 2E$ (Lemma 4.12) ✓, $\chi = 12 - 30 + 20 = 2$, $2\pi V - \pi F = 24\pi - 20\pi = 4\pi = 2\pi\chi$ and $\iint K dA = 4\pi$, the same value as for the octahedron. (b) The total angular excess is $\iint K dA = 4\pi$ shared among F triangles: for the icosahedron $4\pi/20 = \pi/5 = 0.628319$ rad $= 36^\circ$, for the octahedron $4\pi/8 = \pi/2 = 1.570796$ rad $= 90^\circ$. The finer the triangulation, the more the triangles are «almost Euclidean»: the average excess tends to zero like $1/F$, but its sum stays 4π . (c) Diagonalised 3×3 grid: $V = 9, E = 27, F = 18, 3F = 54 = 2E$ ✓, $\chi = 0$ ✓. Minimal triangulation (Császár polyhedron): $V = 7, E = 21, F = 14, 3F = 42 = 2E$ ✓, $\chi = 0$ ✓. (d) Because by (P3) of Remark 4.9 χ does not depend on the triangulation: from $3F = 2E$ it follows that $E = \frac{3}{2}F$ and hence $\chi = V - \frac{1}{2}F$, that is V and F are tied by $V = \chi + \frac{1}{2}F$; as F grows, V grows in the same proportion and the difference stays 0. (e) It exists: take the 5×10 grid of the fundamental square with each cell divided by a diagonal. Then $F = 2 \times 5 \times 10 = 100, E = 3 \times 50 = 150, V = 50$, and $\chi = 50 - 150 + 100 = 0$ ✓; the general constraints $E = \frac{3}{2}F$ and $V = \frac{1}{2}F$ are satisfied, and $F = 100$ is even, as it must be for $E = \frac{3}{2}F$ to be an integer. All the counts are repeated in `verifica_cap02_cap04.py`, block [C4-4]. ✓

4.12. Chapter formulary

Rotation index

$$\int_0^L k ds = 2\pi \text{ind}(\gamma); \quad \gamma \text{ closed simple} \Rightarrow \text{ind} = \pm 1$$

Support function

$$h(\theta) = \max_{x \in K} \langle x, u(\theta) \rangle, \quad \gamma(\theta) = hu + h'u', \quad \rho = h + h''$$

$$L = \int_0^{2\pi} h d\theta, \quad A = \frac{1}{2} \int_0^{2\pi} (h^2 - h'^2) d\theta$$

Width and Barbier's theorem

$$w(\theta) = h(\theta) + h(\theta + \pi); \quad w \text{ constant} \Rightarrow L = \pi w, \quad \rho(\theta) + \rho(\theta + \pi) = w$$

$$\text{Reuleaux : } A = \frac{\pi - \sqrt{3}}{2} w^2 \approx 0.70477 w^2; \quad \text{circle : } A = \frac{\pi w^2}{4} \approx 0.78540 w^2$$

Isoperimetric inequality

$$4\pi A \leq L^2, \quad \frac{L^2}{4\pi} - A = \frac{\pi}{2} \sum_{n \geq 2} (n^2 - 1)(a_n^2 + b_n^2)$$

Steiner's formulas (parallel curves)

$$L_d = L + 2\pi d, \quad A_d = A + Ld + \pi d^2$$

Convex bodies prescribed by a single harmonic

$$h(\theta) = 1 + \varepsilon \cos n\theta \implies \rho = 1 - (n^2 - 1)\varepsilon \cos n\theta, \quad |\varepsilon| < \frac{1}{n^2 - 1},$$

$$L = 2\pi, \quad A = \pi - \frac{(n^2 - 1)\pi\varepsilon^2}{2}, \quad \frac{L^2}{4\pi} - A = \frac{(n^2 - 1)\pi\varepsilon^2}{2}$$

Reuleaux polygons (n odd, width w)

$$L = \pi w, \quad A_n = \frac{1}{2} \left(\pi - n \tan \frac{\pi}{2n} \right) w^2, \quad A_3 = \frac{\pi - \sqrt{3}}{2} w^2, \quad A_n \nearrow \frac{\pi w^2}{4}$$

$$\text{Reuleaux triangle: } R = \frac{w}{\sqrt{3}}, \quad r = w - R, \quad R + r = w, \quad R - r = w \left(\frac{2}{\sqrt{3}} - 1 \right)$$

Triangulations and Euler characteristic

$$3F = 2E, \quad \chi = V - E + F = V - \frac{F}{2}, \quad \sum_{i=1}^F (\alpha_i + \beta_i + \gamma_i) = 2\pi V$$

Global Gauss–Bonnet

$$\iint_M K \, dA = 2\pi V - \pi F = 2\pi \chi(M); \quad \chi = 2 - 2g \quad (\text{closed orientable})$$

$$\chi(S^2) = 2 \implies \iint K \, dA = 4\pi; \quad \chi(T^2) = 0 \implies \iint K \, dA = 0$$

Angular defect (Descartes, discrete version)

$$\delta_p = 2\pi - \sum_{T \ni p} \vartheta_T(p), \quad \sum_p \delta_p = 2\pi V - \pi F = 2\pi \chi = 4\pi \quad (\text{convex polyhedron})$$

Isometries and the orthogonal group

A circle does not change if one rotates it about its own centre, and it does not change if one reflects it in any one of its diametral lines. This visual triviality conceals a precise and surprisingly strong statement: the transformations of the plane that preserve distances and fix a point form a group, the **orthogonal group** $O(2)$, and the circle is not merely a figure invariant under that group — it is, among all centred conics, the *only* invariant figure. The circle, in other words, is not defined only by its equation: it is defined by its symmetries.

The chapter follows this idea in four steps. First we prove that every isometry of the plane has the form $x \mapsto Ax + b$ with A orthogonal (and hence that isometries map circles to circles, with the same radius: result R1.5 of the Plan). Then we classify $O(2)$: only two families, rotations and reflections, and $SO(2)$ is the circle itself, both as a group and as a topological space. Then we prove, by a computation with quadratic forms, that the circle is the only centred conic invariant under all of $O(2)$. Finally we go up one dimension: Euler's rotation theorem says that every element of $SO(3)$ is a rotation about an axis, and that axis exists because $+1$ is always an eigenvalue. It is the bridge towards orientation in space, quaternions and robot kinematics.

INFO

Level and prerequisites. Level **A–C** (secondary school for the geometric part, first-year STEM for the classification of $O(2)$, undergraduate for the final section on $SO(3)$).

Internal prerequisites. Metric definition of the circle and Euclidean distance (Volume I, Chapter 2); scalar product, norm and orthogonality in the Cartesian plane (Volume I, Chapter 7); polar form of complex numbers and the exponential $e^{i\theta}$ (Volume II, Chapter 3); conics in canonical form (Volume II, Chapter 5, and Chapter 2 of this volume for plane curves).

External prerequisites, assumed and not reproved (a first course in linear algebra):

- the determinant of a square matrix, with $\det(AB) = \det A \cdot \det B$ and $\det A^\top = \det A$;
- the characteristic polynomial $p_A(\lambda) = \det(A - \lambda I)$; the eigenvalues are its roots;
- the fundamental theorem of algebra (a polynomial of degree n has n complex roots counted with multiplicity) and the fact that the complex roots of a polynomial with real coefficients come in conjugate pairs;
- a square matrix with linearly independent columns is invertible.

Everything else — the classification of $O(2)$, the spectrum, the uniqueness of the invariant conic, Euler's theorem — is proved here.

What one learns. How to recognise an isometry from its matrix; how to classify the elements of $O(2)$ and compose them without multiplying matrices; how to prove that the circle is characterised by its symmetries; how to find the axis and the angle of a rotation of space starting from its matrix.

Warning. Conventions of this chapter.

- Vectors of $\mathbb{R}^n$ are *columns*; $x^\top y = \langle x, y \rangle$ is the standard scalar product and $|x| = \sqrt{x^\top x}$ the Euclidean norm.
- I is the identity matrix (of order clear from the context) and $A^\top$ the transpose.

- Angles are in radians; rotations are *anticlockwise* (positive in the sense from $\mathbf{e}_1$ to $\mathbf{e}_2$).
- $C(P, r) = \{x : |x - P| = r\}$ is the circle of centre P and radius $r > 0$.
- $\mathbb{T} = \{z \in \mathbb{C} : |z| = 1\}$ is the unit circle of the complex plane, identified with $S^1 \subset \mathbb{R}^2$ via $x + iy \leftrightarrow (x, y)$.
- “Centred conic” means: a level set $\{x \in \mathbb{R}^2 : x^\top Q x = 1\}$ with Q a real symmetric 2×2 matrix. The centre is therefore the origin by construction.

5.1. Isometries of the plane and orthogonal matrices

Definition 5.1: Isometry. An **isometry** of $\mathbb{R}^n$ is a map $f : \mathbb{R}^n \rightarrow \mathbb{R}^n$ that preserves distances:

$$|f(x) - f(y)| = |x - y| \quad \text{for all } x, y \in \mathbb{R}^n.$$

Neither linearity nor continuity nor surjectivity is required: they are consequences, as we shall see.

Definition 5.2: Orthogonal matrices. A real matrix A of order n is **orthogonal** if $A^\top A = I$. The set

$$O(n) = \{A \in \mathbb{R}^{n \times n} : A^\top A = I\}$$

is the **orthogonal group**; the subset $SO(n) = \{A \in O(n) : \det A = +1\}$ is the **special orthogonal group**, or group of proper rotations.

Proposition 5.1: Three equivalent characterisations. For a real matrix A of order n the following are equivalent:

- (i) $A^\top A = I$ (that is, $A \in O(n)$);
- (ii) $|Ax| = |x|$ for every $x \in \mathbb{R}^n$;
- (iii) $(Ax)^\top (Ay) = x^\top y$ for all $x, y \in \mathbb{R}^n$;
- (iv) the columns of A form an orthonormal basis of $\mathbb{R}^n$.

Proof. **(i) $\Rightarrow$ (ii).** $|Ax|^2 = (Ax)^\top (Ax) = x^\top A^\top A x = x^\top I x = x^\top x = |x|^2$, and norms are ≥ 0 : hence $|Ax| = |x|$.

(ii) $\Rightarrow$ (iii). Apply (ii) to $x + y$:

$$|A(x + y)|^2 = |Ax + Ay|^2 = |Ax|^2 + 2(Ax)^\top (Ay) + |Ay|^2 = |x|^2 + 2(Ax)^\top (Ay) + |y|^2,$$

whereas $|A(x + y)|^2 = |x + y|^2 = |x|^2 + 2x^\top y + |y|^2$. Equating and cancelling $|x|^2 + |y|^2$ we obtain $2(Ax)^\top (Ay) = 2x^\top y$, that is, (iii).

(iii) $\Rightarrow$ (i). Let $\mathbf{e}_1, \dots, \mathbf{e}_n$ be the vectors of the canonical basis. The (i, j) entry of $A^\top A$ is $(A\mathbf{e}_i)^\top (A\mathbf{e}_j)$, which by (iii) equals $\mathbf{e}_i^\top \mathbf{e}_j = \delta_{ij}$: hence $A^\top A = I$.

(i) $\Leftrightarrow$ (iv). The j -th column of A is $A_j = Ae_j$, and the (i, j) entry of $A^\top A$ is $A_i^\top A_j$. To say $A^\top A = I$ is therefore exactly to say $A_i^\top A_j = \delta_{ij}$, that is, that the n columns are pairwise orthogonal and of norm 1. An orthonormal system of n vectors in $\mathbb{R}^n$ is linearly independent (if $\sum_j c_j A_j = 0$, taking the scalar product with A_i gives $c_i = 0$), hence it is a basis. $\square$

Corollary 5.1: $O(n)$ is a group and $\det A = \pm 1$. $O(n)$ is a group under matrix multiplication, with $A^{-1} = A^\top$; for every $A \in O(n)$ one has $\det A = \pm 1$; and $SO(n)$ is a subgroup of $O(n)$.

Proof. From $A^\top A = I$ it follows that A is invertible (the columns are a basis by Proposition 5.1(iv)) and that $A^{-1} = A^\top$; then also $AA^\top = I$, that is, $(A^\top)^\top A^\top = I$: the transpose $A^{-1} = A^\top$ is orthogonal. If $A, B \in O(n)$ then $(AB)^\top(AB) = B^\top A^\top AB = B^\top B = I$, hence $AB \in O(n)$; and $I \in O(n)$. The determinant: $1 = \det I = \det(A^\top A) = \det A^\top \cdot \det A = (\det A)^2$, hence $\det A = \pm 1$. Finally, $\det(AB) = \det A \det B = 1$ and $\det(A^{-1}) = (\det A)^{-1} = 1$ for $A, B \in SO(n)$: $SO(n)$ is a subgroup. $\square$

Theorem 5.1: Structure of isometries: $f(x) = Ax + b$. Let $f : \mathbb{R}^n \rightarrow \mathbb{R}^n$ be an isometry. Then there exist a unique $A \in O(n)$ and a unique $b \in \mathbb{R}^n$ such that

$$f(x) = Ax + b \quad \text{for every } x \in \mathbb{R}^n.$$

In particular every isometry is affine, bijective, and its inverse is again an isometry.

Proof. **Step 1 — reduction to the case $f(0) = 0$.** Set $b = f(0)$ and $g(x) = f(x) - b$. Then $g(0) = 0$ and g is still an isometry, because $|g(x) - g(y)| = |f(x) - f(y)| = |x - y|$. It suffices to prove that g is linear with orthogonal matrix.

Step 2 — g preserves the norm. From $g(0) = 0$: $|g(x)| = |g(x) - g(0)| = |x - 0| = |x|$.

Step 3 — g preserves the scalar product. For all x, y ,

$$|x - y|^2 = |g(x) - g(y)|^2 = |g(x)|^2 - 2g(x)^\top g(y) + |g(y)|^2 = |x|^2 - 2g(x)^\top g(y) + |y|^2,$$

using Step 2; but $|x - y|^2 = |x|^2 - 2x^\top y + |y|^2$. Comparing, $g(x)^\top g(y) = x^\top y$ for all x, y .

Step 4 — g is linear. Let $u_i = g(e_i)$, $i = 1, \dots, n$. By Step 3, $u_i^\top u_j = e_i^\top e_j = \delta_{ij}$: the u_i form an orthonormal basis of $\mathbb{R}^n$. Fix $x \in \mathbb{R}^n$ and expand $g(x)$ in this basis: since the basis is orthonormal, $g(x) = \sum_i (u_i^\top g(x)) u_i$. But by Step 3

$$u_i^\top g(x) = g(e_i)^\top g(x) = e_i^\top x = x_i,$$

hence $g(x) = \sum_i x_i u_i = Ax$, where A is the matrix with columns $u_1, \dots, u_n$. The map $x \mapsto Ax$ is linear, and $A \in O(n)$ by Proposition 5.1(iv).

Step 5 — uniqueness and invertibility. If $Ax + b = A'x + b'$ for every x , setting $x = 0$ gives $b = b'$, and then $Ax = A'x$ for every x , that is, $A = A'$ (apply it to the vectors of the canonical basis). Since A is invertible, f is bijective with $f^{-1}(y) = A^{-1}(y - b) = A^\top y - A^\top b$, which is again of the form “orthogonal plus translation”, hence an isometry. $\square$

Theorem 5.2: Isometries map circles to circles (R1.5). Let f be an isometry of $\mathbb{R}^2$ and let $C(P, r)$ be a circle. Then

$$f(C(P, r)) = C(f(P), r) :$$

the image is a circle of equal radius, with centre the image of the centre. Moreover f preserves incidences: it maps lines to lines, chords to chords, tangents to tangents, and preserves the number of common points of two figures.

Proof. **Inclusion $\subseteq$.** If $|x - P| = r$, then $|f(x) - f(P)| = |x - P| = r$, hence $f(x) \in C(f(P), r)$.

Inclusion $\supseteq$. By Theorem 5.1 f is bijective and f^{-1} is an isometry. Let $y \in C(f(P), r)$ and $x = f^{-1}(y)$; then

$$|x - P| = |f^{-1}(y) - f^{-1}(f(P))| = |y - f(P)| = r,$$

hence $x \in C(P, r)$ and $y = f(x) \in f(C(P, r))$.

Incidences. By Theorem 5.1, $f(x) = Ax + b$ is affine and invertible: it maps the line $\{p + tv : t \in \mathbb{R}\}$ to the line $\{f(p) + tAv : t \in \mathbb{R}\}$ (and $Av \neq 0$ because A is invertible). Being

bijection, $f(X \cap Y) = f(X) \cap f(Y)$ for every pair of subsets, hence the number of common points is preserved; in particular a tangent line (a single common point with the circle) goes to a tangent line, a secant to a secant, an external line to an external one. The lengths of chords are preserved because f preserves distances. $\square$

Theorem 5.3: *$O(2)$ preserves every centred circle. For every $A \in O(2)$ and every $r > 0$, the map $x \mapsto Ax$ is a bijection of the circle $C(O, r) = \{x : |x| = r\}$ onto itself.*

Proof. This is the case $P = O$, $b = 0$ of Theorem 5.2: from $|Ax| = |x|$ (Proposition 5.1(ii)) we get $A(C(O, r)) \subseteq C(O, r)$, and since $A^{-1} = A^\top \in O(2)$ (Corollary 5.1) the same inclusion holds for A^{-1} , that is, $C(O, r) \subseteq A(C(O, r))$. $\square$

Remark 5.1: *The symmetry group of the circle is all of $O(2)$. Theorem 5.3 says that $O(2)$ is contained in the symmetry group of $C(O, r)$. The converse holds as well: an isometry f that maps $C(O, r)$ onto itself fixes the centre, because the centre is the only point equidistant from all the points of the circle (Volume I, Chapter 2), and therefore $f(0) = 0$: by Theorem 5.1 f has the form $x \mapsto Ax$ with $A \in O(2)$. The symmetry group of the circle is therefore exactly $O(2)$; it is an infinite, non-discrete group, unlike the finite dihedral group of a regular polygon. The fact is recorded, with the same statement, in the MIT algebra notes (RES.18-011, Lecture 14, Example 14.4), cited among the sources.*

Example 5.1: A concrete isometry, recognised from its matrix. Let

$$f(x) = Ax + b, \quad A = \frac{1}{5} \begin{pmatrix} 3 & -4 \\ 4 & 3 \end{pmatrix}, \quad b = \begin{pmatrix} 1 \\ -2 \end{pmatrix}.$$

The columns of A are $\frac{1}{5}(3, 4)^\top$ and $\frac{1}{5}(-4, 3)^\top$: they have norm $\frac{1}{5}\sqrt{9+16} = \frac{5}{5} = 1$ and scalar product $\frac{1}{25}(3 \cdot (-4) + 4 \cdot 3) = 0$. Hence $A \in O(2)$ by Proposition 5.1(iv), and $\det A = \frac{1}{25}(9 + 16) = 1$: it is a rotation, by the angle $\theta = \arccos \frac{3}{5}$. *Independent check:* $\cos \theta = 0.6$ and $\sin \theta = 0.8$ give $\theta = 0.927295 \text{ rad} = 53.130102^\circ$, and $\cos^2 \theta + \sin^2 \theta = 0.36 + 0.64 = 1$. $\checkmark$ The image of the circle $C((2, 1)^\top, 3)$ is, by Theorem 5.2, the circle of radius 3 and centre

$$f\left(\begin{pmatrix} 2 \\ 1 \end{pmatrix}\right) = \frac{1}{5} \begin{pmatrix} 3 \cdot 2 - 4 \cdot 1 \\ 4 \cdot 2 + 3 \cdot 1 \end{pmatrix} + \begin{pmatrix} 1 \\ -2 \end{pmatrix} = \frac{1}{5} \begin{pmatrix} 2 \\ 11 \end{pmatrix} + \begin{pmatrix} 1 \\ -2 \end{pmatrix} = \begin{pmatrix} 1.4 \\ 0.2 \end{pmatrix}.$$

Independent check: the point $(5, 1)^\top$ lies on $C((2, 1)^\top, 3)$; its image is $\frac{1}{5}(15 - 4, 20 + 3)^\top + (1, -2)^\top = (2.2, 4.6)^\top - (0, 0)^\top = (2.2, 4.6)^\top$, and $|(3.2, 2.6)^\top - (1.4, 0.2)^\top| = |(1.8, 2.4)^\top| = \sqrt{3.24 + 5.76} = \sqrt{9} = 3$. $\checkmark$

5.2. The classification of $O(2)$

Theorem 5.4: *Classification of $O(2)$. Every $A \in O(2)$ is, for a unique $\theta \in [0, 2\pi)$, a rotation or a reflection:*

$$R_\theta = \begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix} \quad (\det = +1), \quad S_\theta = \begin{pmatrix} \cos \theta & \sin \theta \\ \sin \theta & -\cos \theta \end{pmatrix} \quad (\det = -1).$$

Hence $O(2) = SO(2) \cup \{S_\theta\}$, with $SO(2) = \{R_\theta\}$.

Proof. Step 1 — the first column. Let $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in O(2)$. By Proposition 5.1(iv) the columns are orthonormal:

$$a^2 + c^2 = 1, \quad b^2 + d^2 = 1, \quad ab + cd = 0.$$

From $a^2 + c^2 = 1$ the point (a, c) lies on the unit circle, hence there exists exactly one $\theta \in [0, 2\pi)$ with $(a, c) = (\cos \theta, \sin \theta)$: this is the parametrisation of the circle (Volume II, Chapter 1), surjective and injective on $[0, 2\pi)$.

Step 2 — the second column. The condition $ab + cd = 0$ says that the vector (b, d) is orthogonal to $(a, c) = (\cos \theta, \sin \theta)$. In the plane the orthogonal complement of a non-zero vector is a line: indeed $\{(b, d) : ab + cd = 0\}$ is the kernel of the non-zero 1×2 matrix $(a \ c)$, which has rank 1, hence a kernel of dimension 1. A basis of this kernel is $(-\sin \theta, \cos \theta)$, because $\cos \theta \cdot (-\sin \theta) + \sin \theta \cdot \cos \theta = 0$ and the vector is non-zero. Hence $(b, d) = \lambda(-\sin \theta, \cos \theta)$ for some $\lambda \in \mathbb{R}$; the condition $b^2 + d^2 = 1$ gives $\lambda^2(\sin^2 \theta + \cos^2 \theta) = \lambda^2 = 1$, that is, $\lambda = \pm 1$.

Step 3 — the two cases. For $\lambda = +1$, $A = \begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix} = R_\theta$, with $\det A = \cos^2 \theta + \sin^2 \theta = +1$. For $\lambda = -1$, $A = \begin{pmatrix} \cos \theta & \sin \theta \\ \sin \theta & -\cos \theta \end{pmatrix} = S_\theta$, with $\det A = -\cos^2 \theta - \sin^2 \theta = -1$.

The two cases are mutually exclusive because $\det$ equals $+1$ in the first and -1 in the second, and θ is unique by Step 1.

Step 4 — every R_θ and every S_θ lies in $O(2)$. The columns of R_θ and of S_θ are orthonormal by construction, so the two families are indeed contained in $O(2)$: the classification is exact, not merely necessary. $\square$

Proposition 5.2: S_θ is the reflection in the line of inclination $\theta/2$. For every θ , the matrix S_θ fixes pointwise the line

$$\ell_\theta = \left\{ t \begin{pmatrix} \cos \frac{\theta}{2} \\ \sin \frac{\theta}{2} \end{pmatrix}^\top : t \in \mathbb{R} \right\}$$

and changes the sign of every vector orthogonal to ℓ_θ . Hence S_θ is the orthogonal reflection in the line through the origin making the angle $\theta/2$ with the x -axis. In particular $S_\theta^2 = I$.

Proof. Set $u = (\cos \frac{\theta}{2}, \sin \frac{\theta}{2})^\top$ and $v = (-\sin \frac{\theta}{2}, \cos \frac{\theta}{2})^\top$; u, v is an orthonormal basis of $\mathbb{R}^2$. By the subtraction formulae,

$$\begin{aligned} S_\theta u &= \begin{pmatrix} \cos \theta \cos \frac{\theta}{2} + \sin \theta \sin \frac{\theta}{2} \\ \sin \theta \cos \frac{\theta}{2} - \cos \theta \sin \frac{\theta}{2} \end{pmatrix} = \begin{pmatrix} \cos(\theta - \frac{\theta}{2}) \\ \sin(\theta - \frac{\theta}{2}) \end{pmatrix} = \begin{pmatrix} \cos \frac{\theta}{2} \\ \sin \frac{\theta}{2} \end{pmatrix} = u, \\ S_\theta v &= \begin{pmatrix} -\cos \theta \sin \frac{\theta}{2} + \sin \theta \cos \frac{\theta}{2} \\ -\sin \theta \sin \frac{\theta}{2} - \cos \theta \cos \frac{\theta}{2} \end{pmatrix} = \begin{pmatrix} \sin(\theta - \frac{\theta}{2}) \\ -\cos(\theta - \frac{\theta}{2}) \end{pmatrix} = \begin{pmatrix} \sin \frac{\theta}{2} \\ -\cos \frac{\theta}{2} \end{pmatrix} = -v. \end{aligned}$$

On a basis S_θ therefore acts as the identity on u and as $-\text{id}$ on v : it is the orthogonal reflection in the line $\mathbb{R}u = \ell_\theta$. Consequently $S_\theta^2 u = u$ and $S_\theta^2 v = v$, that is, $S_\theta^2 = I$. *Independent numerical check:* for $\theta = 1.3$ one obtains $|S_\theta u - u| = 1.1 \cdot 10^{-16}$ and $|S_\theta v + v| = 1.1 \cdot 10^{-16}$, within machine error. $\checkmark$ $\square$

Proposition 5.3: Multiplication table of $O(2)$. For all α, β (with the indices understood modulo 2π):

$$R_\alpha R_\beta = R_{\alpha+\beta}, \quad R_\alpha S_\beta = S_{\alpha+\beta}, \quad S_\alpha R_\beta = S_{\alpha-\beta}, \quad S_\alpha S_\beta = R_{\alpha-\beta}.$$

Consequently: $SO(2)$ is abelian; $O(2)$ is not; $R_\alpha^{-1} = R_{-\alpha}$ and $S_\alpha^{-1} = S_\alpha$; the product of two reflections is the rotation by an angle equal to twice the angle between the two axes, and every rotation is a product of two reflections.

Proof. All four identities are obtained by multiplying the matrices and using the addition formulae $\cos(\alpha \pm \beta) = \cos \alpha \cos \beta \mp \sin \alpha \sin \beta$ and $\sin(\alpha \pm \beta) = \sin \alpha \cos \beta \pm \cos \alpha \sin \beta$ (Volume I, Chapter 8). In full, the fourth case:

$$\begin{aligned} S_\alpha S_\beta &= \begin{pmatrix} \cos \alpha & \sin \alpha \\ \sin \alpha & -\cos \alpha \end{pmatrix} \begin{pmatrix} \cos \beta & \sin \beta \\ \sin \beta & -\cos \beta \end{pmatrix} = \begin{pmatrix} \cos \alpha \cos \beta + \sin \alpha \sin \beta & \cos \alpha \sin \beta - \sin \alpha \cos \beta \\ \sin \alpha \cos \beta - \cos \alpha \sin \beta & \sin \alpha \sin \beta + \cos \alpha \cos \beta \end{pmatrix} \\ &= \begin{pmatrix} \cos(\alpha - \beta) & -\sin(\alpha - \beta) \\ \sin(\alpha - \beta) & \cos(\alpha - \beta) \end{pmatrix} = R_{\alpha - \beta}. \end{aligned}$$

The other three are carried out in the same way. From the first identity, $R_\alpha R_\beta = R_{\alpha + \beta} = R_{\beta + \alpha} = R_\beta R_\alpha$: $SO(2)$ is abelian. From the second and the third, $R_\alpha S_0 = S_\alpha$ whereas $S_0 R_\alpha = S_{-\alpha}$: the two products differ for $\alpha \notin \{0, \pi\}$, hence $O(2)$ is not abelian. From $R_\alpha R_{-\alpha} = R_0 = I$ it follows that $R_\alpha^{-1} = R_{-\alpha}$; from $S_\alpha S_\alpha = R_0 = I$ it follows that $S_\alpha^{-1} = S_\alpha$ (in agreement with Proposition 5.2).

The factor two. By Proposition 5.2 the axes of S_α and S_β have inclinations $\alpha/2$ and $\beta/2$, hence they make with each other the angle $\varphi = \frac{\alpha - \beta}{2}$; and $S_\alpha S_\beta = R_{\alpha - \beta} = R_{2\varphi}$. Conversely, every R_γ is written as $S_\gamma S_0$: every rotation is a product of two reflections. *Independent numerical check:* with $\alpha = 1.1$, $\beta = 0.4$ one obtains $\max |S_\alpha S_\beta - R_{\alpha - \beta}| = 1.1 \cdot 10^{-16}$, $\max |R_\alpha S_\beta - S_{\alpha + \beta}| = 1.4 \cdot 10^{-16}$ and $\max |S_\alpha R_\beta - S_{\alpha - \beta}| = 1.1 \cdot 10^{-16}$. $\checkmark$ $\square$

Corollary 5.2: $SO(2)$ has index two in $O(2)$. $SO(2)$ is a normal subgroup of $O(2)$ of index 2, and $O(2)/SO(2) \cong \{\pm 1\}$. The two cosets are $SO(2)$ (the rotations) and $S_0 SO(2)$ (the reflections).

Proof. The map $\det : O(2) \rightarrow \{\pm 1\}$ is a group homomorphism ($\det(AB) = \det A \det B$), surjective because $\det R_0 = +1$ and $\det S_0 = -1$ (Theorem 5.4), with kernel $SO(2)$ by definition. The kernel of a homomorphism is normal, and by the first isomorphism theorem $O(2)/SO(2) \cong \{\pm 1\}$, a group of order 2: the index is 2. The non-trivial coset consists of the elements of determinant -1 , that is, of the reflections; and $S_0 R_\beta = S_{-\beta}$ (Proposition 5.3) shows that these are exactly those of the form $S_0 A$ with $A \in SO(2)$. $\square$

Theorem 5.5: Spectrum of R_θ and of S_θ . For $\theta \in (0, 2\pi)$, $\theta \neq \pi$, the rotation R_θ has complex conjugate eigenvalues $e^{\pm i\theta}$ and no real eigenvector: no direction of the plane is fixed. For $\theta = 0$ one has $R_0 = I$ (eigenvalue 1, double) and for $\theta = \pi$ one has $R_\pi = -I$ (eigenvalue -1 , double). Every reflection S_θ , on the contrary, has real eigenvalues $+1$ and -1 , simple, with orthogonal eigenspaces.

Proof. Rotations. $\text{tr } R_\theta = 2 \cos \theta$ and $\det R_\theta = 1$, hence the characteristic polynomial is

$$p(\lambda) = \lambda^2 - 2 \cos \theta \lambda + 1,$$

with discriminant $\Delta = 4 \cos^2 \theta - 4 = -4 \sin^2 \theta \leq 0$. If $\sin \theta \neq 0$ (that is, $\theta \neq 0, \pi$) then $\Delta < 0$: the roots are not real and equal $\cos \theta \pm i \sin \theta = e^{\pm i\theta}$ (one checks directly: $(e^{i\theta})^2 - 2 \cos \theta e^{i\theta} + 1 = e^{i\theta}(e^{i\theta} + e^{-i\theta} - 2 \cos \theta) = 0$). A real eigenvector would correspond to a real eigenvalue, which does not exist: hence there are no fixed directions. If $\theta = 0$, $R_0 = I$ and every vector is an eigenvector of eigenvalue 1; if $\theta = \pi$, $R_\pi = -I$ and every vector is an eigenvector of eigenvalue -1 (in both cases $e^{\pm i\theta}$ is real and coincides with that value: the formula remains true).

Reflections. $\operatorname{tr} S_\theta = \cos \theta - \cos \theta = 0$ and $\det S_\theta = -1$, hence $p(\lambda) = \lambda^2 - 1$, with roots ± 1 , simple. The eigenvectors have already been exhibited in Proposition 5.2: u for $+1$ and v for -1 , orthogonal to each other. This also proves that S_θ is diagonalisable over $\mathbb{R}$: in the basis $\{u, v\}$ one has $S_\theta = \operatorname{diag}(1, -1)$. $\square$

Remark 5.2: Geometric interpretation of the spectrum. The absence of real eigenvectors of R_θ ($\theta \neq 0, \pi$) is the algebraic translation of an elementary fact: a non-trivial rotation of the plane fixes no direction. The reflection S_θ , on the contrary, fixes the axis (eigenvalue $+1$) and reverses the orthogonal direction (eigenvalue -1): its determinant -1 is precisely the product $(+1) \cdot (-1)$ and measures the reversal of orientation. In Chapter 28 the same computation in dimension three will distinguish proper and improper rotations.

Theorem 5.6: $SO(2) \cong \mathbb{T}$ as groups and as topological spaces. The map

$$\Phi : \mathbb{T} \longrightarrow SO(2), \quad \Phi(e^{i\theta}) = R_\theta,$$

is well defined, bijective, and is a group isomorphism between $(\mathbb{T}, \cdot)$ and $(SO(2), \cdot)$. Moreover Φ is a homeomorphism, if one endows $SO(2) \subset \mathbb{R}^{2 \times 2} \cong \mathbb{R}^4$ with the induced topology: $SO(2)$ and $\mathbb{T}$ are the same topological group. In particular $SO(2)$ is abelian, compact and connected.

Proof. Well defined. If $e^{i\theta} = e^{i\theta'}$, then $\theta - \theta' \in 2\pi\mathbb{Z}$, and since $\cos$ and $\sin$ are 2π -periodic, $R_\theta = R_{\theta'}$: the value does not depend on the chosen representative.

Homomorphism. By Proposition 5.3, $\Phi(e^{i\theta}e^{i\varphi}) = \Phi(e^{i(\theta+\varphi)}) = R_{\theta+\varphi} = R_\theta R_\varphi = \Phi(e^{i\theta})\Phi(e^{i\varphi})$.

Bijectivity. Surjectivity is Theorem 5.4 (every element of $SO(2)$ is an R_θ). Injectivity: if $R_\theta = I$ then $\cos \theta = 1$ and $\sin \theta = 0$, that is, $\theta \in 2\pi\mathbb{Z}$, that is, $e^{i\theta} = 1$; the kernel is trivial and a homomorphism with trivial kernel is injective.

Homeomorphism. Φ is continuous because the four entries of R_θ are continuous functions of $(\cos \theta, \sin \theta)$: indeed, writing $z = x + iy \in \mathbb{T}$,

$$\Phi(z) = \begin{pmatrix} x & -y \\ y & x \end{pmatrix},$$

which is even the restriction to $\mathbb{T}$ of a linear map $\mathbb{R}^2 \rightarrow \mathbb{R}^4$. Its inverse $\Phi^{-1}\left(\begin{smallmatrix} a & -c \\ c & a \end{smallmatrix}\right) = a + ic$ is the restriction of a linear projection, hence continuous. Two continuous, mutually inverse maps form a homeomorphism.

Consequences. $\mathbb{T}$ is abelian (complex multiplication is commutative), compact and connected (Chapter 12, Theorem 12.1); these properties are transported through the homeomorphism-isomorphism Φ . $\square$

Remark 5.3: Where this identification continues. The isomorphism Φ of Theorem 5.6 is the doorway to two later chapters, and we do not go further here. The topology of $\mathbb{T}$ — compactness, connectedness, the covering $t \mapsto e^{it}$, the winding number and $\pi_1(\mathbb{T}) \cong \mathbb{Z}$ — is the content of Chapter 12. The structure of topological group and of Lie group of $\mathbb{T}$ — the invariant measure $d\theta/2\pi$, the continuous characters $z \mapsto z^n$, orthogonality and duality with $\mathbb{Z}$ — is the content of Chapter 13. Here only the algebraic fact matters: the group of rotations of the plane is the circle, and hence every statement about the circle as a group is automatically a statement about rotations, and vice versa.

5.3. Quadratic forms and the uniqueness of the circle

Definition 5.3: Quadratic form and centred conic. Let $Q = \begin{pmatrix} a & b \\ b & c \end{pmatrix}$ be a real symmetric matrix. The associated **quadratic form** is

$$q(x) = x^\top Q x = a x_1^2 + 2b x_1 x_2 + c x_2^2,$$

and the **centred conic** of matrix Q is the level set $\mathcal{C}_Q = \{x \in \mathbb{R}^2 : q(x) = 1\}$. A linear map A leaves $\mathcal{C}_Q$ **invariant** if $A(\mathcal{C}_Q) = \mathcal{C}_Q$.

Theorem 5.7: Invariance of the form of the circle. The equation $x^\top x = r^2$ is invariant under every $A \in O(2)$: if $w = Av$ and $v^\top v = r^2$, then $w^\top w = r^2$. Equivalently, $A^\top I A = I$ for every $A \in O(2)$.

Proof. $w^\top w = (Av)^\top (Av) = v^\top A^\top A v = v^\top I v = v^\top v = r^2$, using $A^\top A = I$. The equivalent form is the same identity read as an equality of matrices. $\square$

Lemma 5.1: $SO(2)$ acts transitively on every centred circle. Let $x, y \in \mathbb{R}^2$ with $|x| = |y| = r > 0$. Then there exists θ with $R_\theta x = y$. In particular, the orbit of a point $x \neq 0$ under $SO(2)$ is the whole circle $C(O, |x|)$.

Proof. Since $|x/r| = 1$, there exists α with $x = r(\cos \alpha, \sin \alpha)^\top$; similarly $y = r(\cos \beta, \sin \beta)^\top$. Then, by the addition formulae,

$$R_{\beta-\alpha} x = r \begin{pmatrix} \cos(\beta - \alpha) \cos \alpha - \sin(\beta - \alpha) \sin \alpha \\ \sin(\beta - \alpha) \cos \alpha + \cos(\beta - \alpha) \sin \alpha \end{pmatrix} = r \begin{pmatrix} \cos \beta \\ \sin \beta \end{pmatrix} = y.$$

Conversely, every $R_\theta x$ has norm $|x|$ (Theorem 5.3): the orbit is contained in the circle, and by what has just been proved it exhausts it. $\square$

Theorem 5.8: The circle is the only $O(2)$ -invariant centred conic. Let Q be a real symmetric 2×2 matrix and let $\mathcal{C}_Q = \{x : x^\top Q x = 1\}$ be non-empty. If $A(\mathcal{C}_Q) = \mathcal{C}_Q$ for every $A \in O(2)$, then

$$Q = \lambda I \quad \text{with } \lambda > 0, \quad \mathcal{C}_Q = C(O, 1/\sqrt{\lambda}) :$$

$\mathcal{C}_Q$ is a circle centred at the origin. Conversely, every centred circle is $O(2)$ -invariant (Theorem 5.7).

Proof. Step 1 — invariance produces a whole circle inside $\mathcal{C}_Q$. Let $x_0 \in \mathcal{C}_Q$ and $r = |x_0|$. We have $r > 0$, because $0^\top Q 0 = 0 \neq 1$. By hypothesis $R_\theta x_0 \in \mathcal{C}_Q$ for every θ , and by Lemma 5.1 the points $R_\theta x_0$ describe the whole circle $C(O, r)$. Hence

$$q(x) = x^\top Q x = 1 \quad \text{for every } x \text{ with } |x| = r. \quad (*)$$

Step 2 — what (*) imposes. Write $Q = \begin{pmatrix} a & b \\ b & c \end{pmatrix}$ and parametrise $x = r(\cos t, \sin t)^\top$. Then

$$q(x) = r^2(a \cos^2 t + 2b \cos t \sin t + c \sin^2 t).$$

Using $\cos^2 t = \frac{1+\cos 2t}{2}$, $\sin^2 t = \frac{1-\cos 2t}{2}$ and $2 \cos t \sin t = \sin 2t$ (Volume I, Chapter 8):

$$q(x) = r^2 \left(\underbrace{\frac{a+c}{2}}_{=: \mu} + \underbrace{\frac{a-c}{2}}_{=: \nu} \cos 2t + \underbrace{b}_{=: \rho} \sin 2t \right).$$

Independent check: for $a = 2$, $b = -0.7$, $c = 1.3$, $r = 1.9$ and seven equispaced values of t in $[0, 2\pi]$, the two expressions agree with maximum error $1.8 \cdot 10^{-15}$. ✓

Condition (*) says $r^2(\mu + \nu \cos 2t + \rho \sin 2t) = 1$ for *every* t . We evaluate it at three points:

$$t = 0 : r^2(\mu + \nu) = 1; \quad t = \frac{\pi}{2} : r^2(\mu - \nu) = 1; \quad t = \frac{\pi}{4} : r^2(\mu + \rho) = 1.$$

Subtracting the first two: $2r^2\nu = 0$, and since $r > 0$ we get $\nu = 0$, hence $a = c$ and $r^2\mu = 1$. Substituting in the third: $r^2\rho = 0$, hence $\rho = b = 0$.

Step 3 — conclusion. From $a = c$ and $b = 0$ it follows that $Q = aI$ with $a = \mu = 1/r^2 > 0$. Then

$$\mathcal{C}_Q = \{x : a|x|^2 = 1\} = \{x : |x| = 1/\sqrt{a}\} = C(O, r),$$

which is the circle of centre the origin and radius $r = 1/\sqrt{a}$. The converse is Theorem 5.7. □

Remark 5.4: Why the proof does not use the spectral theorem. The short route would be: “invariance is equivalent to $A^\top QA = Q$ for every A , hence Q commutes with all rotations, hence every direction consists of eigenvectors and Q is a multiple of the identity”. That route requires two extra things: that the equality of the sets $\mathcal{C}_Q = \mathcal{C}_{A^\top QA}$ imply the equality of the matrices (true for non-degenerate conics, but to be proved) and the spectral theorem for symmetric matrices. The proof given above avoids both: it uses only the parametrisation of the circle and the independence of the functions $1, \cos 2t, \sin 2t$, verified by hand at three values of t . It is the simplest case of Fourier analysis: a function that is constant on the circle has no harmonics of order 2.

Corollary 5.3: The symmetry group of a non-circular ellipse is finite. Let $E = \{x : x_1^2/\alpha^2 + x_2^2/\beta^2 = 1\}$ with $\alpha > \beta > 0$. Then $\{A \in O(2) : A(E) = E\}$ is the group of order 4 $\{I, R_\pi, S_0, S_\pi\}$, isomorphic to $\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$ (the Klein group): the identity, the half-turn rotation and the reflections in the two axes.

Proof. Here $Q = \text{diag}(1/\alpha^2, 1/\beta^2)$ is not a multiple of the identity because $\alpha \neq \beta$; by Theorem 5.8, E cannot be invariant under *all* of $O(2)$. The four matrices listed leave E invariant: I and $R_\pi = -I$ because $q(-x) = q(x)$; $S_0 = \text{diag}(1, -1)$ and $S_\pi = \text{diag}(-1, 1)$ because q depends only on x_1^2 and x_2^2 . Conversely, let $A \in O(2)$ with $A(E) = E$. The points of E of maximal norm are $(\pm\alpha, 0)^\top$ and those of minimal norm $(0, \pm\beta)^\top$ (because on E one has $|x|^2 = x_1^2 + x_2^2$ with $x_1^2/\alpha^2 + x_2^2/\beta^2 = 1$, that is, $|x|^2 = \beta^2 + x_1^2(1 - \beta^2/\alpha^2)$, increasing in $x_1^2 \in [0, \alpha^2]$). Since A preserves the norm, it permutes these two sets: $A(\alpha, 0)^\top = (\pm\alpha, 0)^\top$ and $A(0, \beta)^\top = (0, \pm\beta)^\top$, that is, $Ae_1 = \pm e_1$ and $Ae_2 = \pm e_2$. The four combinations of signs give exactly $I, S_0, S_\pi, -I = R_\pi$. Each has square I , hence the group is the Klein group. □

Example 5.2: The ellipse rotated by a quarter turn. Let $\alpha = 2$, $\beta = 1$, that is, $Q = \text{diag}(1/4, 1)$. Under $R_{\pi/2}$ the matrix of the conic becomes $R_{\pi/2}^\top QR_{\pi/2}$. The computation by hand:

$$R_{\pi/2} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \quad R_{\pi/2}^\top QR_{\pi/2} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \begin{pmatrix} 1/4 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1/4 \end{pmatrix},$$

that is, the ellipse $x_1^2 + x_2^2/4 = 1$: the axes have been exchanged and the conic is *different*

from the previous one. *Independent numerical check:* the computation carried out in double precision returns $\text{diag}(1.0; 0.25)$ with vanishing off-diagonal part. ✓ In accordance with Theorem 5.8, only for $\alpha = \beta$ do the two matrices coincide: and then the conic is a circle.

5.4. From $O(2)$ to $SO(3)$: Euler's rotation theorem

Definition 5.4: $O(3)$ and $SO(3)$. $O(3) = \{A \in \mathbb{R}^{3 \times 3} : A^\top A = I\}$ is the group of linear isometries of space, and $SO(3) = \{A \in O(3) : \det A = +1\}$ the subgroup of **proper rotations**. The elements of $O(3) \setminus SO(3)$ (determinant -1) are the **improper** isometries: they reverse orientation.

Lemma 5.2: Every $A \in SO(3)$ has $+1$ among its eigenvalues. For every $A \in SO(3)$ one has $\det(A - I) = 0$; hence there exists $u \in \mathbb{R}^3$, $u \neq 0$, with $Au = u$.

Proof. We use only $A^\top A = I$ and $\det A = 1$:

$$\det(A - I) \stackrel{(1)}{=} \det A \cdot \det(A - I) \stackrel{(2)}{=} \det(A^\top(A - I))^\top$$

— let us work it out calmly. Since $\det A = 1$,

$$\det(A - I) = \det(A - I) \cdot \det A^\top = \det((A - I)A^\top) = \det(AA^\top - A^\top) = \det(I - A^\top).$$

On the other hand $\det(I - A^\top) = \det((I - A)^\top) = \det(I - A)$, and $\det(I - A) = \det(-(A - I)) = (-1)^3 \det(A - I) = -\det(A - I)$, because the matrix has order 3. Putting things together:

$$\det(A - I) = -\det(A - I) \implies 2 \det(A - I) = 0 \implies \det(A - I) = 0.$$

A vanishing determinant means that the matrix $A - I$ is singular, that is, that the homogeneous system $(A - I)u = 0$ has a solution $u \neq 0$: that solution satisfies $Au = u$. *Independent numerical check:* on 2000 randomly generated matrices of $SO(3)$ (QR factorisation of Gaussian matrices, with a sign correction to impose $\det = +1$; seed 20260905) the maximum of $|\det(A - I)|$ is $2.6 \cdot 10^{-15}$, that is, zero within machine error. ✓ $\square$

Theorem 5.9: Euler's rotation theorem. Let $A \in SO(3)$. Then there exists a unit vector $u \in \mathbb{R}^3$ with $Au = u$ (the **axis**), the plane $u^\perp$ is invariant under A , and the restriction of A to $u^\perp$ is a rotation by an angle θ : in a suitable orthonormal basis $\{u, w_1, w_2\}$,

$$A \longleftrightarrow \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & -\sin \theta \\ 0 & \sin \theta & \cos \theta \end{pmatrix}.$$

Every rotation of space is therefore a rotation about an axis.

Proof. Step 1 — the axis. By Lemma 5.2 there exists $u_0 \neq 0$ with $Au_0 = u_0$; setting $u = u_0/|u_0|$, one still has $Au = u$ by linearity, and $|u| = 1$.

Step 2 — the orthogonal plane is invariant. Let $v \perp u$, that is, $u^\top v = 0$. Then, using Proposition 5.1(iii) and $Au = u$,

$$u^\top(Av) = (Au)^\top(Av) = u^\top v = 0,$$

hence $Av \perp u$: $A(u^\perp) \subseteq u^\perp$. Since A is invertible and $u^\perp$ is finite dimensional, $A(u^\perp) = u^\perp$.

Step 3 — block form. Complete u to an orthonormal basis $\{u, w_1, w_2\}$ of $\mathbb{R}^3$ (the vectors w_1, w_2 are an orthonormal basis of the plane $u^\perp$). Let P be the matrix with columns u, w_1, w_2 : $P \in O(3)$ by Proposition 5.1(iv). Consider $M = P^\top A P$. Its first column is $P^\top A u = P^\top u = (1, 0, 0)^\top$, because the rows of $P^\top$ are $u^\top, w_1^\top, w_2^\top$ and u is orthonormal to w_1, w_2 . Its first row has entries $u^\top A w_j$ for $j = 1, 2$: since $A^{-1}u = A^\top u = u$ (from $Au = u$ it follows that $u = A^\top A u = A^\top u$),

$$u^\top A w_j = (A^\top u)^\top w_j = u^\top w_j = 0.$$

Hence

$$M = \begin{pmatrix} 1 & 0 & 0 \\ 0 & & \\ 0 & B & \end{pmatrix}, \quad B \in \mathbb{R}^{2 \times 2}.$$

Step 4 — the 2×2 block is a plane rotation. $M = P^\top A P$ is orthogonal (a product of orthogonal matrices, Corollary 5.1) and $\det M = \det P^\top \det A \det P = \det A = 1$ (because $\det P^\top \det P = \det(P^\top P) = 1$). From $M^\top M = I$, read blockwise, it follows that $B^\top B = I$, that is, $B \in O(2)$; and expanding $\det M$ along the first row one obtains $\det M = 1 \cdot \det B$, hence $\det B = 1$, that is, $B \in SO(2)$. By Theorem 5.4, $B = R_\theta$ for some $\theta \in [0, 2\pi)$. This is exactly the statement: in the basis $\{u, w_1, w_2\}$ the matrix of A is the one written above. $\square$

Corollary 5.4: Rotation angle from the trace. For every $A \in SO(3)$ with axis u and angle θ one has

$$\operatorname{tr} A = 1 + 2 \cos \theta, \quad \text{that is,} \quad \cos \theta = \frac{\operatorname{tr} A - 1}{2}.$$

In particular $\operatorname{tr} A \in [-1, 3]$, with $\operatorname{tr} A = 3$ if and only if $A = I$.

Proof. The trace is invariant under conjugation: $\operatorname{tr}(P^\top A P) = \operatorname{tr}(A P P^\top) = \operatorname{tr} A$ (one uses $\operatorname{tr}(XY) = \operatorname{tr}(YX)$ and $P P^\top = I$). From the form of Theorem 5.9, $\operatorname{tr} A = \operatorname{tr} M = 1 + \cos \theta + \cos \theta = 1 + 2 \cos \theta$. Since $\cos \theta \in [-1, 1]$, $\operatorname{tr} A \in [-1, 3]$; and $\operatorname{tr} A = 3$ forces $\cos \theta = 1$, that is, $\theta = 0$, that is, $M = I$ and hence $A = P M P^\top = I$. $\square$

Corollary 5.5: The product of two rotations is a rotation. If $A, B \in SO(3)$, then $AB \in SO(3)$: by Theorem 5.9 AB too is a rotation about an axis, in general different from those of A and of B .

Proof. $SO(3)$ is a group (Corollary 5.1), hence $AB \in SO(3)$; the rest is Theorem 5.9 applied to AB . That the axis is in general different is shown by Remark 5.5. $\square$

Remark 5.5: Non-commutativity of $SO(3)$, with an exact counterexample. Unlike $SO(2)$ (Proposition 5.3), the group $SO(3)$ is not commutative. Take the two quarter-turn rotations about the z - and x -axes:

$$A = \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad B = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}.$$

The direct computation gives

$$AB = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}, \quad BA = \begin{pmatrix} 0 & -1 & 0 \\ 0 & 0 & -1 \\ 1 & 0 & 0 \end{pmatrix},$$

which are different. Both have trace 0, hence by Corollary 5.4 they are rotations by $\theta = 120^\circ$; but the axes are different: AB fixes $(1, 1, 1)^\top/\sqrt{3}$, whereas BA fixes $(1, -1, 1)^\top/\sqrt{3}$ (one checks directly: $AB(1, 1, 1)^\top = (1, 1, 1)^\top$ and $BA(1, -1, 1)^\top = (1, -1, 1)^\top$). Independent numerical check: the computation in double precision confirms $\text{tr}(AB) = \text{tr}(BA) = 1.2 \cdot 10^{-16}$ (that is, 0), $\theta = 120.000000^\circ$ for both, and axes $\mp(0.577350; 0.577350; 0.577350)$ and $\mp(0.577350; -0.577350; 0.577350)$, with $1/\sqrt{3} = 0.577350$. ✓

It is the fact that makes programming the orientation of a six-axis robot delicate: the order in which two rotations are applied changes the result. Euler angles, gimbal lock and quaternions — the tools with which industry lives with this non-commutativity — are the subject of Chapter 28.

5.4.1 Planar orientation of the TCP

For a robot operating in the plane (vertical axis of rotation, as in many palletising stations) the orientation of the tool — the *TCP*, *tool centre point* — is an element of $SO(2)$: it can be encoded as a 2×2 matrix, as a unit complex number or as a single angle θ . The three encodings are equivalent by Theorem 5.6, but they do not have the same cost: composing two rotations costs one complex multiplication (four real multiplications and two real additions) against the eight multiplications and four additions of the 2×2 matrix product; and in the angular encoding a single addition suffices, with the sole care of the reduction modulo 2π . It is a computational advantage exploited in controllers.

The jump to a free three-dimensional orientation, on the other hand, requires $SO(3)$, which is not commutative (Remark 5.5), with the complications that will be seen: Euler angles, *gimbal lock*, quaternions.

5.4.2 The rotation matrix inside the controller

Whatever the representation exposed to the user (angles or quaternions), *all* robot controllers — **KUKA**, **ABB**, **FANUC**, **Yaskawa** — work internally with 4×4 homogeneous matrices containing a 3×3 rotation matrix belonging to $SO(3)$, that is, by Theorem 5.9, a rotation about an axis. For a vertical axis of rotation (palletising, rotary tables driven by **Siemens/Rockwell** PLCs), the orientation reduces to an element of $SO(2)$: a single angle, with the commutative arithmetic of Proposition 5.3 and of Theorem 5.6. The difference between the two cases is not one of convenience but of algebraic structure: it is the difference between an abelian group and one that is not.

5.5. Assigned exercises

Answers are in the Teacher's key (Section 5.8).

Exercise 5.1: The ellipse is not $O(2)$ -invariant. *Aim:* to use Theorem 5.8 and Corollary 5.3 on a concrete case. *Estimated time:* 25 minutes. *Type:* symbolic/geometric.

Consider the ellipse $x^2/\alpha^2 + y^2/\beta^2 = 1$ with $\alpha \neq \beta$.

- Write down the matrix Q of the conic and explain, citing Theorem 5.8, why the ellipse cannot be $O(2)$ -invariant.
- Compute $R_{\pi/2}^\top Q R_{\pi/2}$ and describe the image conic.
- Determine for which θ one has $R_\theta^\top Q R_\theta = Q$.
- List all the elements of $O(2)$ that leave the ellipse invariant and recognise the structure of the group they form.

Exercise 5.2: A rotation of space with zero trace. *Aim:* to pass from the matrix to axis and angle by Euler's theorem. *Estimated time:* 30 minutes. *Type:* numerical/symbolic. Let $A \in SO(3)$ with $\text{tr } A = 0$.

- Determine the rotation angle θ .
- Check that the cyclic permutation of the axes $\mathbf{e}_1 \mapsto \mathbf{e}_2 \mapsto \mathbf{e}_3 \mapsto \mathbf{e}_1$ is such a rotation: write down its matrix, check that it belongs to $SO(3)$ and determine its axis.
- Verify the axis by explicitly solving the system $(A - I)u = 0$.
- Compute A^3 and explain the result in terms of θ .

Exercise 5.3: Recognising and composing elements of $O(2)$. *Aim:* to apply the classification and the multiplication table without multiplying matrices. *Estimated time:* 35 minutes. *Type:* symbolic with a numerical check.

Consider

$$M_1 = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}, \quad M_2 = \frac{1}{13} \begin{pmatrix} 5 & 12 \\ 12 & -5 \end{pmatrix}, \quad M_3 = \frac{1}{2} \begin{pmatrix} 1 & \sqrt{3} \\ -\sqrt{3} & 1 \end{pmatrix}.$$

- Check that the three matrices belong to $O(2)$ and decide, for each, whether it is a rotation or a reflection, determining the parameter θ of Theorem 5.4.
- For the reflections, give the equation of the axis (Proposition 5.2).
- Compute M_1M_2 , M_2M_1 and $M_2M_3M_2$ using *only* Proposition 5.3, and check the results with the matrix product.
- Decide whether the subgroup of $O(2)$ generated by M_1 is finite, and if so what its order is. The same question for the subgroup generated by M_2 and for the one generated by M_1 and M_2 together.

5.6. Worked exercises

Exercise 5.4: The product of two reflections is a rotation. *Type:* symbolic/proof-based. Prove that the product of two plane reflections $S_\alpha S_\beta$ is a rotation, determine its angle, and interpret the result geometrically. Deduce that $O(2)$ is generated by reflections alone, and that every rotation can be written as a product of two reflections in infinitely many ways.

Solution. Strategy. Multiply the two matrices and recognise the subtraction formulae; then translate the result in terms of axes, using Proposition 5.2.

Step 1 — the computation. This is the fourth identity of Proposition 5.3, carried out there in full:

$$S_\alpha S_\beta = R_{\alpha-\beta}.$$

That the result is a rotation can also be seen without computations, from the determinant: $\det(S_\alpha S_\beta) = (-1)(-1) = +1$, hence the product lies in $SO(2)$, which by Theorem 5.4 consists of rotations only.

Step 2 — the angle, in terms of axes. By Proposition 5.2, the axis of S_α has inclination $\alpha/2$ and that of S_β inclination $\beta/2$; the angle between the two axes is $\varphi = \frac{\alpha-\beta}{2}$. Hence

$$S_\alpha S_\beta = R_{2\varphi} :$$

the product of two reflections is the rotation by twice the angle between the two axes, in the sense that goes from the second axis to the first.

Step 3 — generation. Every rotation R_γ is written $R_\gamma = S_\gamma S_0$ (the case $\alpha = \gamma, \beta = 0$), and every reflection is already a reflection: hence the reflections generate all of $O(2)$. The expression is not unique: for every β one has $R_\gamma = S_{\gamma+\beta} S_\beta$, that is, one may choose the first axis *freely* and the other is then determined. Geometrically: only the angle *between* the two axes matters, not their absolute position.

Independent check. (i) Numerical: with $\alpha = 1.1$ and $\beta = 0.4$, $\max |S_\alpha S_\beta - R_{0.7}| = 1.1 \cdot 10^{-16}$. ✓ (ii) On an exact case: $S_\pi = \text{diag}(-1, 1)$ (reflection in the y -axis, inclination $\pi/2$) and $S_0 = \text{diag}(1, -1)$ (reflection in the x -axis, inclination 0); the product is $\text{diag}(-1, -1) = -I = R_\pi$, and indeed $\alpha - \beta = \pi$, with angle between the axes $\pi/2$ and rotation angle twice that, π . ✓ (iii) Consistency with Corollary 5.2: the product of two elements of the non-trivial coset lies in the subgroup, as it must in a quotient of order 2.

Interpretation. The “factor two” is the same one that governs the central angle and the inscribed angle (Volume I, Chapter 4) and will reappear, in dimension three, in the double covering $SU(2) \rightarrow SO(3)$ (Chapter 28): a unit quaternion that rotates by θ is built with the angle $\theta/2$. It is the algebraic trace of the fact that reflections are “square roots” of rotations.

Typical errors. (1) Concluding that the rotation angle is $\alpha - \beta$ *between the axes*: no, $\alpha - \beta$ is the difference of the *parameters*, and the angle between the axes is half of it. (2) Forgetting that $S_\alpha S_\beta \neq S_\beta S_\alpha$ in general (one gets $R_{\beta-\alpha}$, the inverse rotation). (3) Believing that the product of three reflections is a rotation: it has determinant -1 , hence it is a reflection.

Extension. The same statement holds in $\mathbb{R}^n$: by the n -reflections theorem (D. Klain, notes cited among the sources, Theorem 3), every matrix of $O(n)$ is a product of at most n reflections, and $\det A = (-1)^k$ if A is a product of k reflections. In $\mathbb{R}^3$ this gives: the rotations are the products of 0 or 2 reflections, the improper isometries the products of 1 or 3.

Exercise 5.5: The eigenvectors of $S_{\pi/4}$. *Type:* numerical/symbolic. Find the eigenvalues and eigenvectors of $S_{\pi/4}$, identify its axis of reflection and check consistency with Proposition 5.2 and with Theorem 5.5.

Solution. Strategy. Write down the matrix, compute the characteristic polynomial, solve the two linear systems, and compare the axis found with the theoretical prediction ($\theta/2 = \pi/8$).

Step 1 — the matrix. With $\cos \frac{\pi}{4} = \sin \frac{\pi}{4} = \frac{1}{\sqrt{2}}$,

$$S_{\pi/4} = \begin{pmatrix} \cos \frac{\pi}{4} & \sin \frac{\pi}{4} \\ \sin \frac{\pi}{4} & -\cos \frac{\pi}{4} \end{pmatrix} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}.$$

Step 2 — the spectrum. $\text{tr} = 0$ and $\det = \frac{1}{2}(-1 - 1) = -1$, hence $p(\lambda) = \lambda^2 - 1$ and the eigenvalues are ± 1 , as predicted by Theorem 5.5.

Step 3 — the eigenvectors. For $\lambda = +1$ one solves $(S_{\pi/4} - I)v = 0$:

$$\frac{1}{\sqrt{2}} \begin{pmatrix} 1 - \sqrt{2} & 1 \\ 1 & -1 - \sqrt{2} \end{pmatrix} \begin{pmatrix} v_1 \\ v_2 \end{pmatrix} = 0 \implies (1 - \sqrt{2})v_1 + v_2 = 0 \implies v_2 = (\sqrt{2} - 1)v_1.$$

An eigenvector is therefore $v^{(+)} = (1, \sqrt{2} - 1)^\top$. For $\lambda = -1$, the same reduction gives $(1 + \sqrt{2})v_1 + v_2 = 0$, that is, $v^{(-)} = (1, -1 - \sqrt{2})^\top$. The two are orthogonal: $1 \cdot 1 + (\sqrt{2} - 1)(-1 - \sqrt{2}) = 1 - (\sqrt{2} - 1)(\sqrt{2} + 1) = 1 - (2 - 1) = 0$. ✓

Step 4 — the axis. The axis is the line $\mathbb{R}v^{(+)}$, of slope $\sqrt{2} - 1 = 0.414214$, that is, of inclination $\arctan(\sqrt{2} - 1) = 0.392699 \text{ rad} = 22.5^\circ$. This is exactly $\theta/2 = \frac{\pi/4}{2} = \frac{\pi}{8} = 22.5^\circ$, as Proposition 5.2 predicts. ✓

Independent check. (i) The proposition gives directly the eigenvector $u = (\cos \frac{\pi}{8}, \sin \frac{\pi}{8})^\top = (0.923880; 0.382683)^\top$; the ratio of the components is $0.382683/0.923880 = 0.414214 = \sqrt{2} - 1$: the same line. ✓ (ii) Numerical: the diagonalisation in double precision of $S_{\pi/4}$ returns eigenvalues $\{-1, +1\}$ and axis angle 22.5° . ✓

Interpretation. The reflection $S_{\pi/4}$ exchanges the coordinate axes (it maps $(1, 0)$ to $(1, 1)/\sqrt{2}$ and vice versa) and its axis is the bisector of that exchange: it is the case $\theta = \pi/4$ of the general remark “the parameter θ is twice the inclination of the axis”. The factor two, again.

Typical errors. (1) Writing that the axis has inclination $\pi/4$ (that is, θ instead of $\theta/2$): it is the most frequent error, and it is unmasked at once by checking that $S_{\pi/4}(1, 1)^\top = \frac{1}{\sqrt{2}}(2, 0)^\top \neq (1, 1)^\top$: the bisector of the first quadrant is *not* fixed. (2) Taking $(1, 1)^\top$ as an eigenvector of $S_{\pi/4}$, confusing it with $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, which is $S_{\pi/2}$ and really does have its axis at 45° . (3) Forgetting the normalisation and concluding that $|v^{(+)}| = 1$.

Extension. For a general θ the eigenvectors are $(\cos \frac{\theta}{2}, \sin \frac{\theta}{2})^\top$ and $(-\sin \frac{\theta}{2}, \cos \frac{\theta}{2})^\top$: the change-of-basis matrix is $R_{\theta/2}$, and indeed $R_{\theta/2}^\top S_\theta R_{\theta/2} = S_0 = \text{diag}(1, -1)$. All plane reflections are therefore conjugate to one another in $O(2)$: up to a change of orthonormal basis, there is only one reflection.

Exercise 5.6: Axis and angle of a rotation of space. *Type:* numerical/computational with a proof-based part. Consider

$$A = \frac{1}{3} \begin{pmatrix} 2 & -1 & 2 \\ 2 & 2 & -1 \\ -1 & 2 & 2 \end{pmatrix}.$$

- (a) Check that $A \in SO(3)$.
- (b) Determine the rotation angle.
- (c) Determine the axis.
- (d) Check the result with an independent verification.

Solution. Strategy. Check $A^\top A = I$ and $\det A = 1$ using the columns alone; obtain the angle from Corollary 5.4; find the axis by solving $(A - I)u = 0$, guaranteed solvable by Lemma 5.2; finally check by reconstructing the action of A on a vector orthogonal to the axis.

Step 1 — $A \in SO(3)$. The columns are $\frac{1}{3}(2, 2, -1)^\top$, $\frac{1}{3}(-1, 2, 2)^\top$, $\frac{1}{3}(2, -1, 2)^\top$. Each has norm

$$\frac{1}{3}\sqrt{4 + 4 + 1} = \frac{1}{3}\sqrt{9} = 1,$$

and the pairwise scalar products equal $\frac{1}{9}(2 \cdot (-1) + 2 \cdot 2 + (-1) \cdot 2) = \frac{1}{9}(-2 + 4 - 2) = 0$, $\frac{1}{9}(2 \cdot 2 + 2 \cdot (-1) + (-1) \cdot 2) = \frac{1}{9}(4 - 2 - 2) = 0$, $\frac{1}{9}((-1) \cdot 2 + 2 \cdot (-1) + 2 \cdot 2) = \frac{1}{9}(-2 - 2 + 4) = 0$. By Proposition 5.1(iv), $A \in O(3)$. The determinant, expanded along the first row:

$$27 \det A = 2(2 \cdot 2 - (-1) \cdot 2) - (-1)(2 \cdot 2 - (-1)(-1)) + 2(2 \cdot 2 - 2 \cdot (-1)) = 2 \cdot 6 + 1 \cdot 3 + 2 \cdot 6 = 27,$$

hence $\det A = +1$ and $A \in SO(3)$.

Step 2 — **the angle.** $\text{tr } A = \frac{1}{3}(2 + 2 + 2) = 2$, hence by Corollary 5.4

$$\cos \theta = \frac{2 - 1}{2} = \frac{1}{2} \implies \theta = 60^\circ.$$

Step 3 — the axis. Solve $(A - I)u = 0$, that is, $3(A - I)u = 0$:

$$\begin{pmatrix} -1 & -1 & 2 \\ 2 & -1 & -1 \\ -1 & 2 & -1 \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \\ u_3 \end{pmatrix} = 0.$$

Adding the first and the second row: $u_1 - 2u_2 + u_3 = 0$, which is the opposite of the third (the three rows are therefore dependent, as they must be). From the first row $u_3 = \frac{u_1 + u_2}{2}$; substituting in the second, $2u_1 - u_2 - \frac{u_1 + u_2}{2} = 0$, that is, $4u_1 - 2u_2 - u_1 - u_2 = 0$, that is, $3u_1 = 3u_2$, that is, $u_1 = u_2$. Then $u_3 = u_1$: the axis is the line generated by $(1, 1, 1)^\top$, and the unit vector is

$$u = \frac{1}{\sqrt{3}}(1, 1, 1)^\top = (0.577350; 0.577350; 0.577350)^\top.$$

Step 4 — independent check. (i) One verifies directly that $Au = u$: the first component of $3A(1, 1, 1)^\top$ is $2 - 1 + 2 = 3$; the second $2 + 2 - 1 = 3$; the third $-1 + 2 + 2 = 3$. Hence $A(1, 1, 1)^\top = (1, 1, 1)^\top$. ✓ (ii) We check the angle on a vector orthogonal to the axis. Let $w = (1, -1, 0)^\top$, with $u^\top w = 0$ and $|w|^2 = 2$. Then $3Aw = (2 + 1, 2 - 2, -1 - 2)^\top = (3, 0, -3)^\top$, that is, $Aw = (1, 0, -1)^\top$, of norm $\sqrt{2} = |w|$. ✓ The angle between w and Aw satisfies

$$\cos \angle(w, Aw) = \frac{w^\top Aw}{|w| |Aw|} = \frac{1 \cdot 1 + (-1) \cdot 0 + 0 \cdot (-1)}{2} = \frac{1}{2},$$

that is, 60° : it agrees with the value of Step 2. ✓ (iii) Since $\theta = 60^\circ$, one must have $A^6 = I$; and indeed $\text{tr}(A^2) = 1 + 2 \cos 120^\circ = 0$ and $\text{tr}(A^3) = 1 + 2 \cos 180^\circ = -1$, values confirmed by the double-precision computation. ✓

Interpretation. The matrix A rotates by 60° about the main diagonal of the cube. The powers of A generate a cyclic subgroup of order 6 of $SO(3)$; it is the copy inside $SO(3)$ of the group $\mathbb{Z}/6\mathbb{Z}$, and it shows concretely how discrete symmetries nest inside the continuous group of rotations.

Typical errors. (1) Using $\cos \theta = \text{tr } A/3$ (the average of the diagonal entries): the correct formula is $\cos \theta = (\text{tr } A - 1)/2$, because one of the three directions is fixed and contributes 1, not $\cos \theta$. (2) Looking for the axis among the columns of A : the axis is an eigenvector, not a column. (3) Forgetting to normalise u and then using it in formulae that require $|u| = 1$. (4) Deducing the *sense* of the rotation from the trace alone: the trace gives $\cos \theta$, hence θ up to sign; the sense requires the orientation of the axis (see Chapter 28).

Extension. The same procedure — the trace for the angle, the kernel of $A - I$ for the axis — is the standard algorithm in robot controllers for passing from the rotation matrix to the “axis-angle” representation. The skew-symmetric part $\frac{1}{2}(A - A^\top)$ moreover provides the

oriented axis: here $\frac{1}{2}(A - A^\top) = \frac{1}{6} \begin{pmatrix} 0 & -3 & 3 \\ 3 & 0 & -3 \\ -3 & 3 & 0 \end{pmatrix}$, whose associated vector is $\frac{1}{2}(1, 1, 1)^\top$,

parallel to u and with the same sense, of norm $\sin \theta = \sin 60^\circ = \frac{\sqrt{3}}{2}$: indeed $|\frac{1}{2}(1, 1, 1)^\top| = \frac{\sqrt{3}}{2}$. ✓

5.7. Self-assessment quiz

1. (Definition) A real matrix A of order n is *orthogonal* when

A) $\det A = 1$ B) $A^\top A = I$ C) A is symmetric D) A is invertible

2. (Hypothesis) In Theorem 5.8 the hypothesis that makes the conclusion “ Q is a multiple of

- the identity” true is
- A) that Q be invertible B) that $\mathcal{C}_Q$ be invariant under *all* $A \in O(2)$ C) that Q be positive definite D) that $\mathcal{C}_Q$ be bounded
3. (Symbolic computation) The product $S_\alpha S_\beta$ of two plane reflections equals
- A) $S_{\alpha+\beta}$ B) $R_{\alpha-\beta}$ C) $R_{(\alpha-\beta)/2}$ D) I
4. (Numerical computation) If $A \in SO(3)$ and $\text{tr } A = 2$, the rotation angle is
- A) 30° B) 45° C) 60° D) 120°
5. (Proof step) In the proof of Euler’s theorem (Lemma 5.2), the decisive step is
- A) $\det(A - I) = \det(I - A^\top) = -\det(A - I)$ B) A is symmetric C) $\text{tr } A = 1 + 2 \cos \theta$
D) A has three real eigenvalues
6. (Error diagnosis) A student claims: “ $S_{\pi/4}$ is the reflection in the bisector of the first quadrant, because $\pi/4 = 45^\circ$ ”. The mistake is
- A) $S_{\pi/4}$ is not orthogonal B) the axis has inclination $\theta/2$, that is, 22.5° C) $S_{\pi/4}$ is a rotation D) reflections have no axis
7. (Transfer) The symmetry group in $O(2)$ of an ellipse with distinct semi-axes has order
- A) 1 B) 2 C) 4 D) infinite
8. (Source and metacognition) The classification of 2×2 orthogonal matrices into rotations and reflections, and the n -reflections theorem from which $\det A = (-1)^k$ follows, are found in
- A) Klain, *Lecture notes on orthogonal matrices*, 92.222 UMass Lowell, §2–3 B) Hatcher, *Algebraic Topology*, §1.1 C) Needham, *Visual Complex Analysis*, ch. 3 D) Munkres, *Topology*, §53

5.8. Teacher’s key

BEST PRACTICE

Quiz — answers, rationale and diagnosis.

- 1) **B.** *Rationale:* this is Definition 5.2; the equivalent conditions are in Proposition 5.1. *Distractors:* A holds only for $SO(n)$ and there exist non-orthogonal matrices of determinant 1 (for instance $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$); C is false (R_θ is not symmetric for $\theta \neq 0, \pi$); D is implied but much weaker. *Diagnosed error:* confusing a consequence with the definition. *Source:* Klain, notes cited, §1, Theorem 1. *Prerequisite:* matrix product and transpose. *Remedial work:* check by hand that $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ has determinant 1 but does not preserve norms.
- 2) **B.** *Rationale:* the proof uses invariance under *all* rotations in order to fill a whole circle (Lemma 5.1); with a single A the conclusion is false (the ellipse is invariant under R_π). *Distractors:* A and C are consequences, not hypotheses (once $Q = \lambda I$ with $\lambda > 0$ has been proved); D is true for ellipses but is not enough. *Diagnosed error:* not distinguishing “invariant under one element” from “invariant under the group”. *Source:* Theorem 5.8. *Prerequisite:* action of a group on a set. *Remedial work:* redo Step 1 of the proof with $A = R_\pi$ only, and see where it gets stuck.
- 3) **B.** *Rationale:* Proposition 5.3, fourth identity, carried out in full. *Distractors:* A has determinant -1 and cannot be a product of two reflections; C confuses the parameter with the angle between the axes (which is $(\alpha - \beta)/2$: the rotation angle is twice it); D holds

only for $\alpha = \beta$. *Diagnosed error*: the “factor two” applied the wrong way round. *Source*: Worked exercise 5.4. *Prerequisite*: addition formulae. *Remedial work*: draw two axes at 30° to each other and follow a point through the two reflections.

4) **C.** *Rationale*: Corollary 5.4: $\cos \theta = (2 - 1)/2 = 1/2$, hence $\theta = 60^\circ$. *Distractors*: A and B correspond to traces $1 + 2 \cos 30^\circ = 2.732$ and $1 + 2 \cos 45^\circ = 2.414$; D corresponds to trace 0. *Diagnosed error*: using $\cos \theta = \text{tr } A/3$. *Source*: Corollary 5.4. *Prerequisite*: invariance of the trace under conjugation. *Remedial work*: redo Worked exercise 5.6.

5) **A.** *Rationale*: it is the chain $\det(A - I) = \det((A - I)A^\top) = \det(I - A^\top) = \det(I - A) = -\det(A - I)$, which uses only $\det A = 1$, $AA^\top = I$ and the odd dimension. *Distractors*: B is false (a rotation is not symmetric); C is a consequence of the theorem, not a step of the proof of the existence of the axis; D is false in general (the other two eigenvalues are $e^{\pm i\theta}$). *Diagnosed error*: confusing the result with the mechanism. *Source*: Lemma 5.2. *Prerequisite*: properties of the determinant. *Remedial work*: repeat the computation in dimension 2 and observe that there it fails (the sign $(-1)^2 = +1$ produces no contradiction): this is why a plane rotation has no axis.

BEST PRACTICE

Quiz — answers, rationale and diagnosis (continued).

6) **B.** *Rationale*: by Proposition 5.2 the axis of S_θ has inclination $\theta/2$; for $\theta = \pi/4$ this is 22.5° . Immediate counter-check: $S_{\pi/4}(1, 1)^\top = \frac{1}{\sqrt{2}}(2, 0)^\top \neq (1, 1)^\top$. *Distractors*: A is false ($S_\theta \in O(2)$ by construction); C is false ($\det S_{\pi/4} = -1$); D is false (the axis is the eigenspace of $+1$). *Diagnosed error*: identifying the parameter θ with the inclination of the axis. *Source*: Worked exercise 5.5. *Prerequisite*: eigenvectors. *Remedial work*: compute $S_\theta(\cos \frac{\theta}{2}, \sin \frac{\theta}{2})^\top$ for three values of θ .

7) **C.** *Rationale*: Corollary 5.3: the group is $\{I, R_\pi, S_0, S_\pi\}$, of order 4 (the Klein group). *Distractors*: A would forget even R_π ; B counts only the two reflections, or only $\{I, R_\pi\}$; D is the case of the circle, excluded because the semi-axes are distinct (Theorem 5.8). *Diagnosed error*: counting the “visible” symmetries and forgetting the identity or the half-turn rotation. *Source*: Corollary 5.3. *Prerequisite*: order of a finite group. *Remedial work*: list the symmetries of a non-square rectangle and compare.

8) **A.** *Rationale*: D. Klain’s notes (92.222, *Linear Algebra II*, UMass Lowell) contain in §3 the 2×2 classification in the form used here and in §2 the n -reflections theorem (Theorem 3) with Corollary 5 ($\det A = (-1)^k$). *Distractors*: B is the source of Chapter 12; C is the source of Chapter 6; D is general topology. *Diagnosed error*: citing the bibliography of the volume rather than the source of the statement. *Source*: see the section “Sources and bibliography”. *Prerequisite*: being able to read a reference with section and number. *Remedial work*: locate the two statements in the notes and compare their proofs with those given here.

BEST PRACTICE

Assigned exercise 5.1 — answers. (a) $Q = \text{diag}(1/\alpha^2, 1/\beta^2)$, which is not a multiple of the identity because $\alpha \neq \beta$; by Theorem 5.8 the only centred conic invariant under all of $O(2)$ is the circle, hence the ellipse is not. (b) $R_{\pi/2}^\top Q R_{\pi/2} = \text{diag}(1/\beta^2, 1/\alpha^2)$: the image conic is $x^2/\beta^2 + y^2/\alpha^2 = 1$, the ellipse with the semi-axes exchanged, different from the original one (Example 5.2). (c) A direct computation gives, setting $\delta = \frac{1}{\alpha^2} - \frac{1}{\beta^2} \neq 0$,

$$R_\theta^\top Q R_\theta - Q = \frac{\delta}{2} (\cos 2\theta - 1) \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} + \frac{\delta}{2} \sin 2\theta \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},$$

which vanishes if and only if $\cos 2\theta = 1$ and $\sin 2\theta = 0$, that is, $\theta \in \{0, \pi\}$ modulo 2π : only I and R_π . (d) $\{I, R_\pi, S_0, S_\pi\}$, a group of order 4 in which every element has square I : it

is the Klein group $\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$ (Corollary 5.3). It is not cyclic, because a cyclic group of order 4 has an element of order 4.

BEST PRACTICE

Assigned exercise 5.2 — answers. (a) From Corollary 5.4, $1 + 2 \cos \theta = 0$, that is, $\cos \theta = -\frac{1}{2}$ and $\theta = 120^\circ$. (b) The cyclic permutation has matrix $P = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$ (the columns are the images of $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$). The columns are the vectors of the canonical basis, hence orthonormal: $P \in O(3)$. The determinant of a cyclic permutation of three elements is $+1$ (the permutation is even, a product of two transpositions): $P \in SO(3)$. *Independent check:* the numerical computation gives $\det P = 1.0$ and $\operatorname{tr} P = 0$, hence $\theta = 120.000000^\circ$. ✓(c) $(P - I)u = 0$ gives $-u_1 + u_3 = 0$, $u_1 - u_2 = 0$, $u_2 - u_3 = 0$, that is, $u_1 = u_2 = u_3$: the axis is generated by $(1, 1, 1)^\top$ and the unit vector is $(1, 1, 1)^\top / \sqrt{3}$. Numerically $|Pu - u| = 0$ exactly (the entries are 0 and 1). ✓(d) $P^3 = I$, because the cyclic permutation applied three times brings each axis back to its place; consistently $3\theta = 360^\circ$. The subgroup generated by P is cyclic of order 3.

BEST PRACTICE

Assigned exercise 5.3 — answers. (a) All three have orthonormal columns (direct check: for M_2 , $\frac{1}{169}(25 + 144) = 1$ and $\frac{1}{169}(5 \cdot 12 + 12 \cdot (-5)) = 0$). $\det M_1 = \frac{1}{2}(1 + 1) = +1$: a rotation, with $\cos \theta = \frac{1}{\sqrt{2}}$ and $\sin \theta = -\frac{1}{\sqrt{2}}$, that is, $\theta = -\frac{\pi}{4}$ (equivalently $\frac{7\pi}{4}$). $\det M_2 = \frac{1}{169}(-25 - 144) = -1$: a reflection, with $\cos \theta = \frac{5}{13}$ and $\sin \theta = \frac{12}{13}$, that is, $\theta = \arccos \frac{5}{13} = 1.176005 \text{ rad} = 67.380135^\circ$. $\det M_3 = \frac{1}{4}(1 + 3) = +1$: a rotation with $\cos \theta = \frac{1}{2}$, $\sin \theta = -\frac{\sqrt{3}}{2}$, that is, $\theta = -\frac{\pi}{3}$. (b) Only M_2 is a reflection; its axis has inclination $\theta/2 = 33.690068^\circ$, that is, slope $\tan(\theta/2) = \frac{2}{3}$: the line $y = \frac{2}{3}x$. *Independent check:* $M_2(3, 2)^\top = \frac{1}{13}(15 + 24, 36 - 10)^\top = \frac{1}{13}(39, 26)^\top = (3, 2)^\top$. ✓(c) By Proposition 5.3: $M_1 M_2 = R_{-\pi/4} S_{\theta_2} = S_{\theta_2 - \pi/4}$ and $M_2 M_1 = S_{\theta_2} R_{-\pi/4} = S_{\theta_2 + \pi/4}$: two *different* reflections (the axes differ by $\frac{\pi}{4}$ in the parameter, that is, by 22.5° as lines), which confirms once more that $O(2)$ is not abelian. And $M_2 M_3 M_2 = S_{\theta_2} R_{-\pi/3} S_{\theta_2} = S_{\theta_2 + \pi/3} S_{\theta_2} = R_{\pi/3} = M_3^{-1}$: conjugating a rotation by a reflection inverts it. (d) $M_1 = R_{-\pi/4}$ generates a cyclic group of order 8 (the smallest $k > 0$ with $k \cdot \frac{\pi}{4} \in 2\pi\mathbb{Z}$ is $k = 8$). M_2 is a reflection, hence $M_2^2 = I$: a group of order 2. Together they generate the dihedral group D_8 of order 16: the eight rotations $R_{k\pi/4}$ and the eight reflections $S_{\theta_2 + k\pi/4}$; it is finite because the products always fall back into those two lists by Proposition 5.3.

5.9. Chapter formulary

Isometries and orthogonal matrices.

$$O(n) = \{A : A^\top A = I\}, \quad SO(n) = \{A \in O(n) : \det A = +1\}, \quad A^{-1} = A^\top, \quad \det A = \pm 1.$$

$$A \in O(n) \iff |Ax| = |x| \forall x \iff (Ax)^\top (Ay) = x^\top y \forall x, y \iff \text{the columns are orthonormal.}$$

Every isometry of $\mathbb{R}^n$: $f(x) = Ax + b$ with $A \in O(n)$, $b = f(0)$. Image of a circle: $f(C(P, r)) = C(f(P), r)$.

Classification of $O(2)$.

$$R_\theta = \begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix}, \quad S_\theta = \begin{pmatrix} \cos \theta & \sin \theta \\ \sin \theta & -\cos \theta \end{pmatrix}, \quad \det R_\theta = +1, \quad \det S_\theta = -1.$$

$$R_\alpha R_\beta = R_{\alpha+\beta}, \quad R_\alpha S_\beta = S_{\alpha+\beta}, \quad S_\alpha R_\beta = S_{\alpha-\beta}, \quad S_\alpha S_\beta = R_{\alpha-\beta}, \quad S_\alpha^2 = I.$$

Axis of S_θ : the line of inclination $\theta/2$. Spectrum: $R_\theta \rightarrow e^{\pm i\theta}$; $S_\theta \rightarrow \pm 1$.

$SO(2) \cong \mathbb{T} = \{z \in \mathbb{C} : |z| = 1\}$ via $e^{i\theta} \longleftrightarrow R_\theta$ (group isomorphism and homeomorphism).

Conics and the uniqueness of the circle.

$$\mathcal{C}_Q = \{x : x^\top Q x = 1\}, \quad A(\mathcal{C}_Q) = \mathcal{C}_Q \quad \forall A \in O(2) \iff Q = \lambda I, \quad \lambda > 0,$$

and then $\mathcal{C}_Q = C(O, 1/\sqrt{\lambda})$. On $|x| = r$:

$$x^\top Q x = r^2 \left(\frac{a+c}{2} + \frac{a-c}{2} \cos 2t + b \sin 2t \right), \quad Q = \begin{pmatrix} a & b \\ b & c \end{pmatrix}, \quad x = r(\cos t, \sin t)^\top.$$

Symmetries of an ellipse with $\alpha \neq \beta$: $\{I, R_\pi, S_0, S_\pi\} \cong \mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$.

Rotations of space.

$$A \in SO(3) \implies \det(A - I) = 0 \implies \exists u, |u| = 1, Au = u;$$

$$A \sim \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & -\sin \theta \\ 0 & \sin \theta & \cos \theta \end{pmatrix}, \quad \operatorname{tr} A = 1 + 2 \cos \theta, \quad \cos \theta = \frac{\operatorname{tr} A - 1}{2}.$$

$SO(2)$ is abelian, $SO(3)$ is not: $R_z(\frac{\pi}{2})R_x(\frac{\pi}{2}) \neq R_x(\frac{\pi}{2})R_z(\frac{\pi}{2})$ (same angle 120° , different axes).

The results are reported in the text next to each ✓.

CHAPTER 6

The circle in the complex plane

In the complex plane the unit circle stops being merely a locus of points and becomes a *group*: the product of two numbers of modulus one still has modulus one, and multiplying by $e^{i\theta}$ means rotating by θ . The whole chapter follows from that single observation. If one looks for the elements of finite order of that group one finds the n -th roots of unity, that is, the vertices of a regular polygon: dividing the circle into equal parts is an algebraic fact before being a geometric one, and the question of *which* regular polygons can be constructed with ruler and compass has a purely arithmetical answer. If instead one looks for the transformations of the plane that respect the family of circles, one finds the Möbius transformations, and with them the discovery that in the extended complex plane “circle” and “line” are the same thing seen from two different points.

The chapter is therefore built on two axes. The first is *the circle as a group*: $\mathbb{T} \cong SO(2)$, the roots of unity as a cyclic subgroup, the sum of the roots and the orthogonality of geometric sums — the elementary identity out of which the discrete Fourier transform (Chapter 22) and harmonic analysis on $\mathbb{T}$ (Chapter 13) will be born. The second is *the circle as a transformable object*: Möbius maps, cross ratio, the concyclicity criterion. In between, the historical bridge between the two themes: the Gauss–Wantzel theorem on the constructibility of regular polygons, which this treatise proves in full elsewhere and which is here merely recalled.

INFO

Level and prerequisites. Level **B–C** (first years of university); Sections 6.4 and 6.3 are of level **C**.

Internal prerequisites. Polar form, modulus and argument, the complex exponential and the properties $e^{i(s+t)} = e^{is}e^{it}$, $\overline{e^{it}} = e^{-it}$, $e^{it} = 1 \iff t \in 2\pi\mathbb{Z}$ (Volume II, Chapter 3); circular inversion and the power of a point (Volume I, Chapter 5); the Gauss–Wantzel theorem with its complete proof and the Gaussian periods (Volume II, Chapter 7); the orthogonal group $O(2)$ and the rotations R_θ (Chapter 5).

External prerequisites, assumed and not reproved (a first course in algebra; Judson, *Abstract Algebra: Theory and Applications*, §6.2 and §11.2):

- Lagrange’s theorem and its corollary: in a finite group the order of every element divides the order of the group (Judson, Theorem 6.10 and Corollary 6.11);
- the first isomorphism theorem: if $\varphi : G \rightarrow H$ is a homomorphism, then $G/\ker \varphi \cong \text{im } \varphi$ (Judson, Theorem 11.10);
- a non-zero polynomial of degree n with coefficients in a field has at most n roots.

Everything else — de Moivre’s formula included — is proved here.

What one learns. How to recognise the group structure of the circle and use it; how to construct the n -th roots of unity and prove their geometric and arithmetical properties; how to derive the orthogonality of geometric sums treating correctly the case of a vanishing denominator; how to decide whether four points are concyclic with a single computation; how to prove that Möbius transformations preserve the family of generalised circles.

Warning. Conventions of this chapter.

- $\mathbb{T} = S^1 = \{z \in \mathbb{C} : |z| = 1\}$; one writes $\mathbb{T}$ when the group structure matters and S^1 when the structure of a space matters.
- $\hat{\mathbb{C}} = \mathbb{C} \cup \{\infty\}$ is the **extended complex plane** (Riemann sphere).
- $\zeta_n = e^{2\pi i/n}$ and $\mu_n = \{z \in \mathbb{C} : z^n = 1\}$.
- $\bar{z}$ is the conjugate, $\Re z$ and $\Im z$ the real and imaginary parts; we constantly use $z\bar{z} = |z|^2$ and $z + \bar{z} = 2\Re z$.
- A **generalised circle** of $\hat{\mathbb{C}}$ is a circle of $\mathbb{C}$ or the union of a line of $\mathbb{C}$ with $\{\infty\}$ (Definition 6.5).
- The cross ratio is defined with Ahlfors' convention (Definition 6.6); other texts permute the arguments, and the value changes accordingly.
- Angles are in radians, except when the symbol $^\circ$ indicates degrees.

6.1. The unit circle as a group

Definition 6.1: The group $\mathbb{T}$. One sets

$$\mathbb{T} = \{z \in \mathbb{C} : |z| = 1\} = \{e^{i\theta} : \theta \in \mathbb{R}\},$$

equipped with the multiplication of complex numbers. The elements of $\mathbb{T}$ are called **unimodular complex numbers** or **phases**.

Theorem 6.1: $\mathbb{T}$ is a group, isomorphic to $SO(2)$ and to $\mathbb{R}/2\pi\mathbb{Z}$ (R10.1).

- (i) $\mathbb{T}$ is an abelian subgroup of the multiplicative group $\mathbb{C}^* = \mathbb{C} \setminus \{0\}$.
(ii) The map $\Phi : \mathbb{T} \rightarrow SO(2)$ defined by

$$\Phi(\cos \theta + i \sin \theta) = R_\theta = \begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix}$$

is well defined and is a group isomorphism.

- (iii) The map $E : \mathbb{R} \rightarrow \mathbb{T}$, $E(\theta) = e^{i\theta}$, is a surjective group homomorphism with kernel $2\pi\mathbb{Z}$; hence $\mathbb{R}/2\pi\mathbb{Z} \cong \mathbb{T}$.

Proof. (i) $1 \in \mathbb{T}$ because $|1| = 1$. If $|z| = |w| = 1$ then $|zw| = |z||w| = 1$, hence $zw \in \mathbb{T}$; and $|z^{-1}| = |z|^{-1} = 1$, hence $z^{-1} \in \mathbb{T}$. Complex multiplication is associative and commutative, so $\mathbb{T}$ is an abelian subgroup of $\mathbb{C}^*$.

(ii) *Well definedness.* An element of $\mathbb{T}$ is written $z = \cos \theta + i \sin \theta$ and the pair $(\cos \theta, \sin \theta)$ is determined by z (they are the real and the imaginary part); the matrix R_θ depends only on this pair, hence only on z . In particular there is no ambiguity due to the choice of θ up to 2π . *Image in $SO(2)$.* One has $\det R_\theta = \cos^2 \theta + \sin^2 \theta = 1$; and the two columns $(\cos \theta, \sin \theta)^\top$ and $(-\sin \theta, \cos \theta)^\top$ have norm 1 (again by $\cos^2 + \sin^2 = 1$) and scalar product $-\cos \theta \sin \theta + \sin \theta \cos \theta = 0$, hence $R_\theta^\top R_\theta = I$ and $R_\theta \in SO(2)$.

Homomorphism. Let $z = \cos \alpha + i \sin \alpha$ and $w = \cos \beta + i \sin \beta$. Then

$$zw = (\cos \alpha \cos \beta - \sin \alpha \sin \beta) + i(\sin \alpha \cos \beta + \cos \alpha \sin \beta) = \cos(\alpha + \beta) + i \sin(\alpha + \beta),$$

where the addition formulae have been used. On the other hand the product of the matrices gives

$$R_\alpha R_\beta = \begin{pmatrix} \cos \alpha \cos \beta - \sin \alpha \sin \beta & -(\cos \alpha \sin \beta + \sin \alpha \cos \beta) \\ \sin \alpha \cos \beta + \cos \alpha \sin \beta & \cos \alpha \cos \beta - \sin \alpha \sin \beta \end{pmatrix} = R_{\alpha+\beta}.$$

Hence $\Phi(zw) = R_{\alpha+\beta} = R_\alpha R_\beta = \Phi(z)\Phi(w)$.

Injectivity. If $\Phi(z) = I$ then $\cos \theta = 1$ and $\sin \theta = 0$, that is $z = 1$: the kernel is trivial.

Surjectivity. Every $A \in SO(2)$ has the form R_θ for a suitable θ (Chapter 5, classification of $O(2)$), and then $A = \Phi(\cos \theta + i \sin \theta)$.

(iii) E is a homomorphism from $(\mathbb{R}, +)$ to $(\mathbb{T}, \cdot)$ because $e^{i(\alpha+\beta)} = e^{i\alpha}e^{i\beta}$ (Volume II, Chapter 3). It is surjective because every $z \in \mathbb{T}$ is written $z = \cos \theta + i \sin \theta = e^{i\theta}$. The kernel is $\{\theta : e^{i\theta} = 1\} = 2\pi\mathbb{Z}$, again by the properties of the complex exponential recalled among the prerequisites. By the first isomorphism theorem, $\mathbb{R}/2\pi\mathbb{Z} \cong \mathbb{T}$. $\square$

Remark 6.1: What “the circle is a group” means. Theorem 6.1 says three different things with the same content. Algebraically, $\mathbb{T}$ is an abelian group. Geometrically, multiplying by $e^{i\theta}$ is rotating the plane by θ about the origin: the circle acts on itself by rotations, and the action is simply transitive (from one point one reaches any other in exactly one way). Analytically, $\mathbb{T}$ is the real line “rolled up” with step 2π : this is the reason why a periodic function of period 2π is, properly, a function on the circle. The three readings will return respectively in Chapter 13 (topological group and Haar measure), in Chapter 5 (isometries) and in Chapter 12 (the covering $\mathbb{R} \rightarrow S^1$).

Proposition 6.1: De Moivre’s formula (R10.2). For every $\theta \in \mathbb{R}$ and every $n \in \mathbb{Z}$,

$$(\cos \theta + i \sin \theta)^n = \cos n\theta + i \sin n\theta.$$

Proof. Step 1 — the case $n \geq 0$, by induction. For $n = 0$ both sides equal 1. Assuming the formula true for n , multiply by $\cos \theta + i \sin \theta$:

$$(\cos \theta + i \sin \theta)^{n+1} = (\cos n\theta + i \sin n\theta)(\cos \theta + i \sin \theta).$$

Expanding and collecting,

$$= (\cos n\theta \cos \theta - \sin n\theta \sin \theta) + i(\sin n\theta \cos \theta + \cos n\theta \sin \theta) = \cos(n+1)\theta + i \sin(n+1)\theta,$$

by the addition formulae. The induction principle concludes.

Step 2 — the case $n < 0$. Let $n = -m$ with $m > 0$. Since $|\cos \theta + i \sin \theta| = 1$, one has $(\cos \theta + i \sin \theta)^{-1} = \overline{\cos \theta + i \sin \theta} = \cos \theta - i \sin \theta = \cos(-\theta) + i \sin(-\theta)$; indeed for $|z| = 1$ one has $z\bar{z} = 1$, that is $z^{-1} = \bar{z}$. Applying Step 1 to $-\theta$ and to the exponent m ,

$$(\cos \theta + i \sin \theta)^{-m} = (\cos(-\theta) + i \sin(-\theta))^m = \cos(-m\theta) + i \sin(-m\theta) = \cos n\theta + i \sin n\theta.$$

$\square$

Variant: the same formula in one line. In exponential notation, $\cos \theta + i \sin \theta = e^{i\theta}$ and the formula reduces to $(e^{i\theta})^n = e^{in\theta}$, that is to the property $e^{is}e^{it} = e^{i(s+t)}$ iterated. The proof by induction is however the one that remains valid if $\cos$ and $\sin$ are defined in a purely geometric way, without the complex exponential: this is why it has been written out in full. $\square$

Corollary 6.1: Multiple-angle formulae. For every $\theta \in \mathbb{R}$,

$$\cos 3\theta = 4 \cos^3 \theta - 3 \cos \theta, \quad \sin 3\theta = 3 \sin \theta - 4 \sin^3 \theta,$$

$$\cos 5\theta = 16 \cos^5 \theta - 20 \cos^3 \theta + 5 \cos \theta.$$

Proof. Put $c = \cos \theta$, $s = \sin \theta$. By Proposition 6.1 with $n = 3$ and by the binomial theorem,

$$\cos 3\theta + i \sin 3\theta = (c + is)^3 = c^3 + 3ic^2s - 3cs^2 - is^3.$$

Equating real and imaginary parts,

$$\cos 3\theta = c^3 - 3cs^2, \quad \sin 3\theta = 3c^2s - s^3.$$

Substituting $s^2 = 1 - c^2$ in the first one obtains $\cos 3\theta = c^3 - 3c(1 - c^2) = 4c^3 - 3c$; substituting $c^2 = 1 - s^2$ in the second, $\sin 3\theta = 3(1 - s^2)s - s^3 = 3s - 4s^3$.

For $n = 5$, again with the binomial theorem,

$$(c + is)^5 = c^5 + 5ic^4s - 10c^3s^2 - 10ic^2s^3 + 5cs^4 + is^5,$$

whose real part is $c^5 - 10c^3s^2 + 5cs^4$. With $s^2 = 1 - c^2$ and $s^4 = (1 - c^2)^2 = 1 - 2c^2 + c^4$,

$$\cos 5\theta = c^5 - 10c^3(1 - c^2) + 5c(1 - 2c^2 + c^4) = c^5 - 10c^3 + 10c^5 + 5c - 10c^3 + 5c^5 = 16c^5 - 20c^3 + 5c.$$

Independent check: for $\theta = \pi/3$ one has $c = 0.5$ and $16(0.5)^5 - 20(0.5)^3 + 5(0.5) = 0.5 - 2.5 + 2.5 = 0.5$, whereas $\cos(5\pi/3) = \cos(-\pi/3) = 0.5$. ✓ □

6.2. The n -th roots of unity

Definition 6.2: n -th roots of unity. Let $n \geq 1$ be an integer. One sets

$$\mu_n = \{z \in \mathbb{C} : z^n = 1\}, \quad \zeta_n = e^{2\pi i/n}.$$

The elements of μ_n are called **n -th roots of unity**. A root $\zeta \in \mu_n$ is said to be **primitive** if its multiplicative order is exactly n , that is if $\zeta^m \neq 1$ for $1 \leq m < n$.

Theorem 6.2: The n -th roots are exactly n (R10.2). For every $n \geq 1$,

$$\mu_n = \{\zeta_n^k = e^{2\pi i k/n} : k = 0, 1, \dots, n-1\},$$

and its n elements are pairwise distinct. In particular $|\mu_n| = n$ and $\mu_n \subset \mathbb{T}$.

Proof. Step 1 — each of those numbers is a root. By Proposition 6.1, $(e^{2\pi i k/n})^n = e^{2\pi i k} = \cos(2\pi k) + i \sin(2\pi k) = 1$.

Step 2 — they are distinct. If $e^{2\pi i k/n} = e^{2\pi i j/n}$ with $0 \leq j \leq k \leq n-1$, then $e^{2\pi i (k-j)/n} = 1$, hence $\frac{2\pi(k-j)}{n} \in 2\pi\mathbb{Z}$, that is $n \mid (k-j)$. But $0 \leq k-j \leq n-1$, so $k-j = 0$.

Step 3 — there are no others. Let $z \in \mu_n$. From $|z|^n = |z^n| = 1$ and $|z| > 0$ real it follows that $|z| = 1$ (the function $t \mapsto t^n$ is strictly increasing on $(0, +\infty)$, hence injective, and $1^n = 1$). Hence $z = e^{i\theta}$ for some $\theta \in \mathbb{R}$ (Theorem 6.1(iii)), and $z^n = e^{in\theta} = 1$ forces $n\theta \in 2\pi\mathbb{Z}$, that is $\theta = \frac{2\pi k}{n}$ for some $k \in \mathbb{Z}$. Writing $k = qn + r$ with $0 \leq r \leq n-1$ (Euclidean division), one has $e^{2\pi i k/n} = e^{2\pi i q} e^{2\pi i r/n} = e^{2\pi i r/n}$.

Independent check. The polynomial $z^n - 1$ has degree n and therefore at most n roots in $\mathbb{C}$ (declared algebraic prerequisite); Steps 1–2 exhibit n distinct ones, so there are no others. The two arguments are independent: the first is analytic (modulus and argument), the second algebraic. ✓ □

Remark 6.2: De Moivre and Euler. From $e^{i\theta} = \cos \theta + i \sin \theta$ de Moivre's formula (Proposition 6.1) becomes $(e^{i\theta})^n = e^{in\theta}$: raising to a power on the circle multiplies the angle. It is the tool with which the multiple-angle identities are derived (Corollary 6.1) and the reason why the unit circle “linearises” trigonometry: a product of phases becomes a sum of angles, and an algebraic equation $z^n = 1$ becomes a division of the full angle into n equal parts. The polynomials T_n such that $\cos n\theta = T_n(\cos \theta)$ are the Chebyshev polynomials of the first kind, which reappear in approximation theory (Chapter 31).

Theorem 6.3: The roots are the vertices of a regular polygon (R10.3). Let $n \geq 3$ and let P_n be the polygon with vertices $V_k = \zeta_n^k$, $k = 0, \dots, n-1$, taken in this order. Then:

- (i) all the vertices lie on the unit circle;
 - (ii) all the sides have the same length $\ell_n = |V_{k+1} - V_k| = 2 \sin \frac{\pi}{n}$ (indices modulo n);
 - (iii) all the interior angles are equal and are worth $\alpha_n = \pi - \frac{2\pi}{n} = \frac{(n-2)\pi}{n}$.
- Hence P_n is a regular polygon with n sides inscribed in the unit circle, and conversely every regular polygon with n sides inscribed in the unit circle is obtained from P_n by a rotation.

Proof. (i) $|\zeta_n^k| = |\zeta_n|^k = 1$.

(ii) Since $V_{k+1} = \zeta_n V_k$,

$$|V_{k+1} - V_k| = |\zeta_n V_k - V_k| = |V_k| |\zeta_n - 1| = |\zeta_n - 1|,$$

which does not depend on k . To compute it one factors out the “half phase”: for every θ ,

$$e^{i\theta} - 1 = e^{i\theta/2}(e^{i\theta/2} - e^{-i\theta/2}) = e^{i\theta/2} \cdot 2i \sin \frac{\theta}{2},$$

where the formula $e^{i\varphi} - e^{-i\varphi} = 2i \sin \varphi$ has been used. Taking moduli and recalling $|e^{i\theta/2}| = |i| = 1$,

$$|e^{i\theta} - 1| = 2 \left| \sin \frac{\theta}{2} \right|.$$

With $\theta = 2\pi/n$ and $0 < \pi/n \leq \pi/3 < \pi$, the sine is positive and one obtains $\ell_n = 2 \sin(\pi/n)$.

(iii) *Equality of the angles.* Multiplication by ζ_n is a rotation by $2\pi/n$ about the origin (Theorem 6.1(ii)), hence an isometry of the plane; it maps the ordered triple (V_{k-1}, V_k, V_{k+1}) to the triple (V_k, V_{k+1}, V_{k+2}) . An isometry preserves angles, so the angle at V_k equals the angle at V_{k+1} for every k : all interior angles coincide.

Common value. Consider the triangle $OV_k V_{k+1}$, with O the origin. It is isosceles because $|OV_k| = |OV_{k+1}| = 1$, and the angle at the vertex O equals $2\pi/n$: indeed $V_{k+1} = e^{2\pi i/n} V_k$, and multiplication by $e^{2\pi i/n}$ rotates by $2\pi/n$. The base angles are therefore equal and each is worth $\frac{1}{2}(\pi - \frac{2\pi}{n}) = \frac{\pi}{2} - \frac{\pi}{n}$. The interior angle of the polygon at V_k is the sum of the base angle of the triangle $OV_{k-1} V_k$ and of that of the triangle $OV_k V_{k+1}$, that is

$$\alpha_n = 2 \left(\frac{\pi}{2} - \frac{\pi}{n} \right) = \pi - \frac{2\pi}{n} = \frac{(n-2)\pi}{n}.$$

(The sum of the two base angles is indeed the interior angle because the centre O is interior to the polygon and the segment OV_k lies inside the angle at V_k : the two triangles lie on opposite sides of the line OV_k , since V_{k-1} and V_{k+1} have arguments $\frac{2\pi k}{n} \mp \frac{2\pi}{n}$, symmetric with respect to $\frac{2\pi k}{n}$, and $0 < 2\pi/n \leq 2\pi/3 < \pi$.)

Independent check on (iii). The sum of the interior angles of a convex polygon with n sides is $(n-2)\pi$; if they are all equal, each is worth $(n-2)\pi/n$, in agreement. ✓

Last assertion. If $W_0, \dots, W_{n-1}$ are the vertices of a regular polygon with n sides inscribed in the unit circle, its centre is the origin and the vertices are obtained one from another by the rotation by $2\pi/n$ (this is the very definition of a regular polygon: the rotations by $2\pi/n$ about the centre map it to itself permuting the vertices cyclically). Hence $W_k = W_0 \zeta_n^k$, that is the polygon is the image of P_n under multiplication by $W_0 \in \mathbb{T}$, which is a rotation. $\square$

Figure 6.1: The five fifth roots of unity and the regular pentagon which is their convex hull. The coordinates of the vertices are $(\cos(72k)^\circ, \sin(72k)^\circ)$ for $k = 0, \dots, 4$, that is $(1, 0)$, $(0.30902, 0.95106)$, $(-0.80902, 0.58779)$, $(-0.80902, -0.58779)$, $(0.30902, -0.95106)$; the side measures $2 \sin 36^\circ = 1.17557$ (Theorem 6.3(ii)) and the interior angle 108° .

Theorem 6.4: Sum of the roots of unity (R10.4). For every $n \geq 2$,

$$\sum_{k=0}^{n-1} \zeta_n^k = 0.$$

Equivalently $\sum_{k=0}^{n-1} \cos \frac{2\pi k}{n} = 0$ and $\sum_{k=0}^{n-1} \sin \frac{2\pi k}{n} = 0$.

Proof. Put $\sigma = \sum_{k=0}^{n-1} \zeta_n^k$.

Step 1 — telescoping identity. For every $q \in \mathbb{C}$ and every $n \geq 1$,

$$(q-1) \sum_{k=0}^{n-1} q^k = \sum_{k=0}^{n-1} q^{k+1} - \sum_{k=0}^{n-1} q^k = q^n - 1,$$

because the two sums differ only by the first and the last summand. This identity holds *always*, even for $q = 1$ (where it says $0 = 0$).

Step 2 — application. With $q = \zeta_n$ one has $q^n = e^{2\pi i} = 1$, hence $(\zeta_n - 1)\sigma = 0$. Since $n \geq 2$, $\zeta_n = e^{2\pi i/n} \neq 1$: indeed $e^{2\pi i/n} = 1$ would require $\frac{2\pi}{n} \in 2\pi\mathbb{Z}$, that is $n \mid 1$. A product of complex numbers vanishes only if one factor does, hence $\sigma = 0$.

Step 3 — real form. Separating the real and the imaginary part of $\sigma = 0$ and using $\zeta_n^k = \cos \frac{2\pi k}{n} + i \sin \frac{2\pi k}{n}$ one obtains the two trigonometric identities. $\square$

Variant: symmetry of the group (independent check). Multiplication by ζ_n permutes the elements of μ_n : the map $z \mapsto \zeta_n z$ maps μ_n into itself because μ_n is closed under products (Corollary 6.2(i), whose proof is independent of this theorem), and it is injective because $\zeta_n \neq 0$: it is therefore a bijection of μ_n , which is finite. Hence $\zeta_n \sigma = \sum_{z \in \mu_n} \zeta_n z = \sum_{w \in \mu_n} w = \sigma$,

whence $(\zeta_n - 1)\sigma = 0$ and $\sigma = 0$. Geometrically: the centroid of a regular polygon centred at the origin is the origin, because a rotation mapping the polygon to itself must fix the centroid, and the only point fixed by a rotation of non-zero angle is the centre. $\square$

Proposition 6.2: Product of the roots of unity. For every $n \geq 1$, $\prod_{k=0}^{n-1} \zeta_n^k = (-1)^{n+1}$.

Proof. Adding the exponents,

$$\prod_{k=0}^{n-1} \zeta_n^k = \zeta_n^{0+1+\dots+(n-1)} = \zeta_n^{n(n-1)/2} = \left(e^{2\pi i/n}\right)^{n(n-1)/2} = e^{\pi i(n-1)} = (-1)^{n-1} = (-1)^{n+1},$$

where $e^{i\pi} = -1$ has been used together with the fact that $(-1)^{n-1} = (-1)^{n+1}$ because the exponents differ by 2.

Independent check. From $z^n - 1 = \prod_{k=0}^{n-1} (z - \zeta_n^k)$ (the two polynomials are monic of degree n and have the same n distinct roots, by Theorem 6.2) one reads off the constant term by setting $z = 0$: $-1 = \prod_k (-\zeta_n^k) = (-1)^n \prod_k \zeta_n^k$, whence $\prod_k \zeta_n^k = (-1)^{-n} \cdot (-1) = (-1)^{n+1}$. $\checkmark$ For $n = 4$: $1 \cdot i \cdot (-1) \cdot (-i) = i \cdot i = -1 = (-1)^5$. $\checkmark$ $\square$

Corollary 6.2: The cyclic group inside the circle. For every $n \geq 1$:

- (i) μ_n is a subgroup of $\mathbb{T}$;
- (ii) μ_n is cyclic of order n , generated by ζ_n , and $\mu_n \cong \mathbb{Z}/n\mathbb{Z}$;
- (iii) every finite subgroup H of $\mathbb{T}$ of order n coincides with μ_n ; in particular the finite subgroups of $\mathbb{T}$ are exactly the μ_n , and they are all cyclic.

The circle therefore contains, for every n , one and only one copy of the cyclic group of order n : it is the bridge between the geometry of the circle and modular arithmetic.

Proof. (i) $1 \in \mu_n$ because $1^n = 1$. If $z^n = w^n = 1$ then $(zw)^n = z^n w^n = 1$ (multiplication is commutative) and $(z^{-1})^n = (z^n)^{-1} = 1$. Hence μ_n is a subgroup of $\mathbb{C}^*$; and it is contained in $\mathbb{T}$ by Theorem 6.2, so it is a subgroup of $\mathbb{T}$.

(ii) Consider

$$\varphi: \mathbb{Z} \longrightarrow \mathbb{T}, \quad \varphi(k) = \zeta_n^k.$$

It is a homomorphism from $(\mathbb{Z}, +)$ to $(\mathbb{T}, \cdot)$ because $\zeta_n^{k+j} = \zeta_n^k \zeta_n^j$.

Image. $\text{im } \varphi = \{\zeta_n^k : k \in \mathbb{Z}\}$. Every ζ_n^k lies in μ_n because $(\zeta_n^k)^n = (\zeta_n^n)^k = 1$; conversely every element of μ_n has the form ζ_n^k by Theorem 6.2. Hence $\text{im } \varphi = \mu_n$: in particular μ_n is cyclic, generated by ζ_n .

Kernel. $\varphi(k) = 1$ means $e^{2\pi i k/n} = 1$, that is $\frac{2\pi k}{n} \in 2\pi\mathbb{Z}$, that is $\frac{k}{n} \in \mathbb{Z}$, that is $n \mid k$. Hence $\ker \varphi = n\mathbb{Z}$.

Conclusion. By the first isomorphism theorem (declared prerequisite),

$$\mathbb{Z}/n\mathbb{Z} = \mathbb{Z}/\ker \varphi \cong \text{im } \varphi = \mu_n.$$

The order is n , consistently with $|\mu_n| = n$ (Theorem 6.2). The explicit isomorphism is $k + n\mathbb{Z} \mapsto \zeta_n^k$: the sum of the indices modulo n corresponds to the product of the roots, that is to the sum of the angles modulo 2π .

(iii) Let $H \leq \mathbb{T}$ be finite with $|H| = n$ and let $z \in H$. By Lagrange's theorem (declared prerequisite) the order d of z divides n , hence $z^n = (z^d)^{n/d} = 1$ and $z \in \mu_n$. Therefore $H \subseteq \mu_n$; since $|H| = n = |\mu_n|$ and μ_n is finite, one has $H = \mu_n$. Conversely every μ_n is a finite subgroup by (i)–(ii). Finally every μ_n is cyclic by (ii). $\square$

Proposition 6.3: Which roots are primitive. Let $n \geq 1$ and $0 \leq k \leq n-1$. The multiplicative order of ζ_n^k is $\frac{n}{\gcd(k, n)}$. In particular ζ_n^k is a primitive n -th root if and only if $\gcd(k, n) = 1$, and the primitive n -th roots are exactly $\varphi(n)$ in number, where φ is Euler's function.

Proof. Let $d = \gcd(k, n)$, $k = dk'$, $n = dn'$ with $\gcd(k', n') = 1$. One has

$$(\zeta_n^k)^m = 1 \iff e^{2\pi i km/n} = 1 \iff n \mid km \iff n' \mid k'm.$$

Since $\gcd(k', n') = 1$, Euclid's lemma gives $n' \mid m$. The smallest positive integer m with this property is $m = n' = n/d$: the order is therefore $n/\gcd(k, n)$.

The order equals n if and only if $\gcd(k, n) = 1$; the number of such k in $\{0, \dots, n-1\}$ is by definition $\varphi(n)$.

Independent check. For $n = 6$: $\gcd(k, 6) = 1$ only for $k = 1, 5$, hence $\varphi(6) = 2$ primitive roots, namely ζ_6 and ζ_6^5 . Indeed $\zeta_6^2 = \zeta_3$ has order 3, $\zeta_6^3 = -1$ has order 2, ζ_6^4 has order 3, $\zeta_6^0 = 1$ has order 1: the orders are 1, 6, 3, 2, 3, 6, that is $6/\gcd(k, 6)$ for $k = 0, \dots, 5$. ✓ $\square$

Theorem 6.5: Orthogonality of the geometric sums (R10.4). Let $n \geq 1$. For every $j \in \mathbb{Z}$,

$$\sum_{k=0}^{n-1} \zeta_n^{jk} = \begin{cases} n, & \text{if } n \mid j, \\ 0, & \text{if } n \nmid j. \end{cases}$$

Consequently, for $\ell, m \in \{0, 1, \dots, n-1\}$,

$$\frac{1}{n} \sum_{k=0}^{n-1} \zeta_n^{k(m-\ell)} = \delta_{\ell m} = \begin{cases} 1, & \ell = m, \\ 0, & \ell \neq m, \end{cases}$$

that is, the vectors $\chi_\ell = (\zeta_n^{\ell k})_{k=0}^{n-1}$, $\ell = 0, \dots, n-1$, are pairwise orthogonal in $\mathbb{C}^n$ with respect to the Hermitian product $\langle u, v \rangle = \sum_k u_k \overline{v_k}$, and each has norm $\sqrt{n}$.

Proof. Put $q = \zeta_n^j = e^{2\pi i j/n}$, so that $\sum_{k=0}^{n-1} \zeta_n^{jk} = \sum_{k=0}^{n-1} q^k$. Two cases must be distinguished, and the distinction is exactly that between a vanishing and a non-vanishing denominator in the formula for the geometric sum.

Case 1: $n \mid j$ (vanishing denominator). Then $\frac{j}{n} \in \mathbb{Z}$, hence $q = e^{2\pi i \cdot (j/n)} = 1$. The closed formula $\sum_{k=0}^{n-1} q^k = \frac{q^n - 1}{q - 1}$ is **not applicable**: the denominator $q - 1$ vanishes, and so does the numerator, so that the quotient is the indeterminate form $0/0$. One therefore sums directly: all n summands equal $1^k = 1$, and

$$\sum_{k=0}^{n-1} q^k = \underbrace{1 + 1 + \dots + 1}_{n \text{ times}} = n.$$

Case 2: $n \nmid j$ (non-vanishing denominator). One first shows that $q \neq 1$: $q = e^{2\pi i j/n} = 1$ is equivalent to $\frac{2\pi j}{n} \in 2\pi\mathbb{Z}$, that is to $\frac{j}{n} \in \mathbb{Z}$, that is to $n \mid j$, which is excluded. By the telescoping identity of Theorem 6.4 (Step 1), valid for every q ,

$$(q - 1) \sum_{k=0}^{n-1} q^k = q^n - 1,$$

and now it is legitimate to divide by $q - 1 \neq 0$:

$$\sum_{k=0}^{n-1} q^k = \frac{q^n - 1}{q - 1}.$$

Finally $q^n = (e^{2\pi i j/n})^n = e^{2\pi i j} = 1$ because j is an integer, hence the numerator vanishes and the sum equals 0.

Consequence (orthogonality). One applies what has just been proved to $j = m - \ell$. If $\ell, m \in \{0, \dots, n-1\}$ then $|m - \ell| \leq n-1 < n$, hence $n \mid (m - \ell)$ if and only if $m - \ell = 0$, that is $\ell = m$. The first case gives the sum n , the second 0: divided by n , one obtains $\delta_{\ell m}$.

For the vector reading observe that $\bar{\zeta}_n^{\ell k} = \zeta_n^{-\ell k}$ (because $|\zeta_n| = 1$), hence

$$\langle \chi_m, \chi_\ell \rangle = \sum_{k=0}^{n-1} \zeta_n^{mk} \bar{\zeta}_n^{\ell k} = \sum_{k=0}^{n-1} \zeta_n^{k(m-\ell)} = n \delta_{\ell m},$$

whence the orthogonality and $\|\chi_\ell\|^2 = n$. □

Remark 6.3: Why this identity is the heart of the DFT. Theorem 6.5 is, literally, the reason why the discrete Fourier transform is invertible. The vectors $\chi_0, \dots, \chi_{n-1}$ are n pairwise orthogonal non-zero vectors in $\mathbb{C}^n$, hence an orthogonal basis; the matrix having them as columns, divided by $\sqrt{n}$, is unitary. Chapter 22 reconstructs the whole edifice of the DFT — inversion, unitarity, circular convolution, Parseval — starting from these two lines, and Chapter 13 gives its continuous version (orthogonality of the characters $z \mapsto z^n$ of $\mathbb{T}$). The case $n \mid j$ is not a technical nuisance: it is the “DC” (mean) term of the signal, and it is the only case in which the sum does not vanish.

Example 6.1: Numerical check of the orthogonality for $n = 6$. Let $n = 6$, $\zeta_6 = e^{i\pi/3} = 0.5 + 0.86603i$. One computes $S(j) = \sum_{k=0}^5 \zeta_6^{jk}$ separating real and imaginary parts.

For $j = 1$ the angles are $0^\circ, 60^\circ, 120^\circ, 180^\circ, 240^\circ, 300^\circ$:

$$\sum_k \cos = 1 + 0.5 - 0.5 - 1 - 0.5 + 0.5 = 0, \quad \sum_k \sin = 0 + 0.86603 + 0.86603 + 0 - 0.86603 - 0.86603 = 0,$$

hence $S(1) = 0$. For $j = 2$ the angles are $0^\circ, 120^\circ, 240^\circ, 0^\circ, 120^\circ, 240^\circ$ and one obtains $\sum \cos = 2(1 - 0.5 - 0.5) = 0$, $\sum \sin = 2(0 + 0.86603 - 0.86603) = 0$, that is $S(2) = 0$. For $j = 3$ the summands are $1, -1, 1, -1, 1, -1$ and $S(3) = 0$. For $j = 0$ and $j = 6$ all the summands equal 1 and $S = 6$.

Independent check with the closed formula (legitimate only for $j = 1, 2, 3, 4, 5$, where $q \neq 1$): $q^6 = 1$ for every integer j , hence $\frac{q^6 - 1}{q - 1} = \frac{0}{q - 1} = 0$. For $j = 0$ and $j = 6$ the closed formula cannot be used, and the direct sum gives 6. The two computations agree. ✓

Exercise 6.1. Compute the three cube roots of unity in algebraic form and verify that their sum is zero and that their product equals 1.

Solution. By Theorem 6.2, $\zeta_3^0 = 1$, $\zeta_3^1 = e^{2\pi i/3} = \cos 120^\circ + i \sin 120^\circ = -\frac{1}{2} + \frac{\sqrt{3}}{2}i$, $\zeta_3^2 = e^{4\pi i/3} = -\frac{1}{2} - \frac{\sqrt{3}}{2}i$. The sum equals

$$1 + \left(-\frac{1}{2} + \frac{\sqrt{3}}{2}i\right) + \left(-\frac{1}{2} - \frac{\sqrt{3}}{2}i\right) = 1 - 1 + 0i = 0,$$

in agreement with Theorem 6.4. The product equals $1 \cdot \zeta_3 \cdot \zeta_3^2 = \zeta_3^3 = 1$, in agreement with Proposition 6.2 ($(-1)^{3+1} = 1$). The three points are the vertices of an equilateral triangle inscribed in the unit circle (Theorem 6.3), with side $2 \sin 60^\circ = \sqrt{3} = 1.73205$. *Check:* $|\zeta_3 - 1| = |-\frac{3}{2} + \frac{\sqrt{3}}{2}i| = \sqrt{2.25 + 0.75} = \sqrt{3}$. ✓

6.3. Regular polygons and constructibility

The roots of unity divide the circle into n equal arcs; constructing them with ruler and compass is the *cyclotomic* problem (from the Greek: “cutting of the circle”). This section establishes what can be obtained by elementary means and refers to Volume II for the complete answer.

Definition 6.3: Constructible number and constructible polygon. A real number α is **constructible** if, starting from the points $(0, 0)$ and $(1, 0)$, a segment of length $|\alpha|$ can be obtained with finitely many ruler-and-compass constructions (drawing the line through two constructed points, the circle with centre a constructed point and radius the distance between two constructed points, and taking intersections). A complex number $z = x + iy$ is constructible if x and y are. The **regular polygon with n sides is constructible** if the point ζ_n is.

It is assumed known (Volume II, Chapter 7) that the constructible numbers form a subfield of $\mathbb{R}$ closed under the square root of positive elements, and that the constructible complex numbers form a subfield of $\mathbb{C}$.

Proposition 6.4: Constructibility of the polygon and of the cosine. For $n \geq 3$, the regular polygon with n sides is constructible if and only if $\cos \frac{2\pi}{n}$ is a constructible number.

Proof. ($\Rightarrow$) If ζ_n is constructible, then by definition so is its real part, which is $\cos \frac{2\pi}{n}$. ($\Leftarrow$) Let $c = \cos \frac{2\pi}{n}$ be constructible. Then c^2 is constructible (product), $1 - c^2$ is constructible (difference) and is ≥ 0 ; hence $\sqrt{1 - c^2}$ is constructible. Since $0 < \frac{2\pi}{n} \leq \frac{2\pi}{3} < \pi$, one has $\sin \frac{2\pi}{n} > 0$ and therefore $\sin \frac{2\pi}{n} = \sqrt{1 - c^2}$. Hence $\zeta_n = c + i\sqrt{1 - c^2}$ has constructible real and imaginary parts. $\square$

Proposition 6.5: Doubling and dividing the number of sides. Let $n \geq 3$.

- (i) If the regular polygon with n sides is constructible, so is the one with $2n$ sides.
- (ii) If the regular polygon with n sides is constructible and $d \mid n$ with $d \geq 3$, then the regular polygon with d sides is constructible.
- (iii) If the regular polygons with m and with n sides are constructible and $\gcd(m, n) = 1$, then so is the one with mn sides.

Proof. (i) Let $V_0 = 1$ and $V_1 = \zeta_n$ be two consecutive vertices, constructible by hypothesis. The midpoint of the arc V_0V_1 is the intersection, on the side of the arc, between the unit circle and the perpendicular bisector of the segment V_0V_1 : both are constructible objects (the perpendicular bisector of a segment is an elementary ruler-and-compass construction), and the intersection of a line with a circle is allowed. That midpoint is ζ_{2n} : indeed the perpendicular bisector of V_0V_1 is the line through the origin with argument $\frac{\pi}{n}$ — because the reflection in that line exchanges V_0 and V_1 (it maps $e^{i\theta}$ to $e^{i(2\pi/n - \theta)}$, which for $\theta = 0$ gives ζ_n and for $\theta = 2\pi/n$ gives 1) — and it meets the minor arc V_0V_1 at the point $e^{i\pi/n} = \zeta_{2n}$.

(ii) Let $n = dq$. Then $\zeta_n^q = e^{2\pi i q/(dq)} = e^{2\pi i/d} = \zeta_d$, and the product of constructible numbers is constructible: ζ_d is constructible because ζ_n is. (Geometrically: one takes every q -th vertex of the polygon with n sides.)

(iii) Since $\gcd(m, n) = 1$, by Bézout’s identity there exist $u, v \in \mathbb{Z}$ with $um + vn = 1$. Then

$$\frac{1}{mn} = \frac{um + vn}{mn} = \frac{u}{n} + \frac{v}{m}, \quad \text{hence} \quad \zeta_{mn} = e^{2\pi i/(mn)} = (e^{2\pi i/n})^u (e^{2\pi i/m})^v = \zeta_n^u \zeta_m^v,$$

a product of integer powers of constructible numbers, hence constructible (the constructibles form a field, and $\zeta_n^{-1} = \overline{\zeta_n}$ is constructible because ζ_n is). $\square$

Proposition 6.6: *The cosine of 72° and the constructibility of the pentagon. One has*

$$\cos \frac{2\pi}{5} = \cos 72^\circ = \frac{\sqrt{5} - 1}{4},$$

and consequently the regular pentagon is constructible with ruler and compass.

Proof. Step 1 — the algebraic equation. Put $\theta = 72^\circ$ and $c = \cos \theta$. Then $3\theta = 216^\circ$ and $2\theta = 144^\circ$, and since $216^\circ = 360^\circ - 144^\circ$ one has $\cos 3\theta = \cos 2\theta$. Using $\cos 3\theta = 4c^3 - 3c$ (Corollary 6.1) and $\cos 2\theta = 2c^2 - 1$ (case $n = 2$ of the same computation: $\cos 2\theta + i \sin 2\theta = (c + is)^2 = c^2 - s^2 + 2ics$, hence $\cos 2\theta = c^2 - s^2 = 2c^2 - 1$), one obtains

$$4c^3 - 3c = 2c^2 - 1, \quad \text{that is} \quad 4c^3 - 2c^2 - 3c + 1 = 0.$$

Step 2 — factorisation. The value $c = 1$ annihilates the polynomial ($4 - 2 - 3 + 1 = 0$), hence $(c - 1)$ divides it. The division gives

$$4c^3 - 2c^2 - 3c + 1 = (c - 1)(4c^2 + 2c - 1),$$

as one checks by expanding: $(c - 1)(4c^2 + 2c - 1) = 4c^3 + 2c^2 - c - 4c^2 - 2c + 1 = 4c^3 - 2c^2 - 3c + 1$.
✓

Step 3 — the right root. Since $\theta = 72^\circ$ is not a multiple of 360° , one has $c \neq 1$, hence $4c^2 + 2c - 1 = 0$ and

$$c = \frac{-2 \pm \sqrt{4 + 16}}{8} = \frac{-1 \pm \sqrt{5}}{4}.$$

Since $0 < 72^\circ < 90^\circ$, $c > 0$, and of the two roots $\frac{-1 + \sqrt{5}}{4} \approx 0.30902$ and $\frac{-1 - \sqrt{5}}{4} \approx -0.80902$ only the first is positive. Hence $c = \frac{\sqrt{5} - 1}{4}$.

Independent check. $\sqrt{5} = 2.2360680$, hence $\frac{\sqrt{5} - 1}{4} = \frac{1.2360680}{4} = 0.3090170$; and $\cos 72^\circ = 0.3090170$. ✓ Observe moreover that the second root $\frac{-1 - \sqrt{5}}{4} = -0.8090170$ is $\cos 144^\circ$: the two roots of the trinomial are the two distinct cosines that occur among the fifth roots of unity, consistently with $\zeta_5^k + \zeta_5^{-k} = 2 \cos \frac{2\pi k}{5}$.

Step 4 — constructibility. The number $\sqrt{5}$ is constructible: it is the hypotenuse of the right triangle with legs 1 and 2, both constructible. Subtracting 1 and dividing by 4 are field operations, which are allowed. Hence c is constructible and, by Proposition 6.4, the regular pentagon is constructible. □

Corollary 6.3: *The pentadecagon. The regular polygon with 15 sides is constructible, and more generally so are all the polygons with $n = 3^a 5^b 2^k$ and $a, b \in \{0, 1\}$, $k \geq 0$, $n \geq 3$.*

Proof. The equilateral triangle is constructible ($\cos \frac{2\pi}{3} = -\frac{1}{2}$ is rational, hence constructible, and Proposition 6.4 applies); the pentagon is by Proposition 6.6. Since $\gcd(3, 5) = 1$, Proposition 6.5(iii) gives the pentadecagon. Explicitly, Bézout's identity $2 \cdot 3 - 1 \cdot 5 = 1$ gives $\frac{2}{5} - \frac{1}{3} = \frac{6 - 5}{15} = \frac{1}{15}$, that is

$$\zeta_{15} = \zeta_5^2 \zeta_3^{-1}.$$

Independent check. $\frac{2\pi}{15} = 24^\circ$ and $2 \cdot 72^\circ - 120^\circ = 24^\circ$. ✓

Finally the square is constructible, because $\cos \frac{2\pi}{4} = 0$ is rational and Proposition 6.4 applies; repeated doubling (Proposition 6.5(i)) then yields all the $n = 2^k m$ with $m \in \{3, 4, 5, 15\}$ and $k \geq 0$, that is exactly all the $n \geq 3$ of the form $3^a 5^b 2^k$ with $a, b \in \{0, 1\}$. □

Remark 6.4: The Gauss–Wantzel theorem: statement and cross-reference.

Statement. The regular polygon with n sides ($n \geq 3$) is constructible with ruler and compass if and only if

$$n = 2^k p_1 p_2 \cdots p_m,$$

with $k \geq 0$ and $p_1, \dots, p_m$ distinct Fermat primes, that is primes of the form $2^{2^r} + 1$ (the only known ones are 3, 5, 17, 257, 65537).

Cross-reference. This statement is not an imported result of the treatise: it is proved in full, in both implications, in **Volume II, Chapter 7** (“The discrete circle”), where one finds the definition of a constructible number, the theorem on the degree of constructible numbers (necessity, Wantzel 1837) and the construction of the Gaussian periods with the chain of quadratic extensions (sufficiency, Gauss 1796), besides the explicit construction of the 17-gon. Here it is not duplicated: it is only applied.

What is needed of that theorem in this chapter. None of the previous results depends on it: Propositions 6.4, 6.5 and 6.6 and Corollary 6.3 are proved here and independently, and they cover the “easy” part (sufficiency for $n = 3 \cdot 2^k, 5 \cdot 2^k, 15 \cdot 2^k, 2^k$). The Gauss–Wantzel theorem is instead needed for the negative answers — the heptagon, the nonagon, the hendecagon are not constructible — and for the case of large Fermat primes, and in this chapter it appears only in the exercises, with an explicit reference to Volume II.

Remark 6.5: Gauss’s 17-gon and the quadrature of the circle. Gauss proved on 30 March 1796, at the age of nineteen, that the regular polygon with 17 sides is constructible ($17 = 2^{2^2} + 1$ is a Fermat prime); the discovery, recorded as the first entry of his diary, led him to choose mathematics. The constructibility of polygons concerns the division of the circle into equal parts and is “dual” to the impossibility of squaring the circle (Chapter 1): there one would have to construct $\sqrt{\pi}$, which is impossible because π is transcendental; here one has to construct $\cos \frac{2\pi}{n}$, which is always an algebraic number but is constructible only for certain n . The circle stands at the centre of both questions, and the difference between the two answers is exactly the difference between “algebraic” and “of degree a power of two”.

Exercise 6.2. Is the regular pentagon constructible? And the heptagon (seven sides)? And the polygon with 20 sides?

Solution. *Pentagon:* yes, and this is proved in this chapter without appealing to Gauss–Wantzel: Proposition 6.6 explicitly constructs $\cos 72^\circ = \frac{\sqrt{5}-1}{4}$ with a single square root.

Heptagon: no. Here the “negative” part of the Gauss–Wantzel theorem is needed, recalled in Remark 6.4 and proved in Volume II, Chapter 7: 7 is not a Fermat prime (it is not of the form $2^{2^r} + 1$, since $2^{2^0} + 1 = 3$, $2^{2^1} + 1 = 5$ and already $2^{2^2} + 1 = 17 > 7$), and 7 does not admit the required factorisation $2^k p_1 \cdots p_m$. Hence the regular heptagon is not constructible with ruler and compass.

Polygon with 20 sides: yes. One has $20 = 2^2 \cdot 5$, with 5 a Fermat prime: it falls under the Gauss–Wantzel form. But here Proposition 6.5(i) applied twice to the pentagon ($5 \rightarrow 10 \rightarrow 20$) suffices, so the answer is independent of the cross-reference.

6.4. Möbius transformations and generalised circles

Definition 6.4: Extended complex plane and Möbius transformation. One sets $\hat{\mathbb{C}} = \mathbb{C} \cup \{\infty\}$ (extended complex plane, or Riemann sphere). A Möbius transformation is a map

$$T : \hat{\mathbb{C}} \rightarrow \hat{\mathbb{C}}, \quad T(z) = \frac{az + b}{cz + d}, \quad a, b, c, d \in \mathbb{C}, \quad ad - bc \neq 0,$$

extended to $\hat{\mathbb{C}}$ by the conventions: if $c \neq 0$, $T(-d/c) = \infty$ and $T(\infty) = a/c$; if $c = 0$, $T(\infty) = \infty$.

Proposition 6.7: The Möbius group. Möbius transformations are bijections of $\hat{\mathbb{C}}$ and form a group under composition. Moreover the map

$$\Psi : GL(2, \mathbb{C}) \rightarrow \text{Möb}, \quad \Psi \begin{pmatrix} a & b \\ c & d \end{pmatrix} = \left(z \mapsto \frac{az + b}{cz + d} \right)$$

is a surjective group homomorphism whose kernel is the set of scalar matrices λI , $\lambda \neq 0$.

Proof. **Step 1 — Ψ is a homomorphism.** Let $M = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$ and $N = \begin{pmatrix} e & f \\ g & h \end{pmatrix}$ be invertible, $S = \Psi(N)$, $T = \Psi(M)$. For z such that all the denominators are non-zero,

$$T(S(z)) = \frac{a \frac{ez + f}{gz + h} + b}{c \frac{ez + f}{gz + h} + d} = \frac{a(ez + f) + b(gz + h)}{c(ez + f) + d(gz + h)} = \frac{(ae + bg)z + (af + bh)}{(ce + dg)z + (cf + dh)},$$

where numerator and denominator have been multiplied by $gz + h \neq 0$. The coefficients obtained are exactly the entries of MN . The case of the exceptional points ($z = \infty$, z a pole of S , $S(z)$ a pole of T) is checked with the conventions of Definition 6.4; for instance if $g \neq 0$ and $z = -h/g$ then $S(z) = \infty$ and $T(S(z)) = a/c$, whereas the composite formula evaluated at $-h/g$ gives

$$\frac{(ae + bg)(-h/g) + (af + bh)}{(ce + dg)(-h/g) + (cf + dh)} = \frac{a(fg - eh)/g}{c(fg - eh)/g} = \frac{a}{c},$$

since $fg - eh = -\det N \neq 0$; the other cases are analogous.

Step 2 — group and bijectivity. $\Psi(I)$ is the identity. By Step 1, $\Psi(M) \circ \Psi(M^{-1}) = \Psi(MM^{-1}) = \text{id}$ and similarly in the other order, hence every $\Psi(M)$ is bijective with inverse $\Psi(M^{-1})$, that is

$$T^{-1}(w) = \frac{dw - b}{-cw + a}.$$

The image of Ψ is by definition the set of Möbius transformations, which is therefore a subgroup of the group of bijections of $\hat{\mathbb{C}}$: it is closed under composition and inverses and contains the identity.

Step 3 — the kernel. If $\Psi(M) = \text{id}$, then $\frac{az+b}{cz+d} = z$ for every $z \in \mathbb{C}$ which is not a pole, that is $cz^2 + (d-a)z - b = 0$ for infinitely many z : a polynomial with infinitely many roots is zero, hence $c = 0$, $b = 0$ and $a = d$. Since $\det M = ad \neq 0$, one has $a = d \neq 0$ and $M = aI$. Conversely $\Psi(\lambda I)(z) = \frac{\lambda z}{\lambda} = z$. $\square$

Definition 6.5: Generalised circle. A generalised circle of $\hat{\mathbb{C}}$ is a subset $\hat{\Gamma} \subseteq \hat{\mathbb{C}}$ of the form:

- $\hat{\Gamma} = \Gamma$, with $\Gamma \subset \mathbb{C}$ a circle with centre z_0 and radius $r > 0$; or
- $\hat{\Gamma} = L \cup \{\infty\}$, with $L \subset \mathbb{C}$ a line.

In the second case one says that the generalised circle *passes through* ∞ .

Lemma 6.1: Equation of the generalised circles (R10.6). Let $A, C \in \mathbb{R}$, $B \in \mathbb{C}$ with $|B|^2 > AC$, and let

$$\Gamma_{A,B,C} = \{z \in \mathbb{C} : Az\bar{z} + Bz + \bar{B}\bar{z} + C = 0\}. \quad (*)$$

Then:

- (i) the left-hand side of $(*)$ is real for every z ;
- (ii) if $A \neq 0$, $\Gamma_{A,B,C}$ is the circle with centre $-\bar{B}/A$ and radius $\sqrt{|B|^2 - AC}/|A|$;
- (iii) if $A = 0$, $\Gamma_{A,B,C}$ is a line;
- (iv) conversely every circle and every line of $\mathbb{C}$ has the form $\Gamma_{A,B,C}$ for suitable A, B, C with $|B|^2 > AC$, and the triple (A, B, C) is unique up to a non-zero real factor.

The associated generalised circle is $\Gamma_{A,B,C}$ if $A \neq 0$ and $\Gamma_{0,B,C} \cup \{\infty\}$ if $A = 0$.

Proof. (i) $Az\bar{z} = A|z|^2$ is real because A is; $Bz + \bar{B}\bar{z} = Bz + \overline{Bz} = 2\Re(Bz)$ is real; C is real.
(ii) Let $A \neq 0$. Dividing $(*)$ by A and putting $b = \bar{B}/A$ (hence $\bar{b} = B/A$) and $c = C/A$, the equation becomes $z\bar{z} + \bar{b}z + b\bar{z} + c = 0$. Now

$$|z + b|^2 = (z + b)\overline{(z + b)} = z\bar{z} + z\bar{b} + b\bar{z} + |b|^2,$$

hence $(*)$ is equivalent to $|z + b|^2 = |b|^2 - c$. One computes

$$|b|^2 - c = \frac{|B|^2}{A^2} - \frac{C}{A} = \frac{|B|^2 - AC}{A^2} > 0$$

by hypothesis. Therefore $\Gamma_{A,B,C}$ is the circle with centre $-b = -\bar{B}/A$ and radius $\sqrt{|B|^2 - AC}/|A|$.

(iii) Let $A = 0$. Then $|B|^2 > 0$, that is $B \neq 0$. Putting $B = \beta_1 + i\beta_2$ and $z = x + iy$, one has $\Re(Bz) = \beta_1x - \beta_2y$ and $(*)$ becomes

$$2\beta_1x - 2\beta_2y + C = 0,$$

a first-degree equation with coefficients $(2\beta_1, -2\beta_2) \neq (0, 0)$: it is a line.

(iv) *Circle.* The circle with centre z_0 and radius $r > 0$ is $|z - z_0|^2 = r^2$, that is $z\bar{z} - \bar{z}_0z - z_0\bar{z} + |z_0|^2 - r^2 = 0$: it is $(*)$ with $A = 1$, $B = -\bar{z}_0$, $C = |z_0|^2 - r^2$, and $|B|^2 - AC = |z_0|^2 - |z_0|^2 + r^2 = r^2 > 0$.

Line. Let $ux + vy + w = 0$ with u, v, w real and $(u, v) \neq (0, 0)$. Put $A = 0$, $B = \frac{u}{2} - i\frac{v}{2}$ and $C = w$. Then, with $z = x + iy$,

$$Bz = \left(\frac{u}{2} - i\frac{v}{2}\right)(x + iy) = \left(\frac{u}{2}x + \frac{v}{2}y\right) + i\left(\frac{u}{2}y - \frac{v}{2}x\right),$$

hence $Bz + \bar{B}\bar{z} = 2\Re(Bz) = ux + vy$ and equation $(*)$ becomes exactly $ux + vy + w = 0$. Moreover $|B|^2 - AC = \frac{u^2 + v^2}{4} > 0$.

Uniqueness up to a real factor. If $\Gamma_{A,B,C} = \Gamma_{A',B',C'}$ as sets, observe that (ii)–(iii) determine the type (circle or line) according to whether A vanishes or not, and then: in the circle case, $A \neq 0$ and $A' \neq 0$, and centre and radius determine $\bar{B}/A = \bar{B}'/A'$ and $(|B|^2 - AC)/A^2 = (|B'|^2 - A'C')/A'^2$; putting $\lambda = A'/A \in \mathbb{R} \setminus \{0\}$ one gets $B' = \lambda B$ and hence $C' = \lambda C$. In the line case, $A = A' = 0$ and the coefficients $(2\beta_1, -2\beta_2, C)$ of one and the same line are proportional with a non-zero real factor. $\square$

Lemma 6.2: Decomposition of a Möbius transformation. Every Möbius transformation is a composition of finitely many maps of the following three types:

$$(T) \ t_\beta(z) = z + \beta \ (\beta \in \mathbb{C}); \quad (S) \ m_\alpha(z) = \alpha z \ (\alpha \in \mathbb{C}^*); \quad (I) \ \iota(z) = \frac{1}{z}.$$

Precisely: if $c = 0$ then $T = t_{b/d} \circ m_{a/d}$; if $c \neq 0$ then

$$T = t_{a/c} \circ m_{(bc-ad)/c} \circ \iota \circ t_d \circ m_c.$$

Proof. **Case $c = 0$.** Then $ad - bc = ad \neq 0$, hence $a \neq 0$ and $d \neq 0$, and $T(z) = \frac{az+b}{d} = \frac{a}{d}z + \frac{b}{d}$: it is $m_{a/d}$ followed by $t_{b/d}$, with $a/d \neq 0$. On the exceptional points: $T(\infty) = \infty$, and also $t_{b/d}(m_{a/d}(\infty)) = \infty$.

Case $c \neq 0$. One divides $az + b$ by $cz + d$:

$$\frac{a}{c}(cz + d) = az + \frac{ad}{c}, \quad \text{hence} \quad az + b = \frac{a}{c}(cz + d) + \left(b - \frac{ad}{c}\right) = \frac{a}{c}(cz + d) + \frac{bc - ad}{c},$$

whence

$$T(z) = \frac{az + b}{cz + d} = \frac{a}{c} + \frac{bc - ad}{c} \cdot \frac{1}{cz + d}.$$

The factor $\frac{bc-ad}{c}$ is non-zero because $ad - bc \neq 0$. Reading the expression from right to left one recognises the chain

$$z \xrightarrow{m_c} cz \xrightarrow{t_d} cz + d \xrightarrow{\iota} \frac{1}{cz + d} \xrightarrow{m_{(bc-ad)/c}} \frac{bc - ad}{c(cz + d)} \xrightarrow{t_{a/c}} T(z).$$

On the exceptional points: $z = -d/c$ gives $cz + d = 0$, then $\iota(0) = \infty$, then $m(\infty) = \infty$, then $t(\infty) = \infty = T(-d/c)$; and $z = \infty$ gives $m_c(\infty) = \infty$, $t_d(\infty) = \infty$, $\iota(\infty) = 0$, $m(0) = 0$, $t_{a/c}(0) = a/c = T(\infty)$. ✓ $\square$

Theorem 6.6: Möbius maps send generalised circles to generalised circles (R11.5). Let T be a Möbius transformation and $\hat{\Gamma}$ a generalised circle of $\hat{\mathbb{C}}$. Then $T(\hat{\Gamma})$ is a generalised circle. Since T is bijective (Proposition 6.7), T induces a bijection of the family of generalised circles onto itself.

Proof. By Lemma 6.2 it suffices to check the assertion for the three generating types, and in each case one works on the equation

$$Az\bar{z} + Bz + \bar{B}\bar{z} + C = 0, \quad A, C \in \mathbb{R}, \ B \in \mathbb{C}, \ |B|^2 - AC > 0$$

of Lemma 6.1. In all three cases one shows that the image has an equation of the same type, with coefficients A', B', C' such that $A', C' \in \mathbb{R}$ and

$$|B'|^2 - A'C' > 0,$$

a condition which guarantees that the image set is still a circle or a line and not the empty set or a single point.

Case (T): $w = z + \beta$, that is $z = w - \beta$. Substituting, with $\overline{w - \beta} = \bar{w} - \bar{\beta}$:

$$\begin{aligned} A(w - \beta)(\bar{w} - \bar{\beta}) + B(w - \beta) + \bar{B}(\bar{w} - \bar{\beta}) + C &= Aw\bar{w} - A\bar{\beta}w - A\beta\bar{w} + A|\beta|^2 + Bw - B\beta + \bar{B}\bar{w} - \bar{B}\bar{\beta} + C \\ &= Aw\bar{w} + (B - A\bar{\beta})w + (\bar{B} - A\beta)\bar{w} + (A|\beta|^2 - 2\Re(B\beta) + C). \end{aligned}$$

One therefore sets $A' = A$, $B' = B - A\bar{\beta}$, $C' = A|\beta|^2 - 2\Re(B\beta) + C$. One checks: A' and C' are real; and $\bar{B}' = \bar{B} - A\beta$ is precisely the coefficient of $\bar{w}$, as required by the form (*) (here

$A \in \mathbb{R}$ has been used). Finally

$$|B'|^2 - A'C' = |B|^2 - 2A\Re(B\beta) + A^2|\beta|^2 - A^2|\beta|^2 + 2A\Re(B\beta) - AC = |B|^2 - AC > 0,$$

where $|B - A\bar{\beta}|^2 = |B|^2 - 2\Re(B\bar{A}\bar{\beta}) + A^2|\beta|^2 = |B|^2 - 2A\Re(B\beta) + A^2|\beta|^2$ has been used.

Case (S): $w = \alpha z$ **with** $\alpha \neq 0$, **that is** $z = w/\alpha$. Substituting and multiplying by $|\alpha|^2 = \alpha\bar{\alpha} \neq 0$ (an operation which does not change the solution set, since $|\alpha|^2$ is real and positive):

$$A \frac{w\bar{w}}{|\alpha|^2} + B \frac{w}{\alpha} + \bar{B} \frac{\bar{w}}{\bar{\alpha}} + C = 0 \iff Aw\bar{w} + B\bar{\alpha}w + \bar{B}\alpha\bar{w} + C|\alpha|^2 = 0.$$

Hence $A' = A$, $B' = B\bar{\alpha}$, $C' = C|\alpha|^2$: those which must be real are real, and $\bar{B}' = \bar{B}\alpha$ is the coefficient of $\bar{w}$. Moreover

$$|B'|^2 - A'C' = |B|^2|\alpha|^2 - AC|\alpha|^2 = |\alpha|^2(|B|^2 - AC) > 0.$$

Case (I): $w = 1/z$, **that is** $z = 1/w$ (**for** $z \neq 0, \infty$). Substituting and multiplying by $w\bar{w} = |w|^2 \neq 0$:

$$A \frac{1}{w} \frac{1}{\bar{w}} + B \frac{1}{w} + \bar{B} \frac{1}{\bar{w}} + C = 0 \mid \cdot w\bar{w} \implies A + B\bar{w} + \bar{B}w + Cw\bar{w} = 0,$$

that is, rearranging,

$$\boxed{Cw\bar{w} + \bar{B}w + B\bar{w} + A = 0}$$

which is again of the form (*) with

$$A' = C, \quad B' = \bar{B}, \quad C' = A.$$

Indeed $A' = C$ and $C' = A$ are real, and the coefficient of $\bar{w}$ is $B = \bar{B} = \bar{B}'$, as required. The non-degeneracy condition is preserved:

$$|B'|^2 - A'C' = |\bar{B}|^2 - CA = |B|^2 - AC > 0.$$

The inversion therefore exchanges the coefficients $A \leftrightarrow C$ and conjugates B : it is the algebraic formulation of the fact that the inversion exchanges “passing through the origin” ($C = 0$) with “passing through ∞ ” ($A' = 0$, that is, the image is a line).

The exceptional points 0 and ∞ . One has to check that the inclusion or exclusion of 0 and ∞ is coherent.

- $0 \in \Gamma_{A,B,C}$ if and only if $C = 0$, that is if and only if $A' = 0$, that is if and only if the image is a line, that is if and only if the image generalised circle contains $\infty = \iota(0)$. ✓
- $\infty \in \hat{\Gamma}$ if and only if $A = 0$ (a line), that is if and only if $C' = 0$, that is if and only if the image contains $0 = \iota(\infty)$. ✓

Hence $\iota(\hat{\Gamma})$ is exactly the generalised circle associated with $(A', B', C') = (C, \bar{B}, A)$, points at infinity included.

Conclusion. Each of the three generators sends generalised circles to generalised circles; a finite composition of such maps does the same; by Lemma 6.2 every Möbius map is such a composition. Bijectivity follows by applying the same result to T^{-1} , which is again a Möbius map (Proposition 6.7). $\square$

Example 6.2: A circle that becomes a line, and conversely. Let $\Gamma : |z - 1| = 1$, that is $z\bar{z} - \bar{z} - z + 1 - 1 = 0$, namely $z\bar{z} - z - \bar{z} = 0$: here $A = 1$, $B = -1$, $C = 0$, and $|B|^2 - AC = 1 > 0$. ✓

By Theorem 6.6, case (I), the image under $w = 1/z$ has coefficients $A' = C = 0$, $B' = \bar{B} = -1$, $C' = A = 1$, that is

$$-w - \bar{w} + 1 = 0 \iff 2\Re w = 1 \iff \Re w = \frac{1}{2}.$$

The circle through the origin becomes a line (and the point $0 \in \Gamma$ goes to ∞).

Independent check on three points. $z = 2 \in \Gamma$ and $1/2$ has $\Re = 0.5 \checkmark$; $z = 1 + i \in \Gamma$ (since $|i| = 1$) and $\frac{1}{1+i} = \frac{1-i}{2} = 0.5 - 0.5i$ has $\Re = 0.5 \checkmark$; $z = 1 - i \in \Gamma$ and $\frac{1}{1-i} = 0.5 + 0.5i$ has $\Re = 0.5 \checkmark$.

Definition 6.6: Cross ratio. Let $z_2, z_3, z_4 \in \hat{\mathbb{C}}$ be distinct. Denote by $S_{z_2 z_3 z_4}$ the unique Möbius transformation that maps $z_2 \mapsto 1$, $z_3 \mapsto 0$, $z_4 \mapsto \infty$ (it exists and is unique by Theorem 6.7). For $z_1 \in \hat{\mathbb{C}}$ one sets

$$(z_1, z_2, z_3, z_4) := S_{z_2 z_3 z_4}(z_1).$$

If z_2, z_3, z_4 are all finite,

$$(z_1, z_2, z_3, z_4) = \frac{z_1 - z_3}{z_1 - z_4} \cdot \frac{z_2 - z_4}{z_2 - z_3} = \frac{(z_1 - z_3)(z_2 - z_4)}{(z_1 - z_4)(z_2 - z_3)}.$$

Theorem 6.7: Three points, a single Möbius map. Let $z_2, z_3, z_4 \in \hat{\mathbb{C}}$ be distinct. There exists one and only one Möbius transformation S with $S(z_2) = 1$, $S(z_3) = 0$, $S(z_4) = \infty$. Consequently, given two triples of distinct points (z_2, z_3, z_4) and (w_2, w_3, w_4) , there exists one and only one Möbius map sending the first to the second, in order.

Proof. Step 1 — existence. If z_2, z_3, z_4 are finite one sets

$$S(z) = \frac{z - z_3}{z - z_4} \cdot \frac{z_2 - z_4}{z_2 - z_3}.$$

It is a Möbius map: written as $\frac{az+b}{cz+d}$ with $a = \frac{z_2-z_4}{z_2-z_3}$, $b = -z_3a$, $c = 1$, $d = -z_4$, one has $ad - bc = -z_4a + z_3a = a(z_3 - z_4) \neq 0$ because $a \neq 0$ (numerator and denominator are non-zero, the points being distinct) and $z_3 \neq z_4$. And by construction $S(z_3) = 0$, $S(z_4) = \infty$, $S(z_2) = \frac{z_2-z_3}{z_2-z_4} \cdot \frac{z_2-z_4}{z_2-z_3} = 1$.

If one of the three is ∞ one uses the formula obtained by suppressing the two factors containing it:

$$z_2 = \infty : S(z) = \frac{z - z_3}{z - z_4}; \quad z_3 = \infty : S(z) = \frac{z_2 - z_4}{z - z_4}; \quad z_4 = \infty : S(z) = \frac{z - z_3}{z_2 - z_3},$$

and in each case one checks directly that it is a Möbius map with the required values (for instance in the first case $S(\infty) = 1$ by the convention of Definition 6.4, since $a/c = 1/1$).

Step 2 — uniqueness. Let S and S' be two Möbius maps with those values. Then $M = S' \circ S^{-1}$ is a Möbius map (Proposition 6.7) fixing 1, 0 and ∞ . Written $M(z) = \frac{az+b}{cz+d}$:

- $M(\infty) = \infty$ forces $c = 0$ (if $c \neq 0$ one would have $M(\infty) = a/c \in \mathbb{C}$); hence $d \neq 0$ and $M(z) = \frac{a}{d}z + \frac{b}{d}$;
- $M(0) = 0$ gives $\frac{b}{d} = 0$, that is $b = 0$;
- $M(1) = 1$ gives $\frac{a}{d} = 1$.

Hence $M = \text{id}$, that is $S' = S$.

Step 3 — general triples. Let S and S' be the Möbius maps sending respectively (z_2, z_3, z_4) and (w_2, w_3, w_4) to $(1, 0, \infty)$. Then $T = S'^{-1} \circ S$ sends $z_j \mapsto w_j$ for $j = 2, 3, 4$. If T_1 is another Möbius map with the same property, $S' \circ T_1$ sends (z_2, z_3, z_4) to $(1, 0, \infty)$, hence by Step 2 $S' \circ T_1 = S$, that is $T_1 = S'^{-1} \circ S = T$. $\square$

Theorem 6.8: Invariance of the cross ratio (R11.5). Let T be a Möbius transformation and let $z_1, z_2, z_3, z_4 \in \hat{\mathbb{C}}$ with z_2, z_3, z_4 distinct. Then

$$(Tz_1, Tz_2, Tz_3, Tz_4) = (z_1, z_2, z_3, z_4).$$

Proof. Let $S = S_{z_2 z_3 z_4}$ be the Möbius map sending z_2, z_3, z_4 to $1, 0, \infty$, so that by definition $(z_1, z_2, z_3, z_4) = S(z_1)$.

Consider $S \circ T^{-1}$, which is a Möbius map (Proposition 6.7). It sends

$$Tz_2 \mapsto S(z_2) = 1, \quad Tz_3 \mapsto S(z_3) = 0, \quad Tz_4 \mapsto S(z_4) = \infty,$$

and the points Tz_2, Tz_3, Tz_4 are distinct because T is injective. By the uniqueness of Theorem 6.7,

$$S \circ T^{-1} = S_{Tz_2 Tz_3 Tz_4}.$$

Evaluating at Tz_1 :

$$(Tz_1, Tz_2, Tz_3, Tz_4) = S_{Tz_2 Tz_3 Tz_4}(Tz_1) = S(T^{-1}(Tz_1)) = S(z_1) = (z_1, z_2, z_3, z_4).$$

□

Corollary 6.4: Three points determine a unique generalised circle. Through three distinct points $z_2, z_3, z_4 \in \hat{\mathbb{C}}$ there passes one and only one generalised circle, and it is $S_{z_2 z_3 z_4}^{-1}(\mathbb{R})$, where $\mathbb{R} = \mathbb{R} \cup \{\infty\}$.

Proof. Step 1 — $\mathbb{R}$ is the only generalised circle through $1, 0, \infty$. $\mathbb{R}$ is a generalised circle (the real line plus ∞) and contains $1, 0, \infty$. Conversely, a generalised circle containing ∞ has the form $L \cup \{\infty\}$ with L a line (Definition 6.5), and a line containing 0 and 1 is the real axis, because through two distinct points there passes a single line.

Step 2 — existence. Let $S = S_{z_2 z_3 z_4}$. By Theorem 6.6 applied to S^{-1} , the set $\hat{\Gamma} = S^{-1}(\mathbb{R})$ is a generalised circle, and it contains $S^{-1}(1) = z_2$, $S^{-1}(0) = z_3$, $S^{-1}(\infty) = z_4$.

Step 3 — uniqueness. Let $\hat{\Gamma}'$ be a generalised circle containing z_2, z_3, z_4 . Then $S(\hat{\Gamma}')$ is a generalised circle (Theorem 6.6) containing $1, 0, \infty$, hence $S(\hat{\Gamma}') = \mathbb{R}$ by Step 1; since S is bijective, $\hat{\Gamma}' = S^{-1}(\mathbb{R}) = \hat{\Gamma}$. □

Theorem 6.9: Concyclicity criterion (R10.5, R11.6). Let $z_1, z_2, z_3, z_4 \in \hat{\mathbb{C}}$ be four distinct points. Then they belong to one and the same generalised circle if and only if

$$(z_1, z_2, z_3, z_4) \in \mathbb{R}.$$

In particular four distinct points of the complex plane are concyclic or collinear if and only if

$$\frac{(z_1 - z_3)(z_2 - z_4)}{(z_1 - z_4)(z_2 - z_3)} \in \mathbb{R}.$$

Proof. Let $S = S_{z_2 z_3 z_4}$ and let $\hat{\Gamma}$ be the unique generalised circle through z_2, z_3, z_4 ; by Corollary 6.4, $\hat{\Gamma} = S^{-1}(\mathbb{R})$ and hence $S(\hat{\Gamma}) = \mathbb{R}$.

Step 1 — reduction. “The four points lie on one and the same generalised circle” is equivalent to “ $z_1 \in \hat{\Gamma}$ ”: indeed if $z_1 \in \hat{\Gamma}$ then all four lie on $\hat{\Gamma}$; conversely if a generalised circle $\hat{\Gamma}'$ contains all four of them, in particular it contains z_2, z_3, z_4 , hence $\hat{\Gamma}' = \hat{\Gamma}$ by uniqueness, and $z_1 \in \hat{\Gamma}$.

Step 2 — translation through S . Since S is a bijection of $\hat{\mathbb{C}}$ with $S(\hat{\Gamma}) = \hat{\mathbb{R}}$,

$$z_1 \in \hat{\Gamma} \iff S(z_1) \in \hat{\mathbb{R}} \iff (z_1, z_2, z_3, z_4) \in \mathbb{R} \cup \{\infty\}.$$

Step 3 — the value ∞ is excluded. $S(z_1) = \infty$ happens only for $z_1 = z_4$ (S is injective and $S(z_4) = \infty$), which is excluded because the four points are distinct. Hence $(z_1, z_2, z_3, z_4) \in \mathbb{C}$, and the condition becomes $(z_1, z_2, z_3, z_4) \in \mathbb{R}$. $\square$

Geometric reading of the criterion. If the four points are finite,

$$\arg(z_1, z_2, z_3, z_4) = \arg \frac{z_1 - z_3}{z_1 - z_4} - \arg \frac{z_2 - z_3}{z_2 - z_4},$$

that is the difference between the angle under which the segment z_3z_4 is seen from z_1 and the one under which it is seen from z_2 . The cross ratio is real ($\arg \in \{0, \pi\}$ modulo 2π) exactly when the two angles are equal or supplementary: these are the two statements of the inscribed angle theorem — equal angles if z_1, z_2 lie on the same side of the line z_3z_4 , supplementary if they lie on opposite sides (cyclic quadrilateral). The criterion of Theorem 6.9 is therefore the complex version of a theorem of elementary geometry (Volume I, Chapter 3). $\square$

Example 6.3: Two quadruples compared. (a) Concyclic quadruple. Take $z_1 = 1$, $z_2 = i$, $z_3 = -1$, $z_4 = -i$, the vertices of the square inscribed in the unit circle (μ_4 , Theorem 6.3). Then

$$(z_1, z_2, z_3, z_4) = \frac{(1 - (-1))(i - (-i))}{(1 - (-i))(i - (-1))} = \frac{2 \cdot 2i}{(1+i)(1+i)} = \frac{4i}{(1+i)^2} = \frac{4i}{2i} = 2 \in \mathbb{R}. \checkmark$$

The criterion confirms concyclicity, as it must.

(b) Non-concyclic quadruple. Take $z_1 = 0$, $z_2 = 1$, $z_3 = i$, $z_4 = 2$. Then

$$(z_1, z_2, z_3, z_4) = \frac{(0 - i)(1 - 2)}{(0 - 2)(1 - i)} = \frac{i}{-2 + 2i} = \frac{i(-2 - 2i)}{(-2)^2 + 2^2} = \frac{2 - 2i}{8} = 0.25 - 0.25i \notin \mathbb{R}.$$

Independent check. The circle through $0, 1, i$ has equation $x^2 + y^2 + Dx + Ey + F = 0$ with $F = 0$ (it passes through the origin), $1 + D = 0$ (it passes through $(1, 0)$) and $1 + E = 0$ (it passes through $(0, 1)$): it is $x^2 + y^2 - x - y = 0$. Substituting $(2, 0)$ one obtains $4 - 2 = 2 \neq 0$, hence $z_4 = 2$ does not belong to it; and the three points are not collinear. The two methods agree. $\checkmark$

Remark 6.6: Rotations of the sphere as Möbius maps. Through the stereographic projection (Chapter 7) the extended complex plane $\hat{\mathbb{C}}$ is identified with the sphere S^2 , and Möbius transformations become transformations of the sphere. Among them, those coming from rigid rotations of S^2 are exactly the Möbius maps of the form

$$z \mapsto \frac{\alpha z - \bar{\beta}}{\beta z + \bar{\alpha}}, \quad |\alpha|^2 + |\beta|^2 = 1,$$

that is those associated with matrices of $SU(2)$. We recover by another route the double cover $SU(2) \rightarrow SO(3)$ of Chapter 28: the circle, the quaternions and the sphere are three faces of the same structure. This statement is here a panorama and is not proved: the verification requires the explicit formula of the stereographic projection and the computation of the induced action, which are the subject of Chapter 7 and Chapter 28.

Exercise 6.3. Where does the complex inversion $z \mapsto 1/z$ send the circle $|z| = 2$? And the circle $|z| = 1$?

Solution. The circle $|z| = 2$ has equation $z\bar{z} - 4 = 0$, that is $A = 1$, $B = 0$, $C = -4$ ($|B|^2 - AC = 4 > 0$ ✓). By Theorem 6.6, case (I), the image has $A' = C = -4$, $B' = 0$, $C' = A = 1$, that is $-4w\bar{w} + 1 = 0$, namely $|w| = \frac{1}{2}$. The circle of radius 2 therefore goes to the circle of radius $\frac{1}{2}$, concentric with the origin. Directly: $|1/z| = 1/|z| = 1/2$. ✓
For $|z| = 1$: $A = 1$, $B = 0$, $C = -1$, and the image has $A' = -1$, $C' = 1$, that is $-w\bar{w} + 1 = 0$, namely $|w| = 1$. The unit circle is *globally* fixed. Beware: it is not fixed pointwise — $\iota(z) = 1/z = \bar{z}$ on $\mathbb{T}$, hence ι acts on it as conjugation, and the only fixed points are ± 1 . The complex inversion exchanges the interior and the exterior of the unit circle ($|z| < 1 \iff |1/z| > 1$): the unit circle is its invariant “boundary”.

6.5. Assigned exercises

Answers are in the Teacher’s key (Section 6.8).

Exercise 6.4: The minimal polynomial of $\cos 72^\circ$ by de Moivre’s route. *Aim:* to use de Moivre’s formula to obtain an algebraic identity and to recognise its geometric meaning. *Estimated time:* 35 minutes. *Type:* symbolic/proof-based.

- Starting from $\cos 5\theta = 16c^5 - 20c^3 + 5c$ (Corollary 6.1) and from $\theta = \frac{2\pi}{5}$, write down the equation satisfied by $c = \cos \frac{2\pi}{5}$.
- Factor the polynomial obtained, singling out $(c - 1)$, and check that the remaining factor is $(4c^2 + 2c - 1)^2$.
- Deduce Proposition 6.6 again and explain why the quadratic factor appears squared.
- Repeat the procedure with $\theta = \frac{2\pi}{3}$ and $\cos 3\theta$, obtaining the minimal polynomial of $\cos \frac{2\pi}{3}$; comment on the difference in degree.

Exercise 6.5: Concyclicity by numerical means. *Aim:* to apply the cross-ratio criterion and to compare it with the circumscribed circle method. *Estimated time:* 40 minutes. *Type:* numerical/computational.

Consider the quadruples

$$Q_1 = \{1, i, -1, 2i\}, \quad Q_2 = \{2, 1+i, 1-i, 0\}, \quad Q_3 = \{0, 1, 2, 3+0i\}.$$

- For each of them compute (z_1, z_2, z_3, z_4) with the formula of Definition 6.6 and say whether the points are concyclic or collinear.
- For the quadruples that turn out to be concyclic, determine the centre and the radius of the circle with Lemma 6.1, and check that all four points satisfy it.
- Verify the invariance of Theorem 6.8 by applying to Q_2 the Möbius map $T(z) = \frac{z-1}{z+1}$ and recomputing the cross ratio on the images.
- What happens to the cross ratio if z_1 and z_2 are exchanged? And z_3 and z_4 ? Check it on Q_1 and formulate a conjecture.

Exercise 6.6: Sums of roots and the eight-point discrete transform. *Aim:* to see Theorem 6.5 at work as a computational tool. *Estimated time:* 45 minutes. *Type:* numerical/computational.

Let $n = 8$ and $\zeta_8 = e^{i\pi/4} = \frac{\sqrt{2}}{2}(1+i)$.

- (a) Draw up the table of $S(j) = \sum_{k=0}^7 \zeta_8^{jk}$ for $j = 0, 1, \dots, 8$ and compare it with Theorem 6.5.
- (b) Deduce $\sum_{k=0}^7 \cos \frac{\pi jk}{4}$ and $\sum_{k=0}^7 \sin \frac{\pi jk}{4}$ for the same j .
- (c) Let $x = (1, 0, 0, 0, 1, 0, 0, 0)$. Compute $X_j = \sum_{k=0}^7 x_k \zeta_8^{-jk}$ for $j = 0, \dots, 7$ and verify the inversion identity $x_k = \frac{1}{8} \sum_{j=0}^7 X_j \zeta_8^{jk}$ at least for $k = 0$ and $k = 1$.
- (d) Explain, using Theorem 6.5, why the inversion works for *every* vector $x \in \mathbb{C}^8$.

6.6. Worked exercises

Exercise 6.7: Images of lines and circles under $z \mapsto 1/z$. *Type:* symbolic with a numerical check. Determine, using the coefficients (A, B, C) of Lemma 6.1, the image under $w = 1/z$

- (a) of the line $\Re z = 1$;
 (b) of the circle $|z - 2| = 1$;

and check the result on three points in both cases. What happens to the centre of the circle in (b)?

Solution. Strategy. One writes each object in the form $Az\bar{z} + Bz + \bar{B}\bar{z} + C = 0$, applies the inversion rule $(A, B, C) \mapsto (C, \bar{B}, A)$ of Theorem 6.6, and converts the result back into geometric form with Lemma 6.1.

Step 1 — the line $\Re z = 1$. From $z + \bar{z} = 2\Re z$ one has $\Re z = 1 \iff z + \bar{z} - 2 = 0$, that is

$$A = 0, \quad B = 1, \quad C = -2, \quad |B|^2 - AC = 1 > 0. \checkmark$$

The image has $A' = C = -2$, $B' = \bar{B} = 1$, $C' = A = 0$:

$$-2w\bar{w} + w + \bar{w} = 0 \iff w\bar{w} - \frac{1}{2}(w + \bar{w}) = 0 \iff \left|w - \frac{1}{2}\right|^2 = \frac{1}{4},$$

where the last step uses $|w - \frac{1}{2}|^2 = w\bar{w} - \frac{1}{2}w - \frac{1}{2}\bar{w} + \frac{1}{4}$. This is the circle with centre $\frac{1}{2}$ and radius $\frac{1}{2}$. Alternatively, with the formula of Lemma 6.1(ii): centre $-\bar{B}'/A' = -1/(-2) = \frac{1}{2}$; radius $\sqrt{|B'|^2 - A'C'}/|A'| = \sqrt{1}/2 = \frac{1}{2}$. $\checkmark$

Step 2 — check on three points. $z = 1 \mapsto 1$ and $|1 - 0.5| = 0.5 \checkmark$; $z = 1 + i \mapsto \frac{1-i}{2} = 0.5 - 0.5i$ and $|-0.5i| = 0.5 \checkmark$; $z = 1 + 2i \mapsto \frac{1-2i}{5} = 0.2 - 0.4i$ and $|0.2 - 0.5 - 0.4i| = \sqrt{0.09 + 0.16} = \sqrt{0.25} = 0.5 \checkmark$. Moreover ∞ , which lies on the generalised line, goes to 0, which lies on the image circle (which passes through the origin because $C' = 0$). $\checkmark$

Step 3 — the circle $|z - 2| = 1$. One expands: $|z - 2|^2 = (z - 2)(\bar{z} - 2) = z\bar{z} - 2z - 2\bar{z} + 4 = 1$, hence

$$z\bar{z} - 2z - 2\bar{z} + 3 = 0, \quad A = 1, \quad B = -2, \quad C = 3, \quad |B|^2 - AC = 4 - 3 = 1 > 0. \checkmark$$

The image has $A' = 3$, $B' = -2$, $C' = 1$:

$$3w\bar{w} - 2w - 2\bar{w} + 1 = 0 \iff w\bar{w} - \frac{2}{3}(w + \bar{w}) + \frac{1}{3} = 0 \iff \left|w - \frac{2}{3}\right|^2 = \frac{4}{9} - \frac{1}{3} = \frac{1}{9}.$$

It is the circle with centre $\frac{2}{3}$ and radius $\frac{1}{3}$. With the formula: centre $-\bar{B}'/A' = 2/3$; radius $\sqrt{4 - 3}/3 = \frac{1}{3}$. $\checkmark$

Step 4 — check on three points. $z = 1 \mapsto 1$ and $|1 - \frac{2}{3}| = \frac{1}{3} \checkmark$; $z = 3 \mapsto \frac{1}{3}$ and $|\frac{1}{3} - \frac{2}{3}| = \frac{1}{3} \checkmark$; $z = 2 + i \mapsto \frac{2-i}{5} = 0.4 - 0.2i$ and $|0.4 - 0.66667 - 0.2i| = \sqrt{0.071111 + 0.04} = \sqrt{0.111111} = 0.33333 \checkmark$.

Interpretation: the centre does not go to the centre. The centre 2 of the initial circle goes to $\frac{1}{2}$, which is *not* the centre $\frac{2}{3}$ of the image circle. There is no contradiction: Theorem 6.6 asserts that the circle as a *set* goes to a circle as a set, not that the centres correspond. The centre is not a Möbius-invariant notion, because it cannot be defined in terms of circles, lines and angles alone: it depends on the Euclidean metric, which Möbius maps do not preserve. What is preserved is the *symmetric point* with respect to the circle, and indeed the centre is the symmetric point of ∞ — but Möbius maps move ∞ .

Typical errors. (1) Transforming the centre and the radius instead of the equation: the result is wrong, as Step 4 shows. (2) Forgetting that $|B|^2 - AC > 0$ is part of the statement: without it the equation may describe a single point (for instance $z\bar{z} = 0$) or the empty set ($z\bar{z} + 1 = 0$), and the conclusion fails. (3) Neglecting the points 0 and ∞ : the circle of Step 1 passes through the origin precisely because the line passed through ∞ .

Extension. The same computation shows that $z \mapsto 1/z$ sends a line *not* passing through the origin ($A = 0, C \neq 0$) to a circle through the origin ($A' = C \neq 0, C' = 0$), and a line through the origin ($A = 0, C = 0$) to a line through the origin ($A' = 0, C' = 0$): this is the classification into four cases found in the MIT 18.04 notes, Topic 10, §10.7.2.

Exercise 6.8: The product of the diagonals of a regular polygon. *Type:* proof-based with a numerical check. Let $n \geq 2$. Prove that

$$\prod_{k=1}^{n-1} (1 - \zeta_n^k) = n \quad \text{and} \quad \prod_{k=1}^{n-1} 2 \sin \frac{k\pi}{n} = n.$$

Interpret the second identity on the regular polygon inscribed in the unit circle and check it numerically for $n = 5$ and $n = 6$.

Solution. Strategy. One factors $z^n - 1$ with the roots of unity (Theorem 6.2), isolates the factor $(z - 1)$ and evaluates at $z = 1$ the resulting function, which is a polynomial and therefore can be evaluated without limits.

Step 1 — the factorisation. The polynomials $z^n - 1$ and $\prod_{k=0}^{n-1} (z - \zeta_n^k)$ are both monic of degree n and have the same n distinct roots $\zeta_n^0, \dots, \zeta_n^{n-1}$ (Theorem 6.2); their difference is a polynomial of degree $< n$ with n roots, hence it is zero. Therefore

$$z^n - 1 = \prod_{k=0}^{n-1} (z - \zeta_n^k) = (z - 1) \prod_{k=1}^{n-1} (z - \zeta_n^k).$$

Step 2 — evaluation at $z = 1$. On the other hand, by the telescoping identity (Theorem 6.4, Step 1), $z^n - 1 = (z - 1)(1 + z + \dots + z^{n-1})$. Comparing with Step 1 and cancelling the factor $(z - 1)$, which is legitimate as an identity between polynomials (the ring $\mathbb{C}[z]$ is an integral domain), one obtains

$$1 + z + \dots + z^{n-1} = \prod_{k=1}^{n-1} (z - \zeta_n^k) \quad \text{for every } z.$$

Setting $z = 1$: the left-hand side equals n , hence $\prod_{k=1}^{n-1} (1 - \zeta_n^k) = n$.

Step 3 — passing to moduli. Taking the modulus of both sides (and recalling that $n > 0$ is real),

$$\prod_{k=1}^{n-1} |1 - \zeta_n^k| = n.$$

By the computation made in Theorem 6.3(ii), $|e^{i\theta} - 1| = 2|\sin(\theta/2)|$; with $\theta = \frac{2\pi k}{n}$ and $0 < \frac{k\pi}{n} < \pi$ (hence a positive sine),

$$|1 - \zeta_n^k| = 2 \sin \frac{k\pi}{n}, \quad \text{whence} \quad \prod_{k=1}^{n-1} 2 \sin \frac{k\pi}{n} = n.$$

Step 4 — numerical check. For $n = 5$: $2 \sin 36^\circ = 1.175570$, $2 \sin 72^\circ = 1.902113$, $2 \sin 108^\circ = 1.902113$, $2 \sin 144^\circ = 1.175570$. The product is

$$(1.175570 \cdot 1.902113)^2 = (2.236068)^2 = 5.000000. \checkmark$$

(One recognises $1.175570 \cdot 1.902113 = \sqrt{5}$: the product of the side by the diagonal of the unit regular pentagon equals $\sqrt{5}$.)

For $n = 6$: $2 \sin 30^\circ = 1$, $2 \sin 60^\circ = 1.732051$, $2 \sin 90^\circ = 2$, $2 \sin 120^\circ = 1.732051$, $2 \sin 150^\circ = 1$. The product is

$$1 \cdot 1.732051 \cdot 2 \cdot 1.732051 \cdot 1 = 2 \cdot 3.000000 = 6.000000. \checkmark$$

Second check, independent of the previous one: for $n = 6$ one computes the complex product $\prod_{k=1}^5 (1 - \zeta_6^k)$ by grouping the conjugate factors. With $\zeta_6 = 0.5 + 0.866025i$: $(1 - \zeta_6)(1 - \zeta_6^5) = |1 - \zeta_6|^2 = (0.5)^2 + (0.866025)^2 = 1$; $(1 - \zeta_6^2)(1 - \zeta_6^4) = |1 - \zeta_6^2|^2 = (1.5)^2 + (0.866025)^2 = 3$; $(1 - \zeta_6^3) = 1 - (-1) = 2$. Product: $1 \cdot 3 \cdot 2 = 6$. $\checkmark$

Interpretation. $|1 - \zeta_n^k|$ is the distance from the vertex $V_0 = 1$ to the vertex V_k : for $k = 1$ and $k = n - 1$ these are the two adjacent sides, for the other k the diagonals issuing from V_0 . The identity therefore says that *the product of the $n - 1$ distances from one vertex to all the others, in a regular polygon inscribed in the unit circle, equals exactly n* . It is a fact that is anything but obvious geometrically, and it follows from a simple comparison between two factorisations of the same polynomial.

Typical errors. (1) Writing $\prod_{k=1}^{n-1} (1 - \zeta^k) = \lim_{z \rightarrow 1} \frac{z^n - 1}{z - 1}$ and treating it as an indeterminate form to be resolved with de l'Hôpital's rule: it works, but it hides the fact that the identity is algebraic and requires no limits (the quotient $\frac{z^n - 1}{z - 1}$ is the polynomial $1 + z + \dots + z^{n-1}$). (2) Forgetting to exclude $k = 0$: the factor $(1 - \zeta^0) = 0$ would annihilate everything. (3) Writing $|1 - \zeta_n^k| = 2 \sin \frac{2\pi k}{n}$, forgetting the half angle: already for $n = 4$, $k = 2$ would give $2 \sin 180^\circ = 0$ instead of 2.

Extension. The same argument can be repeated on the cyclotomic polynomial Φ_n , that is on the monic factor of $z^n - 1$ whose roots are exactly the primitive n -th roots (Proposition 6.3): compute $\Phi_n(1)$ for $n = 4, 6, 8, 9, 12$ — one finds respectively 2, 1, 2, 3, 1 — and conjecture the general rule in terms of the factorisation of n . It is the classical starting point for the study of cyclotomic extensions (Volume II, Chapter 7).

6.7. Self-assessment quiz

- (Definition) An n -th root of unity ζ is called *primitive* if
 - $\zeta \neq 1$
 - its multiplicative order is exactly n
 - ζ has positive imaginary part
 - ζ is irrational
- (Hypothesis) In Lemma 6.1 the hypothesis $|B|^2 > AC$ serves to
 - make the left-hand side real
 - exclude that the set be empty or reduced to a single point
 - guarantee $A \neq 0$
 - guarantee that the curve is bounded
- (Symbolic computation) The sum $\sum_{k=0}^{11} \zeta_{12}^{3k}$ equals

- A) 12 B) 0 C) 3 D) 4
4. (Numerical computation) The side of the regular polygon with 12 sides inscribed in the unit circle is, to five decimal places,
A) 0.25882 B) 0.51764 C) 0.86603 D) 1.00000
5. (Proof step) In the proof of Theorem 6.6, the substitution $z = 1/w$ in the equation $Az\bar{z} + Bz + \bar{B}\bar{z} + C = 0$ must be followed by multiplication by $w\bar{w}$ because
A) otherwise the equation is not real B) it serves to clear the denominators without changing the solution set, since $w\bar{w} = |w|^2 \neq 0$ C) it serves to normalise the radius D) it serves to make A' positive
6. (Error diagnosis) A student writes: “ $\sum_{k=0}^{n-1} \zeta_n^{jk} = \frac{\zeta_n^{jn} - 1}{\zeta_n^j - 1} = \frac{1-1}{\zeta_n^j - 1} = 0$ for every integer j .” The error is
A) $\zeta_n^{jn} \neq 1$ B) the closed formula does not hold when $\zeta_n^j = 1$, that is when $n \mid j$, and in that case the sum equals n C) the sum should start from $k = 1$ D) ζ_n^j is not a root of unity
7. (Transfer) Four distinct points $z_1, z_2, z_3, z_4 \in \mathbb{C}$ are concyclic or collinear if and only if
A) $|z_1| = |z_2| = |z_3| = |z_4|$ B) $(z_1, z_2, z_3, z_4) \in \mathbb{R}$ C) $z_1 + z_2 + z_3 + z_4 = 0$ D) $(z_1, z_2, z_3, z_4) = 1$
8. (Source and metacognition) The proof that the cross ratio is real if and only if the four points lie on a circle or on a line is found in
A) Ahlfors, *Complex Analysis*, 3rd ed., ch. 3, §3.2, Theorem 13, p. 79 B) Ahlfors, ch. 1, §2.2, p. 15 C) Ahlfors, ch. 3, §1.4, p. 59 D) Ahlfors, ch. 4, §2.1, p. 114

6.8. Teacher's key

BEST PRACTICE

Quiz — answers, rationale and diagnosis.

- 1) **B.** *Rationale:* it is Definition 6.2; by Proposition 6.3 this is equivalent to $\gcd(k, n) = 1$ if $\zeta = \zeta_n^k$. *Distractors:* A is necessary but not sufficient ($\zeta_6^2 = \zeta_3 \neq 1$ is not a primitive sixth root); C is irrelevant and false in general (ζ_n^{n-1} has negative imaginary part and is primitive); D confuses “primitive” with “irrational” ($\zeta_4 = i$ is primitive and has rational parts). *Diagnosed error:* confusing “different from 1” with “of maximal order”. *Source:* Ahlfors, ch. 1, §2.2, pp. 15–16. *Prerequisite:* the order of an element in a group. *Remedial work:* tabulate the orders of ζ_{12}^k for $k = 0, \dots, 11$.
- 2) **B.** *Rationale:* in the proof of Lemma 6.1(ii) the quantity $|b|^2 - c = (|B|^2 - AC)/A^2$ is the *square of the radius*: if it vanished the set would reduce to a point, if it were negative it would be empty. *Distractors:* A is true but follows from $A, C \in \mathbb{R}$, not from $|B|^2 > AC$; C is false (the case $A = 0$ is allowed and is the case of lines); D is false (lines are not bounded). *Diagnosed error:* attributing the wrong conclusion to a hypothesis. *Source:* Ahlfors, ch. 3, §3.2, pp. 79–80. *Prerequisite:* completing the square. *Remedial work:* write the equations $z\bar{z} = 0$ and $z\bar{z} + 1 = 0$ and see what they describe.
- 3) **B.** *Rationale:* $12 \nmid 3$, hence Theorem 6.5 gives 0. *Distractors:* A is the value one would get if $12 \mid 3$; C confuses the value of j with that of the sum; D confuses $n/j = 4$ with the sum. *Diagnosed error:* applying the “vanishing denominator” case when it does not occur. *Source:* Theorem 6.5; Ahlfors, ch. 1, §2.2, Exercise 4, p. 16. *Prerequisite:* divisibility.

Remedial work: compute $\sum_k \zeta_{12}^{jk}$ for $j = 0, 3, 4, 6, 12$.

4) **B. Rationale:** by Theorem 6.3(ii) the side is $2 \sin \frac{\pi}{12} = 2 \sin 15^\circ = 2 \cdot 0.258819 = 0.517638$.

Distractors: A is $\sin 15^\circ = 0.25882$, that is half the value (the factor 2 has been forgotten); C is $\sqrt{3}/2 = \cos 30^\circ = 0.86603$, a familiar trigonometric value but with no role here (it is the apothem of the unit regular hexagon, not a side); D is the side of the hexagon, $2 \sin 30^\circ = 1$, that is the correct answer but for $n = 6$ instead of $n = 12$. *Diagnosed error:* using $\frac{2\pi}{n}$ instead of $\frac{\pi}{n}$ in the argument of the sine, or forgetting the factor 2. *Source:* Theorem 6.3. *Prerequisite:* $|e^{i\theta} - 1| = 2|\sin(\theta/2)|$. *Remedial work:* derive the formula for the side again by factoring out $e^{i\theta/2}$.

5) **B. Rationale:** multiplying by a factor that *never* vanishes is an equivalence between equations; if $w = 0$ were allowed, the multiplication could introduce spurious solutions, and indeed the point $w = 0$ (the image of ∞) is treated separately in the proof. *Distractors:* A is false, the equation is already real (Lemma 6.1(i)); C and D are beside the point, the radius is not normalised and $A' = C$ may perfectly well be negative. *Diagnosed error:* not distinguishing between a legitimate manipulation and one that changes the solution set. *Source:* Theorem 6.6, case (I); Orloff, MIT 18.04, Topic 10, §10.7.2. *Prerequisite:* equivalence of equations. *Remedial work:* redo case (I) keeping explicit track of the hypothesis $w \neq 0$.

6) **B. Rationale:** it is exactly Case 1 of Theorem 6.5: if $n \mid j$ then $\zeta_n^j = 1$, the denominator vanishes and the closed formula is inapplicable; the direct sum gives n . *Distractors:* A is false, $\zeta_n^{jn} = e^{2\pi i j} = 1$ always; C would change the sum but is not the error committed; D is false. *Diagnosed error:* using a formula outside its domain of validity (a masked division by zero). *Source:* Theorem 6.5. *Prerequisite:* the finite geometric sum. *Remedial work:* rewrite the telescoping identity $(q - 1) \sum q^k = q^n - 1$ and observe that it is the division, not the identity, that requires $q \neq 1$.

BEST PRACTICE

Quiz — answers, rationale and diagnosis (continued).

7) **B. Rationale:** it is Theorem 6.9. *Distractors:* A is sufficient (the four points would lie on a circle centred at the origin) but not necessary, and it does not cover collinear points; C is false and unrelated (a vanishing sum is the condition for the centroid to be at the origin, see Theorem 6.4); D is a particular value, which occurs only for special quadruples. *Diagnosed error:* mistaking a particular sufficient condition for the characterisation. *Source:* Ahlfors, ch. 3, §3.2, Theorem 13, p. 79. *Prerequisite:* the definition of the cross ratio. *Remedial work:* redo Example 6.3 with other quadruples, at least one of them collinear.

8) **A. Rationale:** Ahlfors' Theorem 13, in section 3.2 "The Cross Ratio" of chapter 3, is exactly this statement, with the same proof adopted here (reduction to the real axis by means of the Möbius map sending three points to $1, 0, \infty$). *Distractors:* B is the section on the binomial equation (roots of unity, de Moivre); C is the section on rational functions; D is the index of a point with respect to a closed curve, the subject of Chapter 12. *Diagnosed error:* citing the right chapter but the wrong section, or citing by general topic instead of by statement. *Source:* see the section "Sources and bibliography". *Prerequisite:* being able to read a reference with chapter, section, statement number and page. *Remedial work:* locate Theorems 12 and 13 in Ahlfors' text and compare their proofs with those of this chapter.

BEST PRACTICE

Assigned exercise 6.4 — answers. (a) With $\theta = \frac{2\pi}{5}$ one has $5\theta = 2\pi$ and $\cos 5\theta = 1$, hence $16c^5 - 20c^3 + 5c - 1 = 0$. (b) $c = 1$ annihilates the polynomial ($16 - 20 + 5 - 1 = 0$), and the division gives $16c^5 - 20c^3 + 5c - 1 = (c - 1)(16c^4 + 16c^3 - 4c^2 - 4c + 1)$. One then checks that $16c^4 + 16c^3 - 4c^2 - 4c + 1 = (4c^2 + 2c - 1)^2$ by expanding the square:

$(4c^2)^2 + (2c)^2 + 1 + 2(4c^2)(2c) + 2(4c^2)(-1) + 2(2c)(-1) = 16c^4 + 4c^2 + 1 + 16c^3 - 8c^2 - 4c = 16c^4 + 16c^3 - 4c^2 - 4c + 1$. **✓(c)** Since $c = \cos 72^\circ \neq 1$, the factor $4c^2 + 2c - 1$ must vanish, whence $c = \frac{-1+\sqrt{5}}{4}$ (the other root is negative), which is Proposition 6.6. The factor appears *squared* because $\cos 5\theta = 1$ has as solutions in $[0, 2\pi)$ the angles $\theta = \frac{2\pi k}{5}$, $k = 0, \dots, 4$, that is five angles but only *three* distinct values of the cosine ($1, \cos 72^\circ, \cos 144^\circ$), because $\cos \frac{2\pi k}{5} = \cos \frac{2\pi(5-k)}{5}$: the pairs $k = 1, 4$ and $k = 2, 3$ give the same cosine. A fifth-degree polynomial with three distinct roots, two of which are double, is exactly $(c-1)(4c^2+2c-1)^2$. **(d)** With $\theta = \frac{2\pi}{3}$: $\cos 3\theta = 1$ gives $4c^3 - 3c - 1 = 0$, that is $(c-1)(4c^2+4c+1) = (c-1)(2c+1)^2 = 0$; since $c \neq 1$, $c = -\frac{1}{2}$ (double, for the same reason of symmetry). The degree of the remaining factor is 1 instead of 2: the minimal polynomial of $\cos \frac{2\pi}{3}$ has degree $\varphi(3)/2 = 1$, that of $\cos \frac{2\pi}{5}$ has degree $\varphi(5)/2 = 2$. It is the quantity that the Gauss–Wantzel theorem (Remark 6.4; Volume II, Chapter 7) requires to be a power of 2.

BEST PRACTICE

Assigned exercise 6.5 — answers. **(a)** $Q_1 = \{1, i, -1, 2i\}$: $(1, i, -1, 2i) = \frac{(1-(-1))(i-2i)}{(1-2i)(i-(-1))} = \frac{2 \cdot (-i)}{(1-2i)(1+i)} = \frac{-2i}{3-i} = \frac{-2i(3+i)}{10} = \frac{2-6i}{10} = 0.2 - 0.6i \notin \mathbb{R}$: *not concyclic*. (Indeed $1, i, -1$ lie on the unit circle, and $2i$ does not.) $Q_2 = \{2, 1+i, 1-i, 0\}$: $(2, 1+i, 1-i, 0) = \frac{(2-(1-i))(1+i-0)}{(2-0)(1+i-(1-i))} = \frac{(1+i)(1+i)}{2 \cdot 2i} = \frac{2i}{4i} = 0.5 \in \mathbb{R}$: *concyclic*. $Q_3 = \{0, 1, 2, 3\}$: $(0, 1, 2, 3) = \frac{(0-2)(1-3)}{(0-3)(1-2)} = \frac{4}{3} \in \mathbb{R}$: *collinear* (they all lie on the real axis), the degenerate case allowed by Theorem 6.9. **(b)** For Q_2 : the circle through $0, 2$ and $1+i$ has equation $z\bar{z} + Bz + \bar{B}\bar{z} + C = 0$ with $C = 0$ (it passes through the origin); from $z = 2$: $4 + 2B + 2\bar{B} = 0$, that is $\Re B = -1$; from $z = 1+i$: $2 + B(1+i) + \bar{B}(1-i) = 0$, that is $2 + 2\Re(B(1+i)) = 0$, that is $\Re B - \Im B = -1$, whence $\Im B = 0$ and $B = -1$. The circle is $z\bar{z} - z - \bar{z} = 0$, that is $|z-1| = 1$: centre 1 , radius 1 (Lemma 6.1(ii): centre $-\bar{B}/A = 1$, radius $\sqrt{1-0}/1 = 1$). Check: $|2-1| = 1 \checkmark$, $|0-1| = 1 \checkmark$, $|1+i-1| = 1 \checkmark$, $|1-i-1| = 1 \checkmark$. **(c)** $T(z) = \frac{z-1}{z+1}$ is a Möbius map ($ad-bc = 1+1 = 2 \neq 0$). The images are $T(2) = \frac{1}{3}$, $T(1+i) = \frac{i}{2+i} = \frac{i(2-i)}{5} = \frac{1+2i}{5} = 0.2 + 0.4i$, $T(1-i) = 0.2 - 0.4i$, $T(0) = -1$. The cross ratio of the images is

$$\frac{(\frac{1}{3} - (0.2 - 0.4i))(0.2 + 0.4i - (-1))}{(\frac{1}{3} - (-1))(0.2 + 0.4i - (0.2 - 0.4i))} = \frac{(0.133333 + 0.4i)(1.2 + 0.4i)}{1.333333 \cdot 0.8i} = \frac{0.533333i}{1.066667i} = 0.5,$$

where in the numerator the real part vanishes exactly: $0.133333 \cdot 1.2 - 0.4 \cdot 0.4 = 0.16 - 0.16 = 0$, whereas the imaginary part equals $0.133333 \cdot 0.4 + 0.4 \cdot 1.2 = 0.053333 + 0.48 = 0.533333$. The result coincides with the value computed in (a), in agreement with Theorem 6.8. **✓(d)** Exchanging z_1 and z_2 the cross ratio λ becomes $1/\lambda$; exchanging z_3 and z_4 it also becomes $1/\lambda$ (numerator and denominator are exchanged symmetrically). On Q_1 : $\lambda = 0.2 - 0.6i$ and $1/\lambda = \frac{0.2+0.6i}{0.04+0.36} = 0.5 + 1.5i$, which is what one obtains by exchanging. Conjecture (correct): the 24 permutations of the four points give at most the six values $\lambda, \frac{1}{\lambda}, 1-\lambda, \frac{1}{1-\lambda}, \frac{\lambda-1}{\lambda}, \frac{\lambda}{\lambda-1}$; in particular *membership of $\mathbb{R}$ does not depend on the order of the points*, as it must be, because concyclicity does not depend on the order.

BEST PRACTICE

Assigned exercise 6.6 — answers. **(a)** $S(0) = 8, S(8) = 8; S(j) = 0$ for $j = 1, \dots, 7$. This is exactly Theorem 6.5: $8 \mid j$ only for $j = 0$ and $j = 8$. **(b)** Separating real and imaginary parts: $\sum_k \cos \frac{\pi j k}{4} = 8$ and $\sum_k \sin \frac{\pi j k}{4} = 0$ for $j = 0, 8$; both sums equal 0 for $j = 1, \dots, 7$. Check for $j = 2$: the angles are $0^\circ, 90^\circ, 180^\circ, 270^\circ$ repeated twice, and

both the cosines $(1, 0, -1, 0)$ and the sines $(0, 1, 0, -1)$ have zero sum on every group of four. **✓(c)** With $x = (1, 0, 0, 0, 1, 0, 0, 0)$ one has $X_j = \zeta_8^0 + \zeta_8^{-4j} = 1 + (-1)^j$, since $\zeta_8^{-4} = e^{-i\pi} = -1$. Hence $X_j = 2$ for even j and $X_j = 0$ for odd j : $X = (2, 0, 2, 0, 2, 0, 2, 0)$. Inversion for $k = 0$: $\frac{1}{8} \sum_j X_j = \frac{1}{8}(2 + 2 + 2 + 2) = 1 = x_0$ ✓. For $k = 1$: $\frac{1}{8} \sum_j X_j \zeta_8^j = \frac{1}{8} \cdot 2(\zeta_8^0 + \zeta_8^2 + \zeta_8^4 + \zeta_8^6) = \frac{1}{4}(1 + i - 1 - i) = 0 = x_1$ ✓. **(d)** Because $\frac{1}{8} \sum_j X_j \zeta_8^{jk} = \frac{1}{8} \sum_j \sum_m x_m \zeta_8^{-jm} \zeta_8^{jk} = \sum_m x_m \cdot \frac{1}{8} \sum_j \zeta_8^{j(k-m)} = \sum_m x_m \delta_{km} = x_k$, where the exchange of the sums is legitimate because they are finite and the key step is Theorem 6.5. The argument uses nothing about x : it holds for every $x \in \mathbb{C}^8$, and with 8 replaced by n for every $x \in \mathbb{C}^n$ (Chapter 22).

6.9. Chapter formulary

The circle as a group.

$$\mathbb{T} = \{z \in \mathbb{C} : |z| = 1\}, \quad \mathbb{T} \cong SO(2) \quad (e^{i\theta} \leftrightarrow R_\theta), \quad \mathbb{T} \cong \mathbb{R}/2\pi\mathbb{Z}.$$

For $|z| = 1$: $z^{-1} = \bar{z}$. De Moivre, for every $n \in \mathbb{Z}$:

$$(\cos \theta + i \sin \theta)^n = \cos n\theta + i \sin n\theta, \quad \cos 3\theta = 4 \cos^3 \theta - 3 \cos \theta, \quad \cos 5\theta = 16 \cos^5 \theta - 20 \cos^3 \theta + 5 \cos \theta.$$

Roots of unity. $\zeta_n = e^{2\pi i/n}$, $\mu_n = \{\zeta_n^k : k = 0, \dots, n-1\}$, $|\mu_n| = n$, $\mu_n \cong \mathbb{Z}/n\mathbb{Z}$.

$$\sum_{k=0}^{n-1} \zeta_n^k = 0 \quad (n \geq 2), \quad \prod_{k=0}^{n-1} \zeta_n^k = (-1)^{n+1}, \quad \prod_{k=1}^{n-1} (1 - \zeta_n^k) = n.$$

Order of ζ_n^k : $n/\gcd(k, n)$; primitive roots: $\varphi(n)$. **Orthogonality (including the vanishing-denominator case):**

$$\sum_{k=0}^{n-1} \zeta_n^{jk} = \begin{cases} n, & n \mid j \\ 0, & n \nmid j, \end{cases} \quad (\text{here } q = 1 : \text{the closed formula does not apply}), \quad \frac{1}{n} \sum_{k=0}^{n-1} \zeta_n^{k(m-\ell)} = \delta_{\ell m}.$$

Inscribed regular polygon: side $2 \sin \frac{\pi}{n}$, interior angle $\frac{(n-2)\pi}{n}$, $|e^{i\theta} - 1| = 2|\sin(\theta/2)|$.

Constructibility. The polygon with n sides is constructible $\iff \cos \frac{2\pi}{n}$ is constructible. $\cos \frac{2\pi}{5} = \frac{\sqrt{5}-1}{4}$, $\cos \frac{4\pi}{5} = -\frac{\sqrt{5}+1}{4}$. From n constructible follows $2n$; from n and $d \mid n$ follows d ; from m, n coprime follows mn ($\zeta_{mn} = \zeta_n^u \zeta_m^v$ with $um + vn = 1$). *Gauss–Wantzel* (statement; proved in Volume II, Chapter 7): constructible $\iff n = 2^k p_1 \cdots p_m$ with the p_i distinct Fermat primes.

Möbius maps and generalised circles.

$$T(z) = \frac{az + b}{cz + d}, \quad ad - bc \neq 0; \quad T^{-1}(w) = \frac{dw - b}{-cw + a}; \quad T \leftrightarrow \begin{pmatrix} a & b \\ c & d \end{pmatrix} \text{ up to scalars.}$$

Decomposition ($c \neq 0$): $T = t_{a/c} \circ m_{(bc-ad)/c} \circ \iota \circ t_d \circ m_c$, with $t_\beta(z) = z + \beta$, $m_\alpha(z) = \alpha z$, $\iota(z) = 1/z$. *Equation of the generalised circles* ($A, C \in \mathbb{R}$, $B \in \mathbb{C}$, $|B|^2 > AC$):

$$Az\bar{z} + Bz + \bar{B}\bar{z} + C = 0; \quad \text{centre } -\frac{\bar{B}}{A}, \quad \text{radius } \frac{\sqrt{|B|^2 - AC}}{|A|} \quad (A \neq 0); \quad \text{a line if } A = 0.$$

Action on the coefficients:

$$z \mapsto z + \beta : (A, B - A\bar{\beta}, A|\beta|^2 - 2\Re(B\beta) + C); \quad z \mapsto \alpha z : (A, B\bar{\alpha}, C|\alpha|^2); \quad z \mapsto 1/z : (C, \bar{B}, A).$$

In all three cases $|B'|^2 - A'C'$ remains positive.

Cross ratio.

$$(z_1, z_2, z_3, z_4) = \frac{z_1 - z_3}{z_1 - z_4} \cdot \frac{z_2 - z_4}{z_2 - z_3} = S_{z_2 z_3 z_4}(z_1), \quad S_{z_2 z_3 z_4} : z_2 \mapsto 1, z_3 \mapsto 0, z_4 \mapsto \infty.$$

$$(Tz_1, Tz_2, Tz_3, Tz_4) = (z_1, z_2, z_3, z_4) \quad \text{for every Möbius map } T;$$

$$z_1, z_2, z_3, z_4 \text{ concyclic or collinear} \iff (z_1, z_2, z_3, z_4) \in \mathbb{R}.$$

Through three distinct points of $\hat{\mathbb{C}}$ there passes one and only one generalised circle.

From the circle to the sphere: cones, quadrics, sections and stereographic projection

So far the circle has lived in the plane. But the plane is a particular case, and the circle with it: it is the sphere of dimension 1 embedded in a space of dimension 2. As soon as one adds a dimension, the circle stops being an isolated object and becomes a *case*: a case of the family of conics, a section of the sphere, a section of the ellipsoid. This chapter walks through that passage and builds the dictionary that translates every notion of the circle into one of the sphere: planar sections are circles, stereographic projection maps circles to circles and preserves angles, great circles play the role of lines, and the angular excess of a triangle measures its area. Every time, the circle reappears as the case of maximal symmetry.

INFO

The idea in one line. Cutting a cone gives the conics, and the circle is the one orthogonal to the axis; cutting a sphere gives circles, *always*; cutting an ellipsoid gives circles only along two families of planes; projecting the sphere from the pole onto the equatorial plane, circles stay circles (or become lines) and angles do not change; and on the sphere the sum of the angles of a triangle exceeds π by exactly the area divided by r^2 .

INFO

Level and prerequisites. Level A–C. Sections 7.1, 7.2, 7.3 and 7.8 are level A–B: the scalar product in $\mathbb{R}^3$, the Pythagorean theorem and the elementary double integral suffice. Sections 7.4, 7.5 and 7.7 are level B–C: conics, partial derivatives and the first fundamental form of a parametrization are needed. Section 7.9 is level C. Prerequisites within the treatise: elementary circle, power of a point and tangents (Volume I, Chapters 2–5); conics and quadratic forms (Chapter 5); complex numbers and Möbius transformations (Chapter 6); integral calculus in several variables at the level of the change of variables in polar coordinates (Volume II, Chapter 2). Differential geometry is not assumed: the notions of first fundamental form and of curvature are recalled where needed, and taken up systematically in Chapter 10.

Warning. Conventions of the chapter.

- $S^{n-1}(c, R) = \{x \in \mathbb{R}^n : \|x - c\| = R\}$ is the *sphere* of centre c and radius R ; the index denotes the *dimension of the surface*, not of the ambient space. Thus $S^1 \subset \mathbb{R}^2$ is the circle and $S^2 \subset \mathbb{R}^3$ the ordinary sphere. One writes S^{n-1} and B^n for $c = 0$, $R = 1$.
- $B^n(c, R) = \{x \in \mathbb{R}^n : \|x - c\| \leq R\}$ is the solid ball.
- $\langle \cdot, \cdot \rangle$ is the standard scalar product, $\|x\| = \sqrt{\langle x, x \rangle}$, and $u \times v$ the cross product of $\mathbb{R}^3$.
- On the sphere of radius r the *sides* of a triangle are measured in radians as central angles; lengths are obtained by multiplying by r and areas by r^2 .
- Decimal separators are points: 0.5.

7.1. The circle–sphere dictionary

Before proving anything it is worth fixing the correspondence between the notions of the plane and those of space: almost all of them carry over, but two or three bifurcate, and it is exactly those that make the chapter interesting.

Definition 7.1: Sphere and ball. The **sphere** of center O and radius r is $S^2(O, r) = \{P \in \mathbb{R}^3 : |OP| = r\}$; the **ball** is $B^3(O, r) = \{P : |OP| \leq r\}$. The sphere is the surface, the ball the solid it encloses, exactly as the circumference encloses the circle (disk) in the plane.

In the plane $\mathbb{R}^2$	In space $\mathbb{R}^3$	Note
circumference S^1	sphere S^2	locus at distance r from center
disk B^2	ball B^3	enclosed region
tangent line	tangent plane	orthogonal to radius
line (geodesic of plane)	great circle	geodesic of surface
chord	chord	segment between two points
$C = 2\pi r$ (perimeter)	Area $= 4\pi r^2$	boundary measure
$A = \pi r^2$ (area)	Vol $= \frac{4}{3}\pi r^3$	interior measure
$SO(2)$ (rotations)	$SO(3)$ (rotations)	symmetries, commutative only in 2D
full angle 2π	solid angle 4π (sterad.)	full “turn”
sum of angles $= \pi$	sum of angles $> \pi$	the excess measures the area

Remark 7.1: What is conserved and what changes. Some notions transfer effortlessly (radius, chords, diameters, tangency). Others bifurcate: in the plane there is only one type of “line”, on the sphere the role of lines is played by great circles (Theorem 7.7), and through two antipodal points infinitely many pass. Most importantly, while $SO(2)$ is commutative, $SO(3)$ is not: it is the mathematical root of gimbal lock and of the delicacy of 3D orientation in robots. Both statements are proved in Chapter 11 (Theorem 11.7 and Example 11.2) and taken up in Chapter 28. The last row of the table — the sum of the angles — has no planar analogue at all: it is the signature of curvature, and section 7.9 quantifies it exactly.

7.2. The cone and its sections

Definition 7.2: Right circular cone. Let $V \in \mathbb{R}^3$ be a point (the **vertex**), u a unit vector (the **axis**) and $\alpha \in (0, \pi/2)$ (the **half-angle**). The **right circular cone** with these data is

$$\mathcal{C} = \left\{ P \in \mathbb{R}^3 : |\langle P - V, u \rangle| = \|P - V\| \cos \alpha \right\},$$

the locus of points seen from V at an angle α from the axis. The lines through V contained in $\mathcal{C}$ are the **generators**.

Theorem 7.1: Sections orthogonal to the axis are circles. Let π be a plane orthogonal to the axis u and not through V , at distance $h > 0$ from the vertex. Then $\mathcal{C} \cap \pi$ is a circle of radius $h \tan \alpha$, centred at the foot of the perpendicular from V .

Proof. Step 1 — choice of coordinates. Put V at the origin and $u = (0, 0, 1)$. The condition of Definition 7.2 becomes, for $P = (x, y, z)$,

$$|z| = \sqrt{x^2 + y^2 + z^2} \cos \alpha.$$

Squaring and rearranging:

$$z^2(1 - \cos^2 \alpha) = (x^2 + y^2) \cos^2 \alpha \implies x^2 + y^2 = z^2 \tan^2 \alpha.$$

Step 2 — intersection. The plane is $z = h$. Substituting,

$$x^2 + y^2 = h^2 \tan^2 \alpha,$$

which by the very definition of a circle (Volume I) is the circle with centre $(0, 0, h)$ and radius $h \tan \alpha$.

Step 3 — consistency. The radius grows linearly with the distance from the vertex, with coefficient $\tan \alpha$: this is the operational definition of the half-angle. As $\alpha \rightarrow 0$ the cone degenerates into the axis and the circles shrink; as $\alpha \rightarrow \pi/2$ the cone flattens into the plane orthogonal to the axis. $\checkmark$ $\square$

Theorem 7.2: Dandelin's theorem. Let π be a plane cutting a single nappe of the cone $\mathcal{C}$ in a closed bounded curve. Let $\mathcal{S}_1, \mathcal{S}_2$ be the two spheres inscribed in the nappe, tangent to π from one side and the other respectively, and let F_1, F_2 be their points of tangency with π . Then the section $\mathcal{C} \cap \pi$ is an **ellipse** with foci F_1 and F_2 ; and the sum of the distances equals the distance, measured along a generator, between the two circles of tangency of the spheres with the cone.

Proof. Step 1 — existence of the spheres. The spheres inscribed in the nappe with centre on the axis form a one-parameter family (the radius grows linearly with the distance from the vertex). The distance of such a sphere from the plane π varies continuously and is negative on one side, positive on the other: by the intermediate value theorem there is, on each side, a sphere tangent to π . Call them $\mathcal{S}_1$ and $\mathcal{S}_2$.

Step 2 — the circles of tangency. Every inscribed sphere touches the cone along a circle, because by rotational symmetry about the axis the set of tangency points is rotation-invariant; call these circles c_1 and c_2 , contained in planes orthogonal to the axis.

Step 3 — the tangent-segment lemma. From a point P outside a sphere, all tangent segments have the same length. Indeed, with O the centre and r the radius, for every tangency point T the triangle OTP has a right angle at T , hence $|PT| = \sqrt{|PO|^2 - r^2}$, independent of T . (It is the power-of-a-point theorem of Volume I, in three-dimensional form.)

Step 4 — the decisive computation. Let P be a point of the section $\mathcal{C} \cap \pi$. The generator through P meets c_1 at a point A and c_2 at a point B . Now:

- PA and PF_1 are both tangent segments from P to $\mathcal{S}_1$ (PA along the generator, PF_1 in the plane π), so $|PF_1| = |PA|$ by Step 3;
- likewise $|PF_2| = |PB|$.

Adding,

$$|PF_1| + |PF_2| = |PA| + |PB| = |AB|,$$

P lying between A and B along the generator, which happens because the two spheres lie on opposite sides of π .

Step 5 — the constant. The length $|AB|$ is the distance, along a generator, between the two planes containing c_1 and c_2 ; since both planes are orthogonal to the axis and all generators make the same angle with it, that length *does not depend on the chosen generator*. It is therefore a constant $2a$.

Step 6 — conclusion. Every point of the section satisfies $|PF_1| + |PF_2| = 2a$ constant: by the bifocal definition, the section is an ellipse with foci F_1, F_2 and semi-major axis a .

Step 7 — the circle case. If π is orthogonal to the axis, then by symmetry the two spheres are tangent to π at the same point, i.e. $F_1 = F_2$: the ellipse degenerates into the circle, in agreement with Theorem 7.1. *The circle is therefore the conic with coincident foci:* the conic of zero eccentricity.

Step 8 — the other cases. If the plane is parallel to exactly one generator, one of the two spheres escapes to infinity and one obtains the parabola (one focus); if it cuts both nappes, the two spheres lie in different nappes and the same construction gives $||PF_1| - |PF_2|| = \text{constant}$, the hyperbola. The proof is the same, with only a sign change at Step 4. The method, due to Germinal Pierre Dandelin (1822), replaces an entire analytic computation by two spheres. $\square$

***Remark 7.2: A hierarchy of symmetries.** Theorem 7.2 places the circle within a family and explains its privileged position. The eccentricity*

$$e = \frac{\text{focal distance}}{2a} = \frac{|F_1 F_2|}{2a}$$

measures how far the section departs from orthogonality to the axis: it is 0 for the circle, $0 < e < 1$ for the ellipse, 1 for the parabola, $e > 1$ for the hyperbola. The circle is the case in which the symmetry group is largest: all rotations about the centre, against the mere two reflections of the generic ellipse. This is a theme we shall meet in every section of this chapter.

Figure 7.1: Dandelin's spheres, seen in the axial section of the cone. The two spheres are inscribed in the cone (in section: the two circles tangent to both generators) and tangent to the cutting plane π (in red). The tangency points F_1 and F_2 are the foci of the conic section; the circles k_1, k_2 along which the spheres touch the cone determine the directrices. For a point P on the conic, the segments PF_1 and PF_2 have the same length as the generator segments between P and k_1, k_2 : hence $PF_1 + PF_2 = \overline{k_1 k_2}$ is constant, i.e. the ellipse.

7.3. The sphere and its sections

Definition 7.3: Sphere in $\mathbb{R}^n$. For $n \geq 1$, $R > 0$ and $c \in \mathbb{R}^n$ one sets

$$S^{n-1}(c, R) = \{x \in \mathbb{R}^n : \|x - c\| = R\}, \quad B^n(c, R) = \{x \in \mathbb{R}^n : \|x - c\| \leq R\}.$$

One writes S^{n-1} and B^n for the case $c = 0$, $R = 1$. In particular $S^0 = \{-1, +1\}$ (two points), S^1 is the circle, S^2 the ordinary sphere.

Theorem 7.3: Every plane section of a sphere is a circle. Let $S = S^2(c, R) \subset \mathbb{R}^3$ and π a plane at distance d from c . Then

$$S \cap \pi = \begin{cases} \text{a circle of radius } \sqrt{R^2 - d^2} & \text{if } d < R, \\ \text{a point} & \text{if } d = R, \\ \emptyset & \text{if } d > R. \end{cases}$$

The centre of the circle is the foot of the perpendicular from c to π . More generally, in $\mathbb{R}^n$, the intersection of $S^{n-1}(c, R)$ with a hyperplane at distance $d < R$ is a sphere S^{n-2} of radius $\sqrt{R^2 - d^2}$.

Proof. **Step 1 — orthogonal decomposition.** Let H be the foot of the perpendicular from c to π , so that $\|c - H\| = d$ and $c - H$ is orthogonal to every direction vector of π .

Step 2 — Pythagoras. For $P \in \pi$ the vectors $c - H$ and $H - P$ are orthogonal, hence

$$\|P - c\|^2 = \|P - H\|^2 + \|H - c\|^2 = \|P - H\|^2 + d^2.$$

Step 3 — translating the condition. Therefore

$$P \in S \cap \pi \iff \|P - c\| = R \iff \|P - H\|^2 = R^2 - d^2.$$

If $d < R$ the right side is positive and the condition describes, *inside the plane* π , the circle with centre H and radius $\sqrt{R^2 - d^2}$. If $d = R$ one gets $P = H$; if $d > R$ there are no solutions.

Step 4 — the n -dimensional case. The proof never uses the dimension: Step 2 is Pythagoras in $\mathbb{R}^n$, valid by the very definition of the Euclidean norm. Replacing “plane” by “hyperplane” and “circle” by “ $(n-2)$ -dimensional sphere”, the argument is identical.

Step 5 — great circles. The radius of the section is largest for $d = 0$, i.e. when the hyperplane passes through the centre: one obtains the **great circles** (in $\mathbb{R}^3$) and more generally the *great spheres*. They have the same radius as the sphere, and are the only sections sharing its centre.

Step 6 — consequence. Since the section is a circle for *every* plane, the sphere is, in a precise sense, “made of circles in all directions”. It is this property — and not merely the equation — that is characteristic: one proves (Exercise S2) that a closed surface all of whose plane sections are circles is necessarily a sphere. $\square$

Definition 7.4: Great circles and small circles. A **great circle** of $S^2(O, r)$ is the intersection of the sphere with a plane through O : by Theorem 7.3 it has radius r , the largest possible, and centre O . Every other non-empty planar section not reduced to a point is called a **small circle**. Two **antipodal** points are two points P and $-P$ (with respect to O); through two non-antipodal points there passes one and only one great circle, the one cut by the plane $\text{span}\{OP, OQ\}$, whereas through two antipodal points infinitely many pass.

Corollary 7.1: The circle lives in the sphere. Let C be a circle in space, of centre Q , radius ρ and plane π , and let $r \geq \rho$. Then there exist exactly two spheres of radius r containing C , whose centres are

$$O_{\pm} = Q \pm du, \quad d = \sqrt{r^2 - \rho^2},$$

with u a unit normal of π ; on each of them C is the whole section with the plane π . The two spheres coincide if and only if $\rho = r$, and in that case C is a great circle. If instead $\rho > r$ no sphere of radius r contains C .

Proof. Step 1 — the two candidate spheres. Let u be a unit vector orthogonal to π and $d = \sqrt{r^2 - \rho^2} \geq 0$ (well defined because $\rho \leq r$). Set $O_{\pm} = Q \pm du$.

Step 2 — C lies on both. Let $P \in C$. The vector $P - Q$ lies in π , hence is orthogonal to u ; by the Pythagorean theorem

$$\|P - O_{\pm}\|^2 = \|(P - Q) \mp du\|^2 = \|P - Q\|^2 + d^2 = \rho^2 + d^2 = r^2,$$

that is $P \in S^2(O_{\pm}, r)$.

Step 3 — C is the whole section. The distance of $O_{\pm}$ from the plane π is d and the foot of the perpendicular is Q . By Theorem 7.3 the section $S^2(O_{\pm}, r) \cap \pi$ is the circle of centre Q and radius $\sqrt{r^2 - d^2} = \rho$: it is exactly C . So C is not merely contained in the sphere, it is a planar section of it.

Step 4 — there are no others. Let O be the centre of any sphere of radius r containing C , and write $O - Q = w_{\parallel} + w_{\perp}$ with $w_{\parallel}$ in the direction plane of π and $w_{\perp}$ parallel to u . For every $P \in C$,

$$r^2 = \|P - O\|^2 = \|P - Q\|^2 - 2\langle P - Q, O - Q \rangle + \|O - Q\|^2 = \rho^2 - 2\langle P - Q, w_{\parallel} \rangle + \|O - Q\|^2,$$

having used $\langle P - Q, w_{\perp} \rangle = 0$. The first and third summands do not depend on P , so $\langle P - Q, w_{\parallel} \rangle$ is constant on C . But as P runs over the circle that scalar product takes all values in $[-\rho\|w_{\parallel}\|, \rho\|w_{\parallel}\|]$; constancy forces $w_{\parallel} = 0$, i.e. O lies on the axis of C . Then $r^2 = \rho^2 + \|w_{\perp}\|^2$ gives $\|w_{\perp}\| = d$ and hence $O = O_{+}$ or $O = O_{-}$.

Step 5 — limiting cases. If $\rho = r$ then $d = 0$ and $O_{+} = O_{-} = Q$: the sphere is unique and C is a great circle (Definition 7.4). If $\rho < r$ the two spheres are distinct and symmetric with respect to π . If $\rho > r$ every planar section of a sphere of radius r has radius $\sqrt{r^2 - d^2} \leq r < \rho$ (Theorem 7.3) and cannot be C .

Step 6 — numerical check. With $r = 1$ and $\rho = 0.6$ one gets $d = \sqrt{1 - 0.36} = 0.8$, and the check $\rho^2 + d^2 = 0.36 + 0.64 = 1.00 = r^2$. ✓ With $r = 13$ and $\rho = 12$ one gets $d = \sqrt{169 - 144} = 5$, the Pythagorean triple $(5, 12, 13)$. ✓

Step 7 — reading. The circle is not “replaced” by the sphere: it is contained in it, and in two ways. Moving to dimension three does not eliminate the object of the treatise, it puts it in a family — exactly as Theorem 7.2 had put it in the family of conics. □

Exercise 7.1. At what distance from the center is the earth parallel at latitude 45° , and what is its radius (spherical Earth of radius R)?

Solution. The parallel at latitude ϕ is the section at distance $d = R \sin \phi$ from the center (the plane is horizontal, raised by $R \sin \phi$). Its radius is $\sqrt{R^2 - d^2} = R \cos \phi$. For $\phi = 45^\circ$: $d = R/\sqrt{2} \approx 0.707R$ and radius $R \cos 45^\circ = R/\sqrt{2} \approx 0.707R$. The parallel at 45° has radius equal to 70.7% of the equatorial one. By Corollary 7.1 the spheres of radius R containing that parallel are two: the Earth and its mirror image with respect to the plane of the parallel.

Example 7.1: Circles of latitude and navigation. On the Earth, approximated by a sphere of radius $R = 6371$ km, the parallel of latitude φ is the section by the horizontal plane at distance $d = R \sin \varphi$ from the centre. By Theorem 7.3 its radius is

$$r(\varphi) = \sqrt{R^2 - R^2 \sin^2 \varphi} = R \cos \varphi.$$

Numerical check. At $\varphi = 45^\circ$: $r = 6371 \times 0.707107 = 4505.0$ km, and the length of the parallel is $2\pi r = 28\,305$ km, against the 40 030 km of the equator. The ratio is $\cos 45^\circ = 0.7071$. ✓

Why it matters. Only the equator and the meridians are great circles; the parallels (except the equator) are not. Since the shortest path between two points of a sphere is the arc of a great circle (Exercise S3), flying from Rome to New York along the parallel of 41° N would be longer than the actual route, which passes far to the north. That is why transatlantic routes look curved on Mercator charts: they are straight on the sphere, not on the map.

Theorem 7.4: Girard's theorem: the area of a spherical triangle. Let T be a spherical triangle on the sphere of radius R , bounded by three arcs of great circles, with interior angles A, B, C . Then

$$\text{Area}(T) = R^2(A + B + C - \pi).$$

In particular $A + B + C > \pi$: on the sphere the angle sum of a triangle always exceeds a straight angle, and the excess measures the area.

Proof. Step 1 — the area of a lune. Two great circles meet at two antipodal points and divide the sphere into four *lunes*. A lune of dihedral angle θ occupies a fraction $\theta/2\pi$ of the sphere, hence has area

$$\frac{\theta}{2\pi} \cdot 4\pi R^2 = 2\theta R^2.$$

Step 2 — the three lunes. The three great circles bounding T determine, at each vertex, a pair of opposite lunes: the one containing T and the one containing the antipodal triangle T' . Their areas are $2AR^2$, $2BR^2$, $2CR^2$ for the lunes containing T , and the same for the opposite ones.

Step 3 — counting with multiplicity. The six lunes (three plus the three opposite) cover the whole sphere. Every point of the sphere is covered once, except the points of T and T' , which are covered three times each (once by each lune). Hence

$$\underbrace{2 \cdot (2AR^2 + 2BR^2 + 2CR^2)}_{\text{sum of the six lune areas}} = \underbrace{4\pi R^2}_{\text{sphere}} + 2 \cdot 2 \cdot \text{Area}(T),$$

the correction term accounting for the fact that T and T' (of equal area) are counted three times instead of once, i.e. twice in excess each.

Step 4 — solving. Simplifying,

$$4R^2(A + B + C) = 4\pi R^2 + 4 \text{Area}(T) \implies \text{Area}(T) = R^2(A + B + C - \pi).$$

Step 5 — check on the trirectangular triangle. The triangle with vertices at the North Pole and two points of the equator 90° apart has $A = B = C = \pi/2$. The formula gives

$$\text{Area} = R^2 \left(\frac{3\pi}{2} - \pi \right) = \frac{\pi R^2}{2},$$

that is one eighth of the surface $4\pi R^2$: and indeed three coordinate planes divide the sphere into eight equal triangles. ✓

Step 6 — the plane limit. For triangles small compared with R the area tends to zero and with it the excess: one recovers $A+B+C \rightarrow \pi$, Euclidean geometry. The sphere is thus locally flat, and the angular excess measures curvature: it is the first instance of the Gauss–Bonnet theorem, which generalises this formula to arbitrary surfaces.

Step 7 — and the circle? On a sphere the “circles” — the loci of points at geodesic distance ρ from a centre — have circumference $2\pi R \sin(\rho/R)$, less than $2\pi\rho$. The ratio circumference/radius, which in the plane is exactly 2π (Volume I), is therefore *smaller* than 2π on the sphere. This too is an effect of curvature, and its measure — the defect with respect to 2π — is the circular analogue of Girard’s excess (Exercise S4). $\square$

Figure 7.2: A plane section of a sphere is always a circle. If the plane π is at distance $d < R$ from the centre O , the right triangle with legs d and r and hypotenuse R immediately gives $r = \sqrt{R^2 - d^2}$: the radius of the section depends only on the distance of the plane from the centre, not on its orientation. For $d = 0$ we get the great circle ($r = R$), and as $d \rightarrow R$ the circle shrinks to a point. It is the same relation as for the chord of a circle in Volume I, moved up one dimension.

7.4. Quadrics and ellipsoids: where the circles hide

Definition 7.5: Quadric and ellipsoid. A **quadric** of $\mathbb{R}^3$ is the zero locus of a second-degree polynomial in the three coordinates. If the quadratic part is positive definite, a rigid motion reduces the quadric to the canonical form

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1, \quad a \geq b \geq c > 0,$$

the **ellipsoid** with semi-axes a, b, c . For $a = b = c$ one obtains the sphere.

Theorem 7.5: Circular sections of the ellipsoid. Let E be the ellipsoid with semi-axes $a > b > c$ (all distinct). Then:

- (i) every plane section of E is an ellipse (possibly degenerate);
- (ii) non-degenerate circular sections exist, all of radius $\leq b$, and those of maximal radius b lie in the planes

$$z = \pm kx, \quad k = \frac{c}{a} \sqrt{\frac{a^2 - b^2}{b^2 - c^2}},$$

and in their parallel translates;

- (iii) there are therefore exactly two families of circle-cutting planes, and both families con-

tain the intermediate axis y .

If two semi-axes coincide the two families merge into one (ellipsoid of revolution); if all three coincide every plane cuts a circle (sphere, Theorem 7.3).

Proof. (i) The intersection of a quadric with a plane is a conic: substituting the parametric equation of the plane into that of the ellipsoid gives a second-degree polynomial in two variables. Since E is bounded, the conic is bounded, hence an ellipse (or a point, or empty).

(ii) Step 1 — the idea. A plane cuts E along a circle of radius ρ centred at the origin if and only if that plane meets both E and the sphere $x^2 + y^2 + z^2 = \rho^2$ in the same set. So we study the intersection $E \cap S$ with S the sphere of radius ρ .

Step 2 — the system. Subtracting the equation of the sphere, divided by ρ^2 , from that of the ellipsoid:

$$x^2 \left(\frac{1}{a^2} - \frac{1}{\rho^2} \right) + y^2 \left(\frac{1}{b^2} - \frac{1}{\rho^2} \right) + z^2 \left(\frac{1}{c^2} - \frac{1}{\rho^2} \right) = 0.$$

Step 3 — choosing ρ . For this equation to represent a pair of planes through the origin, one of the three coefficients must vanish and the other two must have opposite signs. Since $a > b > c$,

$$\frac{1}{a^2} < \frac{1}{b^2} < \frac{1}{c^2},$$

and the only possible choice is $\rho = b$: then the coefficient of y^2 vanishes, that of x^2 is negative and that of z^2 positive. (With $\rho = a$ or $\rho = c$ the two remaining coefficients would have the same sign and the equation would give only the origin.)

Step 4 — the two planes. With $\rho = b$ the equation becomes

$$z^2 \frac{b^2 - c^2}{b^2 c^2} = x^2 \frac{a^2 - b^2}{a^2 b^2},$$

that is

$$z = \pm kx, \quad k = \frac{c}{a} \sqrt{\frac{a^2 - b^2}{b^2 - c^2}},$$

two distinct planes (since $a \neq b$ and $b \neq c$), both containing the y -axis.

Step 5 — they really are circles. The intersection $E \cap S$ is contained in the union of the two planes; conversely every point of E on one of those planes satisfies the equation of Step 2 and hence lies on S . So $E \cap \{z = kx\} = S \cap \{z = kx\}$, which by Theorem 7.3 is a circle of radius b (the plane passes through the centre).

Step 6 — parallel planes. A plane parallel to one of the two cuts E along a curve similar to the one through the centre: substituting $z = kx + h$ into the equation gives a conic whose coefficients of x^2 and y^2 remain equal to each other (because the choice of k made them equal) and whose mixed term xy remains zero. The section is therefore again a circle, of smaller radius.

(iii) The two families are the planes parallel to $z = kx$ and to $z = -kx$; no other plane gives a circle, because Step 3 showed $\rho = b$ to be the only possible choice and the two planes found are the only ones.

Step 7 — degenerate cases. If $a = b > c$ (oblate ellipsoid) then $k = 0$ and the two families merge into the plane $z = 0$ and its parallels: the circles of the equator. If $a > b = c$ (prolate), $k \rightarrow \infty$ and the families merge into the planes $x = \text{constant}$. If $a = b = c$ every ρ works and one recovers the sphere.

Step 8 — numerical check. With $a = 3$, $b = 2$, $c = 1$:

$$k = \frac{1}{3} \sqrt{\frac{9-4}{4-1}} = \frac{1}{3} \sqrt{\frac{5}{3}} = \frac{1.290994}{3} = 0.430331.$$

The planes are $z = \pm 0.430331x$ and cut circles of radius 2. Direct check: the point $(x, y, z) = (0, 2, 0)$ lies on both planes and on the ellipsoid ($4/4 = 1$ ✓) and is at distance 2 from the origin ✓. The point with $y = 0$ on the plane $z = kx$ satisfies $\frac{x^2}{9} + \frac{k^2 x^2}{1} = 1$, i.e. $x^2(0.111111 + 0.185185) = 1$, whence $x^2 = 3.375$, $x = 1.837$, $z = 0.7906$; its distance from the origin is $\sqrt{3.375 + 0.625} = \sqrt{4.000} = 2.000$. ✓ $\square$

Remark 7.3: Why the circles hide. A generic ellipsoid has no rotational symmetry: its symmetry group is finite (the reflections in the coordinate planes and their compositions). Yet it contains infinitely many circles. There is no contradiction: the circles are not orbits of symmetries of the ellipsoid, but intersections with a suitable sphere. The lesson, which recurs, is that the circle survives the loss of symmetry: it hides in one-parameter families even inside objects with no apparent trace of it. It is the principle underlying the machining of toric lenses in optics, and the tracing of ellipsoidal surfaces with rotating tools in mechanics.

Figure 7.3: Where the circles hide inside an ellipsoid with semi-axes $a > b > c$ (here $3 > 2 > 1$). The figure shows the principal section in the xz plane: the ellipse with semi-axes a and c . The radius vector from the centre takes every value between c and a , and equals exactly the intermediate semi-axis b at four points, lying on two lines through the centre (in red). The two planes through these lines and the y axis cut the ellipsoid along genuine circles of radius b (dashed blue): these are the only two families of circular sections, and they coincide when $a = b$ or $b = c$, i.e. for an ellipsoid of revolution.

7.5. Stereographic projection

The sphere and the plane are not the same object — one is compact, the other is not — and yet there is between them an almost perfect correspondence: stereographic projection, which misses only one point. It is the construction that allows every spherical question to be transported to the plane, and it underlies the Riemann sphere and conformal nautical charts.

Definition 7.6: Stereographic projection. Let $N = (0, 0, r)$ be the north pole of $S^2 = S^2(O, r)$ with O at the origin. The **stereographic projection** $\sigma : S^2 \setminus \{N\} \rightarrow \pi_0$ onto the equatorial plane $\pi_0 = \{z = 0\}$, identified with $\mathbb{R}^2$, sends P to the intersection with π_0 of the line NP .

Proposition 7.1: Stereographic coordinates. The following formulas hold:

$$\sigma(x, y, z) = \frac{r}{r - z} (x, y), \quad X(u, v) = \frac{r}{u^2 + v^2 + r^2} (2ru, 2rv, u^2 + v^2 - r^2),$$

and $X : \mathbb{R}^2 \rightarrow S^2 \setminus \{N\}$ is a C^∞ bijection, inverse to σ . In particular σ is well defined and bijective, and the chart X covers the whole sphere except the single point N , without the

degeneracies at the poles of spherical coordinates.

Proof. Step 1 — the formula for σ . The line through $N = (0, 0, r)$ and $P = (x, y, z)$ is $N + t(P - N) = (tx, ty, r + t(z - r))$. On S^2 one has $z = r$ only at N (because $z = r$ forces $x^2 + y^2 = 0$), so for $P \neq N$ we have $z < r$ and the third coordinate vanishes for $t = r/(r - z) > 0$. Substituting gives $\sigma(P) = \frac{r}{r-z}(x, y)$.

Step 2 — X takes values on the sphere. Setting $s = u^2 + v^2$ and $D = s + r^2 \geq r^2 > 0$,

$$\|X\|^2 = \frac{r^2}{D^2} (4r^2u^2 + 4r^2v^2 + (s - r^2)^2) = \frac{r^2}{D^2} (4r^2s + s^2 - 2r^2s + r^4) = \frac{r^2}{D^2} (s + r^2)^2 = r^2.$$

Step 3 — X avoids the pole. The third coordinate equals $z = r \frac{s-r^2}{D} = r - \frac{2r^3}{D} < r$, hence $X(u, v) \neq N$ for every (u, v) .

Step 4 — $\sigma \circ X = \text{id}$. From $z = r - 2r^3/D$ we get $r - z = 2r^3/D$, hence $\frac{r}{r-z} = \frac{D}{2r^2}$ and

$$\sigma(X(u, v)) = \frac{D}{2r^2} \cdot \frac{1}{D} (2r^2u, 2r^2v) = (u, v).$$

Step 5 — $X \circ \sigma = \text{id}$. Let $P = (x, y, z) \in S^2 \setminus \{N\}$ and $(u, v) = \sigma(P)$. Then, using $x^2 + y^2 = r^2 - z^2$,

$$s = u^2 + v^2 = \frac{r^2(r^2 - z^2)}{(r - z)^2} = \frac{r^2(r + z)}{r - z}, \quad D = s + r^2 = r^2 \frac{(r + z) + (r - z)}{r - z} = \frac{2r^3}{r - z},$$

whence $\frac{2r^2}{D} = \frac{r-z}{r}$. The first two components of $X(u, v)$ then equal $\frac{2r^2u}{D} = \frac{r-z}{r} \cdot \frac{rx}{r-z} = x$ and similarly y ; the third equals $r(1 - \frac{2r^2}{D}) = r(1 - \frac{r-z}{r}) = z$. Hence $X(\sigma(P)) = P$, and together with Step 4 this proves that σ and X are inverse bijections.

Step 6 — regularity and absence of poles. The components of X are quotients of polynomials with denominator $D \geq r^2 > 0$: X is C^∞ on all of $\mathbb{R}^2$. Moreover by Theorem 7.6 (Step 2) one has $\|X_u\| = \|X_v\| = 2r^2/D > 0$ and $\langle X_u, X_v \rangle = 0$, so $X_u \times X_v$ never vanishes: the chart is *regular at every point*. Spherical coordinates (Definition 7.7) degenerate instead at the poles, where $X_\varphi = 0$.

Step 7 — numerical check. With $r = 1$ and $(u, v) = (2, 0)$: $D = 5$, $X = (\frac{4}{5}, 0, \frac{3}{5}) = (0.8, 0, 0.6)$, and $\|X\|^2 = 0.64 + 0.36 = 1.00$ ✓. Going back, $\sigma(0.8, 0, 0.6) = \frac{1}{1-0.6}(0.8, 0) = (2, 0)$ ✓. $\square$

Theorem 7.6: Properties of stereographic projection. The stereographic projection σ of Definition 7.6 enjoys the following two properties.

(i) **It is conformal:** it preserves the size of angles between curves that meet. Precisely, the chart X has first fundamental form

$$E = \|X_u\|^2 = \frac{4r^4}{(u^2 + v^2 + r^2)^2} = G = \|X_v\|^2, \quad F = \langle X_u, X_v \rangle = 0,$$

that is $\langle dX(w), dX(w') \rangle = \lambda^2 \langle w, w' \rangle$ with $\lambda(u, v) = 2r^2/(u^2 + v^2 + r^2) > 0$.

(ii) **It maps circles to circles or lines:** if $\Gamma \subset S^2$ is a circle through N , then $\sigma(\Gamma \setminus \{N\})$ is a line of π_0 ; if Γ does not pass through N , then $\sigma(\Gamma)$ is a circle. Writing $\Gamma = S^2 \cap \{ax + by + cz = k\}$ with $a^2 + b^2 + c^2 = 1$ and $|k| < r$, the image circle has centre $-\frac{r^2}{cr - k}(a, b)$ and radius $\frac{r\sqrt{r^2 - k^2}}{|cr - k|}$.

Proof. (i) Step 1 — the derivatives of the chart. With $s = u^2 + v^2$ and $D = s + r^2$ one has $X = (2r^2u/D, 2r^2v/D, r - 2r^3/D)$; since $D_u = 2u$ and $D_v = 2v$,

$$X_u = \frac{1}{D^2} (2r^2(D - 2u^2), -4r^2uv, 4r^3u), \quad X_v = \frac{1}{D^2} (-4r^2uv, 2r^2(D - 2v^2), 4r^3v).$$

Step 2 — the computation of E, F, G . For E :

$$D^4 \|X_u\|^2 = 4r^4(D - 2u^2)^2 + 16r^4u^2v^2 + 16r^6u^2 = 4r^4[(D - 2u^2)^2 + 4u^2v^2 + 4r^2u^2],$$

and the bracket equals

$$D^2 - 4u^2D + 4u^4 + 4u^2v^2 + 4r^2u^2 = D^2 - 4u^2D + 4u^2(u^2 + v^2 + r^2) = D^2,$$

hence $E = 4r^4/D^2$; by symmetry $G = 4r^4/D^2$. For F :

$$D^4 \langle X_u, X_v \rangle = -8r^4uv(D - 2u^2) - 8r^4uv(D - 2v^2) + 16r^6uv = 8r^4uv[-2D + 2u^2 + 2v^2 + 2r^2] = 0,$$

because $u^2 + v^2 + r^2 = D$.

Step 3 — from $E = G, F = 0$ to conformality. For $w = (w_1, w_2)$ and $w' = (w'_1, w'_2)$ in $\mathbb{R}^2$,

$$\langle dX(w), dX(w') \rangle = E w_1 w'_1 + F(w_1 w'_2 + w_2 w'_1) + G w_2 w'_2 = \lambda^2 \langle w, w' \rangle, \quad \lambda = \frac{2r^2}{D}.$$

In particular $\|dX(w)\| = \lambda \|w\|$ and

$$\cos(\widehat{dX(w), dX(w')}) = \frac{\lambda^2 \langle w, w' \rangle}{\lambda \|w\| \cdot \lambda \|w'\|} = \frac{\langle w, w' \rangle}{\|w\| \|w'\|} = \cos(\widehat{w, w'}) :$$

angles are preserved by X , and hence also by its inverse σ . (That λ depends on the point means that *lengths* are not preserved: stereographic projection is conformal but not isometric, and indeed it dilates the neighbourhood of N enormously.)

Step 4 — numerical check of (i). With $r = 1$ and $(u, v) = (1, 1)$ one has $D = 3$ and

$$X_u = \frac{1}{9}(2, -4, 4), \quad X_v = \frac{1}{9}(-4, 2, 4),$$

whence $\|X_u\|^2 = (4 + 16 + 16)/81 = 36/81 = 0.444444$ and $\langle X_u, X_v \rangle = (-8 - 8 + 16)/81 = 0$, against the predicted value $4r^4/D^2 = 4/9 = 0.444444$. ✓

(ii) Step 5 — what a circle of the sphere is. By Theorem 7.3 every circle $\Gamma \subset S^2$ is the intersection with a plane $ax + by + cz = k$; normalizing $a^2 + b^2 + c^2 = 1$, the distance of the plane from the centre is $|k|$, and the intersection is a circle (non-empty, not a point) if and only if $|k| < r$. Its radius is $\rho = \sqrt{r^2 - k^2}$.

Step 6 — the substitution. A point $X(u, v)$ belongs to Γ if and only if

$$a \frac{2r^2u}{D} + b \frac{2r^2v}{D} + c \frac{r(s - r^2)}{D} = k,$$

that is, multiplying by $D = s + r^2$ and rearranging,

$$(cr - k)(u^2 + v^2) + 2r^2au + 2r^2bv - r^3c - kr^2 = 0, \quad \text{which we call } (\star).$$

Since X is a bijection onto $S^2 \setminus \{N\}$ (Proposition 7.1), the solution set of $(\star)$ is *exactly* $\sigma(\Gamma \setminus \{N\})$.

Step 7 — the case of the line. One has $N = (0, 0, r) \in \Gamma$ if and only if $cr = k$. In that case $-r^3c - kr^2 = -r^3c - cr^3 = -2cr^3$ and $(\star)$ becomes

$$2r^2(au + bv) = 2cr^3, \quad \text{that is} \quad au + bv = cr.$$

It cannot be $a = b = 0$: otherwise $c = \pm 1$ and $k = cr = \pm r$, against $|k| < r$. Hence it is a genuine line, and $\sigma(\Gamma \setminus \{N\})$ is a line.

Step 8 — the case of the circle. If $cr \neq k$, dividing $(\star)$ by $cr - k$ we obtain

$$u^2 + v^2 + \frac{2r^2a}{cr - k}u + \frac{2r^2b}{cr - k}v - \frac{r^2(rc + k)}{cr - k} = 0,$$

that is a circle of centre $(u_0, v_0) = -\frac{r^2}{cr - k}(a, b)$ and radius R_Γ with

$$R_\Gamma^2 = u_0^2 + v_0^2 + \frac{r^2(rc + k)}{cr - k} = \frac{r^4(a^2 + b^2) + r^2(rc + k)(cr - k)}{(cr - k)^2} = \frac{r^2[r^2(a^2 + b^2) + r^2c^2 - k^2]}{(cr - k)^2} = \frac{r^2(r^2 - k^2)}{(cr - k)^2},$$

where we used $(rc + k)(cr - k) = r^2c^2 - k^2$ and then $a^2 + b^2 + c^2 = 1$. Since $|k| < r$ the numerator is positive: it is a genuine circle, of radius $R_\Gamma = r\sqrt{r^2 - k^2}/|cr - k| = r\rho/|cr - k|$.

Step 9 — numerical check of (ii). Let $r = 1$. (a) *The equator*, $a = b = 0$, $c = 1$, $k = 0$: then $cr - k = 1$, the centre is the origin and the radius $\sqrt{1 - 0}/1 = 1$. And indeed σ fixes the equator pointwise, since for $z = 0$ one has $\sigma(x, y, 0) = (x, y)$. ✓ (b) *A parallel*, $z = \frac{1}{2}$, that is $c = 1$, $k = \frac{1}{2}$: centre at the origin and radius $\sqrt{1 - 1/4}/(1/2) = 0.866025/0.5 = 1.732051 = \sqrt{3}$.

Direct check on the point $(\frac{\sqrt{3}}{2}, 0, \frac{1}{2}) \in \Gamma$: $\sigma = \frac{1}{1-0.5}(0.866025, 0) = (1.732051, 0)$, of modulus $\sqrt{3}$. ✓ (c) *A circle through the pole*, plane $x + z = 1$, that is $a = c = 1/\sqrt{2}$, $k = 1/\sqrt{2} = cr$: the image is the line $u/\sqrt{2} = 1/\sqrt{2}$, i.e. $u = 1$. Check on two points of Γ : $(1, 0, 0)$ gives $\sigma = (1, 0)$, and $(\frac{1}{2}, \frac{1}{\sqrt{2}}, \frac{1}{2})$ — which satisfies $x + z = 1$ and $x^2 + y^2 + z^2 = 0.25 + 0.5 + 0.25 = 1$ — gives $\sigma = \frac{1}{1-0.5}(0.5, 0.707107) = (1, 1.414214)$. Both lie on $u = 1$. ✓

Step 10 — reading. Meridians and parallels are circles meeting at right angles; their images are respectively lines through the origin and circles centred at the origin, which still meet at right angles: conformality in action. It is the property that makes stereographic projection the preferred chart in polar cartography and in crystallography, and that, by Chapter 6, links it to Möbius transformations: those too map circles and lines to circles and lines. $\square$

Remark 7.4: The Riemann sphere: closing the plane with a point. Identifying the equatorial plane with $\mathbb{C}$ and adding the “point at infinity” $\infty \leftrightarrow N$, stereographic projection realizes $S^2 \cong \mathbb{C} \cup \{\infty\}$, the **Riemann sphere**. The complex plane of Volume II is therefore not “open”: compactified with a single point it becomes a sphere. Möbius transformations $z \mapsto \frac{az+b}{cz+d}$ (Chapter 6) correspond to transformations of the sphere and — consistently with Theorem 7.6(ii) — map circles and lines to circles and lines. It is the bridge between the circle ($\mathbb{T} \subset \mathbb{C}$) and the sphere as a complex object, resumed in Chapter 15 and, for the Hopf fibration, in Chapter 11.

7.6. Sphere parametrizations

Definition 7.7: Spherical coordinates. On the sphere $S^2(O, r)$ centred at the origin one sets

$$X(\varphi, \vartheta) = r(\sin \vartheta \cos \varphi, \sin \vartheta \sin \varphi, \cos \vartheta),$$

with **longitude** $\varphi \in [0, 2\pi)$ and **colatitude** $\vartheta \in [0, \pi]$. Meridians are $\varphi = \text{constant}$ (great semicircles), parallels $\vartheta = \text{constant}$ (small circles, except the equator $\vartheta = \pi/2$). The **latitude** is $\phi = \pi/2 - \vartheta$.

Figure 7.4: Stereographic projection, seen in the axial section of the unit sphere ($r = 1$). The point $P_1 = (0.8, 0, -0.6)$ of the southern hemisphere projects to $\sigma(P_1) = (0.5, 0)$, *inside* the equatorial circle, because $u = x/(1 - z) = 0.8/1.6 = 0.5$; the point $P_2 = (0.6, 0, 0.8)$ of the northern hemisphere projects to $\sigma(P_2) = (3, 0)$, very far away, because $u = 0.6/0.2 = 3$. The equator stays fixed pointwise, and approaching the pole N the image escapes to infinity: this is why N corresponds to the point at infinity of the Riemann sphere.

Lemma 7.1: Area element in spherical coordinates. For the parametrization of Definition 7.7 one has

$$\|X_\varphi\| = r \sin \vartheta, \quad \|X_\vartheta\| = r, \quad \langle X_\varphi, X_\vartheta \rangle = 0,$$

and therefore $dA = \|X_\varphi \times X_\vartheta\| d\varphi d\vartheta = r^2 \sin \vartheta d\varphi d\vartheta$. The chart is regular for $\vartheta \in (0, \pi)$ and degenerates at the two poles, where $X_\varphi = 0$.

Proof. Step 1 — the derivatives. Differentiating,

$$X_\varphi = r \sin \vartheta (-\sin \varphi, \cos \varphi, 0), \quad X_\vartheta = r (\cos \vartheta \cos \varphi, \cos \vartheta \sin \varphi, -\sin \vartheta).$$

Step 2 — norms and orthogonality. $\|X_\varphi\| = r \sin \vartheta$ because $\sin^2 \varphi + \cos^2 \varphi = 1$ and $\sin \vartheta \geq 0$ on $[0, \pi]$; moreover $\|X_\vartheta\|^2 = r^2 (\cos^2 \vartheta + \sin^2 \vartheta) = r^2$; finally

$$\langle X_\varphi, X_\vartheta \rangle = r^2 \sin \vartheta \cos \vartheta (-\sin \varphi \cos \varphi + \cos \varphi \sin \varphi) = 0.$$

Step 3 — the area element. For two orthogonal vectors $\|X_\varphi \times X_\vartheta\| = \|X_\varphi\| \|X_\vartheta\| = r^2 \sin \vartheta$.

Step 4 — global check. Integrating, $\int_0^{2\pi} \int_0^\pi r^2 \sin \vartheta d\vartheta d\varphi = 2\pi r^2 [-\cos \vartheta]_0^\pi = 4\pi r^2$, the area of the sphere (Theorem 7.9). ✓ $\square$

Exercise 7.2. Where does the south pole $S = (0, 0, -r)$ go under stereographic projection from the north pole?

Solution. The line NS is the z axis; it intersects the plane $z = 0$ at the origin. Hence $\sigma(S) = (0, 0)$: the south pole goes to the center of the plane. In formulas, Proposition 7.1 gives $\sigma(0, 0, -r) = \frac{r}{r+r}(0, 0) = (0, 0)$. Parallels near S go to small circles around the origin, those near N to huge circles — consistent with $N \leftrightarrow \infty$ and with the radius $\sqrt{(1+z_0)/(1-z_0)}$ computed in Exercise 7.8.

7.7. Great circles, distance and geodesics

On the sphere the role of lines is played by great circles. That this is not a convention but a theorem is the content of this section: among all curves traced on the sphere, those of minimal

length are arcs of great circles. The proof that follows is *direct* and does not use the calculus of variations: the variational characterization, valid on an arbitrary surface, is in Chapter 9.

Theorem 7.7: Great circles are the geodesics. Let $A, B \in S^2(O, r)$ be two distinct points. For every continuous, piecewise C^1 curve $\gamma : [0, 1] \rightarrow S^2(O, r)$ with $\gamma(0) = A$ and $\gamma(1) = B$ one has

$$L(\gamma) = \int_0^1 \|\gamma'(t)\| dt \geq r \arccos \frac{\langle A, B \rangle}{r^2},$$

and the right-hand side is attained. If A and B are not antipodal, equality holds if and only if γ traverses monotonically the **minor arc** of the (unique) great circle through A and B , possibly resting at the endpoints. If A and B are antipodal the minimum is πr and is attained by every great semicircle joining them.

Proof. Step 1 — reduction to the unit sphere. If γ is a curve on $S^2(O, r)$, then $\tilde{\gamma} = \gamma/r$ is a curve on $S^2(O, 1)$, with $L(\gamma) = r L(\tilde{\gamma})$ and $\langle A, B \rangle / r^2 = \langle \tilde{A}, \tilde{B} \rangle$. It therefore suffices to prove the statement for $r = 1$, which is assumed from now on.

Step 2 — the angular distance from the starting point. Set $u(t) = \langle A, \gamma(t) \rangle \in [-1, 1]$ and, on the stretches where $|u(t)| < 1$, $g(t) = \arccos u(t) \in (0, \pi)$, which is the central angle between A and $\gamma(t)$.

Step 3 — the pointwise inequality $|g'| \leq \|\gamma'\|$. From $\|\gamma\|^2 \equiv 1$, differentiating, $\langle \gamma, \gamma' \rangle = 0$. Decompose $A = u\gamma + A_\perp$ with $\langle A_\perp, \gamma \rangle = 0$; then $\|A_\perp\|^2 = \|A\|^2 - u^2 = 1 - u^2$ and

$$u' = \langle A, \gamma' \rangle = \langle A_\perp, \gamma' \rangle, \quad \text{hence} \quad |u'| \leq \|A_\perp\| \|\gamma'\| = \sqrt{1 - u^2} \|\gamma'\|$$

by the Cauchy–Schwarz inequality. Since where $|u| < 1$ one has $g' = -u'/\sqrt{1 - u^2}$, we conclude

$$|g'(t)| \leq \|\gamma'(t)\|.$$

Step 4 — the last passage through A . The set $\{t \in [0, 1] : \gamma(t) = A\}$ is closed (by continuity), contains 0 and does not contain 1 (because $B \neq A$): let $c < 1$ be its maximum. Then $\gamma(c) = A$, $u(c) = 1$, and $u(t) < 1$ for every $t \in (c, 1]$.

Step 5 — the case in which γ avoids the antipode of A after c . Suppose $\gamma(t) \neq -A$ for every $t \in [c, 1]$. Then $|u| < 1$ on $(c, 1]$, so g is defined and piecewise C^1 on $(c, 1]$; moreover g is continuous up to c with $g(c) = \arccos 1 = 0$. For every $\varepsilon \in (0, 1 - c)$, using the pointwise inequality of Step 3,

$$L(\gamma) \geq \int_{c+\varepsilon}^1 \|\gamma'\| dt \geq \int_{c+\varepsilon}^1 |g'| dt \geq \left| \int_{c+\varepsilon}^1 g' dt \right| = g(1) - g(c + \varepsilon),$$

and letting $\varepsilon \rightarrow 0^+$, by the continuity of g at c ,

$$L(\gamma) \geq g(1) - g(c) = \arccos \langle A, B \rangle.$$

Step 6 — the case in which γ touches the antipode. If there is $t \in [c, 1]$ with $\gamma(t) = -A$, let τ be the least such t . On (c, τ) one has $|u| < 1$ and Step 5 is repeated on the interval $[c, \tau]$ (letting both margins tend to zero), obtaining $L(\gamma) \geq g(\tau) - g(c) = \arccos(-1) = \pi \geq \arccos \langle A, B \rangle$. The inequality of the statement therefore always holds.

Step 7 — the minimum is attained. Let $\theta = \arccos \langle A, B \rangle$. If $\theta < \pi$, the vectors A and B are linearly independent; setting $w = (B - \langle A, B \rangle A) / \|B - \langle A, B \rangle A\|$ (well defined and unit, orthogonal to A), the curve

$$\gamma_0(t) = \cos(\theta t) A + \sin(\theta t) w, \quad t \in [0, 1],$$

satisfies $\|\gamma_0\| \equiv 1$, $\gamma_0(0) = A$, $\gamma_0(1) = B$ and $\|\gamma'_0\| \equiv \theta$, so $L(\gamma_0) = \theta$: it is the arc of the great circle in the plane $\text{span}\{A, w\} = \text{span}\{A, B\}$. If $\theta = \pi$ the same formula works with any unit vector $w \perp A$.

Step 8 — the equality case: the curve stands still, then climbs. Let $L(\gamma) = \theta < \pi$ (i.e. $B \neq -A$; we are in the case of Step 5, since Step 6 would give $L \geq \pi > \theta$). Then all the inequalities of Step 5 are equalities, and in particular:

- (a) $\int_0^c \|\gamma'\| = 0$, hence $\gamma \equiv A$ on $[0, c]$;
- (b) $\|\gamma'\| = |g'|$ almost everywhere on $(c, 1)$, i.e. equality holds in Cauchy–Schwarz at Step 3: $\gamma'(t)$ is parallel to $A_\perp(t) = A - u(t)\gamma(t)$, and hence $\gamma' \in \text{span}\{A, \gamma\}$;
- (c) $g' \geq 0$ almost everywhere, i.e. g is non-decreasing.

Step 9 — from (b) it follows that γ lies on a great circle. Since $\gamma(1) = B$ and A, B are linearly independent, the unit vector $n = (A \times B)/\|A \times B\|$ is well defined, orthogonal to A and to B . Set $\psi(t) = \langle \gamma(t), n \rangle$; then $\psi(1) = 0$ and, writing $\gamma' = \alpha A + \beta \gamma$ with α, β piecewise continuous functions (Step 8(b)),

$$\psi' = \alpha \langle A, n \rangle + \beta \langle \gamma, n \rangle = \beta \psi,$$

because $\langle A, n \rangle = 0$. Hence $(\psi e^{-\int \beta})' = 0$, i.e. $\psi e^{-\int \beta}$ is constant; vanishing at $t = 1$, it is identically zero, and therefore $\psi \equiv 0$. The curve lies in the plane $n^\perp$ through the origin: it lies on the great circle through A and B .

Step 10 — it is the minor arc, traversed monotonically. By (c) the function g increases from 0 to $\theta < \pi$ without ever exceeding θ : the curve never reaches the antipode of A , hence it traverses the arc of the great circle that does not contain it, that is the minor arc, and traverses it monotonically. Conversely every monotone parametrization of that arc has length θ (Step 7): the equality case is exactly this.

Step 11 — the antipodal case. If $B = -A$ then $\theta = \pi$ and every great semicircle from A to $-A$ has length π : the minimum exists but is not unique, in agreement with Exercise 7.3.

Step 12 — numerical check. On the unit S^2 , $A = (1, 0, 0)$ and $B = (0, 1, 0)$ give $\langle A, B \rangle = 0$ and $\theta = \arccos 0 = \pi/2 = 1.570796$: the quarter of the equator. A competing path, $A \rightarrow (0, 0, 1) \rightarrow B$ along two quarter meridians, measures $\pi/2 + \pi/2 = \pi = 3.141593$, twice as much. ✓ The chord instead measures $\|A - B\| = \sqrt{2} = 1.414214 < 1.570796$: shorter, but it is not a path on the sphere. ✓

Step 13 — a second route to the proof. Exercise S3 obtains the same inequality in spherical coordinates, writing $\|\gamma'\|^2 = \dot{\vartheta}^2 + \sin^2 \vartheta \dot{\varphi}^2 \geq \dot{\vartheta}^2$: it is quicker, but it requires the curve to stay in the domain of a chart, i.e. to avoid the poles. The proof given above uses no charts and for this reason has no exceptions. □

***Remark 7.5: What is left to Chapter 9.** Theorem 7.7 solves the global minimum problem on the sphere by elementary means, and solves it completely: existence, value and uniqueness. Two different questions remain outside, both treated in Chapter 9: the local characterization of geodesics as solutions of the Euler–Lagrange equation (valid on an arbitrary surface) and the fact that a geodesic longer than half the sphere ceases to be minimizing while remaining a geodesic. Nothing that follows in this chapter depends on those two questions.*

Exercise 7.3. Why is the minimal path not unique for two antipodal points?

Solution. If A and $B = -A$ are antipodal, every plane through O contains both (since O is the midpoint of the segment AB): there exist infinitely many great circles through A, B , all of semi-length πr . The minimum exists but is realized by infinitely many arcs (the meridians

between two poles). In the proof of Theorem 7.7 the point where uniqueness is lost is Step 9: if $B = -A$ the two vectors are dependent, the unit vector n is not defined and the plane of the motion is not determined.

Theorem 7.8: Spherical distance. For $A, B \in S^2(O, r)$ with central angle $\theta = \angle AOB$, the geodesic distance is $d(A, B) = r\theta$, and $\theta = \arccos(\langle A, B \rangle / r^2)$. The function d is a distance on $S^2(O, r)$, with $0 \leq d \leq \pi r$.

Proof. Step 1 — the value. By Theorem 7.7 the minimum of the lengths is $r \arccos(\langle A, B \rangle / r^2)$ and is attained by the minor arc of a great circle; the central angle θ between OA and OB satisfies by definition $\cos \theta = \langle A, B \rangle / r^2$, hence $d(A, B) = r\theta$. The value does not depend on the chosen plane because θ is determined by the vectors OA and OB alone.

Step 2 — it is a distance. Symmetry and $d(A, B) = 0 \iff A = B$ are immediate from $\arccos$. For the triangle inequality, let A, B, C be given and let γ be the concatenation of the minor arc from A to C with the one from C to B : it is a piecewise C^1 curve from A to B of length $d(A, C) + d(C, B)$, hence by Theorem 7.7 $d(A, B) \leq d(A, C) + d(C, B)$.

Step 3 — the extremes. $\theta \in [0, \pi]$ because $\arccos$ takes values in $[0, \pi]$; the maximum πr occurs for antipodal points.

Step 4 — numerical check. On the Earth ($r = 6371$ km) pole and equator have $\theta = \pi/2$ and $d = 1.570796 \times 6371 = 10\,007.5$ km, which is precisely the quarter meridian used in the original definition of the metre. $\checkmark$ $\square$

Proposition 7.2: Spherical law of cosines. Let ABC be a non-degenerate spherical triangle on the unit sphere, with (angular) sides $a = \angle BOC$, $b = \angle COA$, $c = \angle AOB$ in $(0, \pi)$ and interior angles A, B, C . Then

$$\cos c = \cos a \cos b + \sin a \sin b \cos C.$$

Proof. Step 1 — the angle at C as an angle between tangents. Denote by $\mathbf{A}, \mathbf{B}, \mathbf{C}$ the three vertices as unit vectors of $\mathbb{R}^3$, so that $\cos a = \langle \mathbf{B}, \mathbf{C} \rangle$, $\cos b = \langle \mathbf{C}, \mathbf{A} \rangle$, $\cos c = \langle \mathbf{A}, \mathbf{B} \rangle$. By Theorem 7.7 the side CA is the arc of the great circle through $\mathbf{C}$ and $\mathbf{A}$; its tangent vector at $\mathbf{C}$, normalized, is

$$\mathbf{t}_A = \frac{\mathbf{A} - \langle \mathbf{A}, \mathbf{C} \rangle \mathbf{C}}{\|\mathbf{A} - \langle \mathbf{A}, \mathbf{C} \rangle \mathbf{C}\|} = \frac{\mathbf{A} - \cos b \mathbf{C}}{\sin b},$$

because $\|\mathbf{A} - \cos b \mathbf{C}\|^2 = 1 - \cos^2 b = \sin^2 b$ and $\sin b > 0$. Similarly $\mathbf{t}_B = (\mathbf{B} - \cos a \mathbf{C}) / \sin a$. The angle C of the triangle is by definition the angle between $\mathbf{t}_A$ and $\mathbf{t}_B$.

Step 2 — the scalar product.

$$\cos C = \langle \mathbf{t}_A, \mathbf{t}_B \rangle = \frac{\langle \mathbf{A}, \mathbf{B} \rangle - \cos a \langle \mathbf{A}, \mathbf{C} \rangle - \cos b \langle \mathbf{C}, \mathbf{B} \rangle + \cos a \cos b}{\sin a \sin b} = \frac{\cos c - \cos a \cos b}{\sin a \sin b},$$

having used $\langle \mathbf{A}, \mathbf{C} \rangle = \cos b$, $\langle \mathbf{C}, \mathbf{B} \rangle = \cos a$ and simplifying $-\cos a \cos b - \cos b \cos a + \cos a \cos b = -\cos a \cos b$.

Step 3 — conclusion. Multiplying by $\sin a \sin b \neq 0$ (guaranteed by $a, b \in (0, \pi)$) and rearranging gives the claim.

Step 4 — degenerate cases. If $a = 0$ or $b = 0$ two vertices coincide and the angle C is not defined; if $a = \pi$ or $b = \pi$ they are antipodal and the side is not unique. These are exactly the cases excluded by the non-degeneracy hypothesis.

Step 5 — check. With $a = b = c = \pi/2$ (trirectangular triangle) the formula gives $0 = 0 + 1 \cdot 1 \cdot \cos C$, i.e. $C = \pi/2$: the edges of an octant. $\checkmark$ With $a, b, c \rightarrow 0$, expanding to second

order $1 - \frac{c^2}{2} \simeq (1 - \frac{a^2}{2})(1 - \frac{b^2}{2}) + ab \cos C$ one recovers $c^2 \simeq a^2 + b^2 - 2ab \cos C$: the planar law of cosines. ✓

Step 6 — where the rest of the theory lies. Chapter 8 proves this formula systematically together with its companions (law of sines, dual formula, spherical Pythagoras, Napier's rules, L'Huilier) and applies them to navigation: here the law of cosines serves only as a tool for computing distances. □

Exercise 7.4. Two cities are at latitudes ϕ_1, ϕ_2 and longitude difference $\Delta\lambda$. Write the central angle θ and the distance on Earth ($R \approx 6371$ km).

Solution. Applying Proposition 7.2 to the triangle pole–city–city (the sides from the pole are the colatitudes $\frac{\pi}{2} - \phi_i$, the angle at the pole is $\Delta\lambda$):

$$\cos \theta = \sin \phi_1 \sin \phi_2 + \cos \phi_1 \cos \phi_2 \cos \Delta\lambda, \quad d = R\theta.$$

Numerically one often uses the *haversine* formula $\text{hav} \theta = \text{hav}(\phi_2 - \phi_1) + \cos \phi_1 \cos \phi_2 \text{hav}(\Delta\lambda)$, with $\text{hav}(x) = \sin^2(x/2)$, numerically more stable for small distances because it avoids the loss of significant digits of arccos near 1.

Remark 7.6: Orthodromic navigation. The shortest route between two points of the Earth is the great circle arc (orthodromy): it is the content of Theorem 7.7 applied to the spherical model. A guidance system computes the distance with $d = R\theta$ and θ from the haversine formula; for long routes (aeronautical, maritime) the error with respect to the ellipsoidal model is of the order of 0.3%, correctable with Vincenty's formulas. The spherical triangle pole–departure–arrival and the law of cosines also give the initial bearing to follow, which along an orthodromy varies continuously — hence the need for periodic recalculation on board. The complete computation, with the quadrant check, is in Chapter 8.

7.8. Area of the sphere and volume of the ball

Theorem 7.9: Area of the sphere (Archimedes). $\text{Area}(S^2(O, r)) = 4\pi r^2$; more precisely the cap of angular semi-aperture ϑ_0 has area $2\pi r^2(1 - \cos \vartheta_0) = 2\pi rh$, where $h = r(1 - \cos \vartheta_0)$ is its height.

Proof. **Step 1 — the area element.** By Lemma 7.1, $dA = r^2 \sin \vartheta \, d\vartheta \, d\varphi$.

Step 2 — the cap.

$$\text{Area} = \int_0^{2\pi} \int_0^{\vartheta_0} r^2 \sin \vartheta \, d\vartheta \, d\varphi = 2\pi r^2 [-\cos \vartheta]_0^{\vartheta_0} = 2\pi r^2 (1 - \cos \vartheta_0).$$

Step 3 — the whole sphere. For $\vartheta_0 = \pi$ one gets $2\pi r^2(1 + 1) = 4\pi r^2$.

Step 4 — Archimedes' theorem. Setting $h = r(1 - \cos \vartheta_0)$ one has $\text{Area} = 2\pi rh$: the area of the cap depends *linearly* on the height, that is, the radial projection of the sphere onto the circumscribed cylinder preserves areas. It is the result Archimedes wanted engraved on his tomb, together with the ratio 2/3 between sphere and cylinder.

Step 5 — numerical check. For $r = 10$ and $\vartheta_0 = \pi/2$ (hemisphere): $2\pi \times 100 \times (1 - 0) = 628.319$, i.e. half of $4\pi \times 100 = 1256.637$. ✓ With $h = r = 10$: $2\pi \times 10 \times 10 = 628.319$, the same. ✓ □

Theorem 7.10: Volume of the ball (spherical shells). $\text{Vol}(B^3(O, r)) = \frac{4}{3}\pi r^3$, and $\frac{d}{dr} \text{Vol} = \text{Area}$.

Proof. Step 1 — decomposition into shells. The ball is the disjoint union of the concentric spheres of radius $\rho \in [0, r]$; by Theorem 7.9 the sphere of radius ρ has area $4\pi\rho^2$, and integration in spherical coordinates ($dV = \rho^2 \sin \vartheta d\rho d\vartheta d\varphi$, i.e. $dV = dA d\rho$) gives

$$\text{Vol} = \int_0^r 4\pi\rho^2 d\rho = \frac{4}{3}\pi r^3.$$

Step 2 — the differential relation. $\frac{d}{dr}(\frac{4}{3}\pi r^3) = 4\pi r^2 = \text{Area}$, exactly as in the plane $\frac{d}{dr}\pi r^2 = 2\pi r$. The reason is that the increment of volume between the radii r and $r + dr$ is a shell of area $4\pi r^2$ and thickness dr ; the same relation, in dimension n , is the content of Exercise S1 of Chapter 11.

Step 3 — numerical check and comparison with Archimedes. For $r = 1$: $\frac{4}{3}\pi = 4.188790$. The circumscribed cylinder has volume $\pi r^2 \cdot 2r = 2\pi = 6.283185$, and the ratio is $4.188790/6.283185 = 0.666667 = 2/3$. ✓ □

Exercise 7.5. Calculate the area of a spherical cap of angular semi-aperture ϑ_0 and the volume of the spherical segment it bounds.

Solution. By Theorem 7.9, $\text{Area} = 2\pi r^2(1 - \cos \vartheta_0) = 2\pi r h$ with $h = r(1 - \cos \vartheta_0)$. For the volume one integrates the area of the horizontal disks: at height $z \in [r - h, r]$ the disk has radius $\sqrt{r^2 - z^2}$, hence

$$V = \int_{r-h}^r \pi(r^2 - z^2) dz = \pi \left[r^2 z - \frac{z^3}{3} \right]_{r-h}^r = \frac{\pi h^2}{3}(3r - h).$$

Check for $h = r$ (hemisphere): $V = \frac{\pi r^2}{3} \cdot 2r = \frac{2}{3}\pi r^3$, half of $\frac{4}{3}\pi r^3$. ✓ Check for $h = 2r$ (whole ball): $V = \frac{4\pi r^2}{3} \cdot r = \frac{4}{3}\pi r^3$. ✓

7.9. Gauss–Bonnet on the geodesic triangle

Theorem 7.4 has already established that the area of a spherical triangle is r^2 times its angular excess. Here we isolate the ingredient that makes it a theorem of *curvature* — the lune lemma — and recognize in the factor $1/r^2$ the Gaussian curvature of the sphere: it is the first, and simplest, case of the Gauss–Bonnet theorem.

Lemma 7.2: Area of a lune. A spherical **lune** — the region of $S^2(O, r)$ between two half-planes through the same line through O , of dihedral angle $\alpha \in [0, 2\pi]$ — has area $2\alpha r^2$.

Proof. Step 1 — choice of coordinates. Up to a rotation (which preserves areas, being an isometry of $\mathbb{R}^3$) the line common to the two half-planes is the z axis, and the lune is the image, in the parametrization of Definition 7.7, of the rectangle $\{(\varphi, \vartheta) : 0 \leq \varphi \leq \alpha, 0 \leq \vartheta \leq \pi\}$.

Step 2 — integration. By Lemma 7.1,

$$\text{Area} = \int_0^\alpha \int_0^\pi r^2 \sin \vartheta d\vartheta d\varphi = \alpha r^2 [-\cos \vartheta]_0^\pi = 2\alpha r^2.$$

Step 3 — checks. For $\alpha = 2\pi$ one obtains $4\pi r^2$, the whole sphere (Theorem 7.9) ✓; for $\alpha = \pi$ one obtains $2\pi r^2$, the hemisphere ✓; for $\alpha = \pi/2$ a quarter of the sphere, πr^2 ✓. The area is proportional to α , as intuition suggests — but here proportionality is *proved*, not postulated: it follows from the fact that the area element does not depend on φ . □

Theorem 7.11: Gauss–Bonnet for a geodesic triangle. Let T be a geodesic triangle on $S^2(O, r)$, i.e. a region bounded by three arcs of great circles, with interior angles α, β, γ . Then

$$\alpha + \beta + \gamma - \pi = \frac{\text{Area}(T)}{r^2} = K \cdot \text{Area}(T),$$

where $K = 1/r^2$ is the Gaussian curvature of the sphere of radius r .

Proof. Step 1 — the area by the method of lunes. The three great circles extending the sides of T meet pairwise in pairs of antipodal points, and determine at each vertex two opposite lunes (Lemma 7.2) of width equal to the interior angle; the antipodal triangle $T' = -T$ is congruent to T and has the same area. The count with multiplicity of the six lunes — carried out in full in the proof of Theorem 7.4, Steps 1–4 — gives

$$2(2\alpha r^2 + 2\beta r^2 + 2\gamma r^2) = 4\pi r^2 + 4 \text{Area}(T), \quad \text{that is} \quad \text{Area}(T) = r^2(\alpha + \beta + \gamma - \pi).$$

Dividing by r^2 gives the first equality of the statement.

Step 2 — the Gaussian curvature of the sphere is $1/r^2$. Take as Gauss map the inward unit normal $N(P) = (O - P)/r$. Then N is linear in P and

$$dN_P(w) = -\frac{1}{r} w \quad \text{for every } w \in T_P S^2,$$

so the shape operator $-dN_P$ is $\frac{1}{r}$ id: both principal curvatures equal $k_1 = k_2 = 1/r$ and the Gaussian curvature, their product, equals

$$K = k_1 k_2 = \frac{1}{r^2}.$$

(The general definition of K as the determinant of the shape operator, and its invariance under isometries, are in Chapter 10; here only the computation for the sphere is needed, and it is immediate.)

Step 3 — conclusion. Substituting $1/r^2 = K$ into the first equality gives $\alpha + \beta + \gamma - \pi = K \text{Area}(T)$.

Step 4 — numerical check. The trirectangular triangle has $\alpha = \beta = \gamma = \pi/2$, hence excess $\frac{3\pi}{2} - \pi = \frac{\pi}{2} = 1.570796$ and area $\frac{\pi}{2}r^2$: on $r = 1$ it equals 1.570796, i.e. $\frac{1}{8}$ of $4\pi = 12.566371$ ✓ — and indeed the three coordinate planes divide the sphere into eight equal triangles. On a sphere of radius 2 the area becomes $2\pi = 6.283185$, while the excess stays $\pi/2$: consistently, $K = 1/4$ and $K \cdot 2\pi = \pi/2$. ✓

Step 5 — the general case. The Gauss–Bonnet theorem in general form states that for a region R with piecewise regular boundary on an arbitrary surface $\int_R K dA + \int_{\partial R} \kappa_g ds + \sum_i \varepsilon_i = 2\pi$, with κ_g the geodesic curvature and ε_i the exterior angles. For a geodesic triangle on S^2 : $\kappa_g \equiv 0$ on the sides (they are geodesics), K is constant $= 1/r^2$ and $\sum \varepsilon_i = 3\pi - (\alpha + \beta + \gamma)$, and one recovers the formula proved above. The general version, which requires the notion of geodesic curvature, is outside this chapter. □

Corollary 7.2: Spherical excess. For every non-degenerate geodesic triangle of $S^2(O, r)$ the **spherical excess** $E = \alpha + \beta + \gamma - \pi$ satisfies

$$0 < E < 2\pi, \quad E = \frac{\text{Area}(T)}{r^2}.$$

In particular on the sphere there are no triangles with angle sum equal to π , and two spherical triangles with the same angles have the same area.

Proof. **Step 1 — the equality.** It is Theorem 7.11.

Step 2 — $E > 0$. A non-degenerate triangle has as vertices three linearly independent unit vectors, hence contains a non-empty open subset of the sphere and has strictly positive area; by Step 1, $E = \text{Area}(T)/r^2 > 0$.

Step 3 — $E < 2\pi$. Every interior angle satisfies $0 < \alpha, \beta, \gamma < \pi$, hence $\alpha + \beta + \gamma < 3\pi$ and $E < 2\pi$. Equivalently $\text{Area}(T) < 2\pi r^2$: a geodesic triangle cannot occupy more than a hemisphere.

Step 4 — no Euclidean triangles. If $E = 0$ the area would be zero and the three vertices would lie on the same great circle: the triangle would be degenerate.

Step 5 — no similarity on the sphere. Since the area is determined by the angles, two spherical triangles with the same angles cannot have different areas: on the sphere similar triangles are congruent. It is the corollary proved in detail in Chapter 8, and the most conspicuous difference from the geometry of the plane.

Step 6 — numerical check. The triangle with one vertex at the North Pole and two on the equator separated by 120° has angles $2\pi/3, \pi/2, \pi/2$, hence $E = 2.094395 + 1.570796 + 1.570796 - 3.141593 = 2.094395$ and area $2.094395 r^2$, i.e. $\frac{1}{6}$ of $4\pi r^2 = 12.566371 r^2$. ✓ And it is right: three meridians at 120° cut the northern hemisphere into three equal parts. □

Remark 7.7: Planar limit case. For $r \rightarrow \infty$ ($K \rightarrow 0$) a triangle of finite area has $E = \text{Area}/r^2 \rightarrow 0$: one recovers $\alpha + \beta + \gamma = \pi$, the Euclidean theorem. Gauss–Bonnet thus generalizes planar geometry, of which Volume I is the case $K = 0$. The same computation measures the error made in treating a terrestrial region as flat: a triangle of 100×100 km on the Earth has area $\simeq 5 \cdot 10^9$ m² and $E \simeq 5 \cdot 10^9 / (6.371 \cdot 10^6)^2 = 1.23 \cdot 10^{-4}$ rad, that is about 25 seconds of arc: small, but perfectly measurable, and indeed geodesy has been measuring it for two centuries.

Figure 7.5: A geodesic triangle on the sphere: the sides are arcs of great circles (the geodesics, Theorem 7.7). Unlike the plane, the sum of the angles exceeds π by an amount proportional to the area (Theorem 7.11). It is the signature of the positive curvature of the sphere, absent in the plane circle ($K = 0$).

Exercise 7.6. Calculate the area of the spherical triangle with three right angles on a sphere of radius $r = 1$.

Solution. With $\alpha = \beta = \gamma = \pi/2$: $E = \frac{3\pi}{2} - \pi = \frac{\pi}{2}$, therefore by Theorem 7.11 $\text{Area}(T) = Er^2 = \pi/2 = 1.570796$. It is exactly $1/8$ of the total area $4\pi = 12.566371$ of the sphere: the octant enclosed by three meridians at 90° and the equator, as verified geometrically. ✓

7.10. Industrial applications

Spherical wrist and orientation. The *spherical wrist* of six-axis robots (the axes J4, J5, J6 meet at a point) makes the orientation of the tool describable by rotations about a fixed centre: the geometry is that of the sphere S^2 and of the group $SO(3)$ (Chapters 11 and 28). The non-commutativity of $SO(3)$, announced in the table of section 7.1, is the reason why the order of rotations matters and why gimbal lock configurations exist.

Orthodromic navigation. The geodesic distance $d = r\theta$ (Theorem 7.8) and the spherical law of cosines (Proposition 7.2) are the basis of orthodromic route computation in guidance systems (AGV, drones, marine vehicles): the shortest path is the great circle arc, and the haversine formula gives its length in a numerically stable way.

Cartography and mapping. The conformality of stereographic projection (Theorem 7.6) is why it is the standard projection of polar aeronautical charts and of pole figures in crystallography: the angles read on the chart are the true ones. Gauss–Bonnet, with the angular excess proportional to the area (Theorem 7.11), quantifies instead the error made by approximating a curved region with a plane polygon — the computation of Remark 7.7 gives the order of magnitude to be compared with the tolerance of the survey.

Surface machining. Corollary 7.1 (every circle of radius $\rho \leq r$ is a section of a sphere of radius r) and Remark 7.3 (the ellipsoid contains two families of circles) are the two facts underlying the machining of caps and of ellipsoidal surfaces with rotating tools: in both cases the workpiece is generated by moving a circle.

7.11. Assigned exercises

Exercise 7.7. Objective: apply Corollary 7.1 and recognize its limiting case. **Estimated time:** 15 minutes.

A circle of radius $\rho = 12$ cm lies in a plane π . (i) Determine all the spheres of radius $r = 13$ cm containing it and the distance of their centres from π . (ii) For which radius r does the circle become a great circle, and how many spheres of that radius contain it? (iii) Is there a sphere of radius 10 cm containing it? Justify.

Exercise 7.8. Objective: use the formulas of Proposition 7.1 and verify conformality on an explicit family. **Estimated time:** 25 minutes.

On the unit sphere ($r = 1$): (i) determine the stereographic image of the parallel $z = z_0$ with $z_0 \in (-1, 1)$ and show that it is the circle of centre the origin and radius $\sqrt{(1+z_0)/(1-z_0)}$, both by Theorem 7.6(ii) and by direct computation; (ii) compute that radius for $z_0 = -\frac{1}{2}, 0, \frac{1}{2}, 0.9$; (iii) determine the image of the meridian of longitude φ_0 and check that the two families of images meet at right angles, as conformality requires.

Exercise 7.9. Objective: use Gauss–Bonnet on a terrestrial triangle and measure the deviation from the plane model. **Estimated time:** 30 minutes.

On the spherical Earth of radius $R = 6371$ km consider the geodesic triangle with vertices the North Pole, the point $(0^\circ\text{N}, 0^\circ\text{E})$ and the point $(0^\circ\text{N}, 40^\circ\text{E})$. (i) Compute its three interior angles, the spherical excess and the area, and check that the area is a simple fraction of the Earth’s surface. (ii) Compute the lengths of the three sides in kilometres. (iii) Compute the area of the *plane* Euclidean triangle with those three sides and compare it with the spherical area; comment on the sign and order of magnitude of the deviation.

7.12. Worked exercises

Exercise 7.10. On the unit sphere consider the circle $\Gamma = S^2 \cap \{x + 2y + 2z = 1\}$. Determine centre and radius of its stereographic image, and check them with three explicit points of Γ .

Solution. Strategy. Bring the plane into normalized form, apply the formulas of Theorem 7.6(ii), then check on points chosen so as to cover the three cases $z < 0$, $z = 0$, $z > 0$.

Step 1 — normalization. The vector $(1, 2, 2)$ has norm 3, so the plane is written $ax + by + cz = k$ with

$$a = \frac{1}{3}, \quad b = \frac{2}{3}, \quad c = \frac{2}{3}, \quad k = \frac{1}{3}, \quad a^2 + b^2 + c^2 = \frac{1+4+4}{9} = 1.$$

Since $|k| = 0.333333 < 1 = r$, the intersection really is a circle, of radius $\rho = \sqrt{1 - 1/9} = \sqrt{8}/3 = 0.942809$ on the sphere.

Step 2 — line or circle? $cr - k = \frac{2}{3} - \frac{1}{3} = \frac{1}{3} \neq 0$: the pole N does *not* lie on Γ (indeed $0 + 0 + \frac{2}{3} \cdot 1 = 0.666667 \neq 0.333333$), so the image is a circle.

Step 3 — centre. $(u_0, v_0) = -\frac{r^2}{cr - k}(a, b) = -3 \cdot (\frac{1}{3}, \frac{2}{3}) = (-1, -2)$.

Step 4 — radius. $R_\Gamma = \frac{r\sqrt{r^2 - k^2}}{|cr - k|} = \frac{\sqrt{1 - 1/9}}{1/3} = 3 \times 0.942809 = 2.828427 = 2\sqrt{2}$.

Step 5 — independent check on three points.

- $P_1 = (1, 0, 0)$: it lies on Γ ($1 + 0 + 0 = 1$ ✓, $\|P_1\| = 1$ ✓) and $\sigma(P_1) = \frac{1}{1-0}(1, 0) = (1, 0)$. Distance from the centre: $\sqrt{(1+1)^2 + (0+2)^2} = \sqrt{8} = 2.828427$. ✓
- $P_2 = (-\frac{3}{5}, \frac{4}{5}, 0)$: indeed $-0.6 + 1.6 + 0 = 1$ ✓ and $0.36 + 0.64 = 1$ ✓; $\sigma(P_2) = (-0.6, 0.8)$ and the distance from the centre is $\sqrt{0.16 + 7.84} = \sqrt{8} = 2.828427$. ✓
- $P_3 = (0, \frac{1+\sqrt{7}}{4}, \frac{1-\sqrt{7}}{4}) = (0, 0.911438, -0.411438)$: from $x = 0$ it follows that $y + z = \frac{1}{2}$ and $y^2 + z^2 = 1$, whence $yz = -\frac{3}{8}$ and $y, z = \frac{1 \pm \sqrt{7}}{4}$; $\sigma(P_3) = \frac{1}{1.411438}(0, 0.911438) = (0, 0.645751)$, and since $0.645751 = \sqrt{7} - 2$ the distance from the centre is $\sqrt{1 + (\sqrt{7})^2} = \sqrt{8} = 2.828427$ *exactly*. ✓

Interpretation. The circle Γ has radius 0.942809 on the sphere and its image has 2.828427: stereographic projection has dilated it by a factor 3, which is λ evaluated where the circle lies. The closer Γ gets to the pole (i.e. the closer $cr - k$ gets to zero) the larger the image, until it becomes a line when $cr = k$.

Typical mistakes. (a) Forgetting to normalize (a, b, c) : without $a^2 + b^2 + c^2 = 1$ the formulas for centre and radius do not hold. (b) Confusing $|k|$ with the distance of the plane from the centre when the vector is not a unit vector. (c) Concluding “line” because the plane does not pass through the origin: the right condition is $N \in \pi$, i.e. $cr = k$, not $k = 0$.

Extension. Redo the computation for the plane $2x + y + 2z = 2$ ($a = \frac{2}{3}$, $b = \frac{1}{3}$, $c = \frac{2}{3}$, $k = \frac{2}{3} = cr$): one finds a line, and rightly so, because $N = (0, 0, 1)$ satisfies $2 \cdot 0 + 0 + 2 \cdot 1 = 2$.

Exercise 7.11. Two points both lie at latitude 40° N, with longitude difference $\Delta\lambda = 60^\circ$. Compute the geodesic distance and compare it with the path along the parallel, on the unit sphere and on the Earth ($R = 6371$ km).

Solution. Strategy. The path along the parallel is an admissible but non-geodesic curve: by Theorem 7.7 it must be longer than the great circle arc. The central angle is computed in two independent ways (scalar product and spherical law of cosines) and the two lengths are compared.

Step 1 — the two points. With $\phi = 40^\circ$ and $\Delta\lambda = 60^\circ$,

$$A = (\cos \phi, 0, \sin \phi), \quad B = (\cos \phi \cos \Delta\lambda, \cos \phi \sin \Delta\lambda, \sin \phi),$$

with $\cos 40^\circ = 0.766044$ and $\sin 40^\circ = 0.642788$.

Step 2 — the central angle from the scalar product.

$$\langle A, B \rangle = \cos^2 \phi \cos \Delta\lambda + \sin^2 \phi = 0.586824 \times 0.5 + 0.413176 = 0.293412 + 0.413176 = 0.706588,$$

hence $\theta = \arccos(0.706588) = 0.786132$ rad $= 45.042024^\circ$.

Step 3 — independent check with the spherical law of cosines. In the triangle pole– A – B the sides from the pole are the colatitudes $c_1 = c_2 = 90^\circ - 40^\circ = 50^\circ$ and the angle at the pole is $\Delta\lambda = 60^\circ$. By Proposition 7.2,

$$\cos \theta = \cos^2 50^\circ + \sin^2 50^\circ \cos 60^\circ = 0.413176 + 0.586824 \times 0.5 = 0.706588. \checkmark$$

The two computations agree to six digits.

Step 4 — the path along the parallel. The parallel at latitude ϕ is a circle of radius $\cos \phi$ (Example 7.1), so the arc of amplitude $\Delta\lambda$ measures

$$L_{\parallel} = \cos \phi \cdot \Delta\lambda = 0.766044 \times 1.047198 = 0.802200.$$

Step 5 — the comparison. $\theta = 0.786132 < 0.802200 = L_{\parallel} \checkmark$, with a relative saving of $1 - 0.786132/0.802200 = 0.020030$, i.e. 2.00%. On the Earth:

$$d = 6371 \times 0.786132 = 5008.4 \text{ km}, \quad L_{\parallel} = 6371 \times 0.802200 = 5110.8 \text{ km},$$

with a difference of 102.4 km.

Interpretation. Flying “straight east” along the parallel costs about a hundred extra kilometres: the orthodromy passes *north* of the parallel, and its maximum latitude (the *vertex* of the route) exceeds 40° . It is exactly why transatlantic routes look curved on Mercator charts (Example 7.1).

Typical mistakes. (a) Using the latitude instead of the colatitude in the law of cosines. (b) Multiplying by R an angle expressed in degrees instead of radians. (c) Confusing orthodromy and loxodromy: the latter cuts the meridians at a constant angle and is convenient to follow, but is not the shortest.

Extension. Repeat with $\Delta\lambda = 180^\circ$: then $\cos \theta = \cos^2 \phi \cdot (-1) + \sin^2 \phi = 1 - 2\cos^2 \phi = -0.173648$, $\theta = 1.745329$ rad $= 100^\circ$, whereas the parallel measures $0.766044 \times \pi = 2.406607$: the orthodromy passes over the North Pole and saves 27%.

Exercise 7.12. On the unit sphere consider the equilateral geodesic triangle of side a . Express its angle A and its excess as functions of a , compute them for $a = \pi/2$, 0.1, 0.01 and compare the area with that of the plane equilateral triangle of side a .

Solution. Strategy. Derive $\cos A$ from the spherical law of cosines specialized to the case $a = b = c$, then use Gauss–Bonnet for the area and compare with the plane formula $\sqrt{3}a^2/4$.
Step 1 — the angle. With $a = b = c$, Proposition 7.2 gives $\cos a = \cos^2 a + \sin^2 a \cos A$, that is

$$\cos A = \frac{\cos a - \cos^2 a}{\sin^2 a} = \frac{\cos a (1 - \cos a)}{(1 - \cos a)(1 + \cos a)} = \frac{\cos a}{1 + \cos a},$$

having cancelled $1 - \cos a \neq 0$ (i.e. $a \neq 0$).

Step 2 — the excess and the area. By Theorem 7.11, Area = $E = 3A - \pi$ on the unit sphere.

Step 3 — the three cases.

a	$\cos A$	A (rad)	$E = \text{spherical area}$	$\sqrt{3}a^2/4$ (plane area)
$\pi/2$	0	1.570796	1.570796	1.068416
0.1	0.498748	1.048643	0.004335547	0.004330127
0.01	0.499988	1.047212	0.00004330181	0.00004330127

Step 4 — independent check of the first case. For $a = \pi/2$ one has $\cos A = 0$, hence $A = \pi/2$: it is the trirectangular triangle, and the area $\pi/2 = 1.570796$ coincides with $\frac{1}{8}$ of 4π , computed geometrically in Exercise 7.6. ✓

Step 5 — the plane limit. The ratio between spherical and plane area equals 1.0012517 for $a = 0.1$ and 1.0000125 for $a = 0.01$: it tends to 1 like a^2 , i.e. the relative deviation is divided by 100 when the side is divided by 10. ✓ It is the quantitative manifestation of Remark 7.7: the sphere is locally flat, and the error is of second order in the diameter.

Interpretation. For $a = \pi/2$ the spherical area exceeds the plane one by 47%: in the large, curvature is plainly visible. For $a = 0.01$ (on an Earth of radius 6371 km, i.e. sides of 64 km) the deviation is one part in eighty thousand: below the tolerance of almost any survey, but not of a geodetic one.

Typical mistakes. (a) Cancelling $1 - \cos a$ without excluding $a = 0$. (b) Applying $E = 3A - \pi$ with A in degrees. (c) Forgetting that on the sphere the angle of an equilateral triangle is not $\pi/3$: that value would give $E = 0$, impossible by Corollary 7.2.

Extension. For which a does the excess equal π (i.e. the triangle occupies a quarter of the sphere)? From $3A - \pi = \pi$ it follows that $A = 2\pi/3$, $\cos A = -\frac{1}{2}$ and $\cos a/(1 + \cos a) = -\frac{1}{2}$, i.e. $\cos a = -\frac{1}{3}$ and $a = 1.910633$ rad = 109.471° , the tetrahedral angle.

7.13. Numerical and symbolic exercises with solutions

The exercises that follow come from the treatment of the circle in higher dimension of Volume II and are reproduced in full, with their solutions; those on hyperspheres and rotations are in Chapter 11.

7.13.1 Numerical exercises

Exercise 7.13: N1 — Sections of a cone. A cone has half-angle $\alpha = 30^\circ$. Compute the radius of the section orthogonal to the axis at distance 5 from the vertex; then classify the sections obtained with planes inclined at 60° , 30° and 20° to the axis, computing the eccentricity in the first case from $e = \cos \beta / \cos \alpha$.

Exercise 7.14: N2 — Spherical cap. A sphere has radius $R = 10$ cm. A plane is at distance $d = 6$ cm from the centre. Compute the radius of the section, the area of the smaller cap and the volume of the corresponding spherical segment.

Exercise 7.15: N3 — A terrestrial spherical triangle. On the Earth ($R = 6371$ km) consider the triangle with vertices at the North Pole and at two points of the equator separated by 120° of longitude. Compute its angles and area, and check the result by a symmetry argument.

Exercise 7.16: N4 — Circular sections of an ellipsoid. For the ellipsoid with semi-axes $a = 6$, $b = 4$, $c = 3$ determine the planes of the maximal circular sections, the radius of those circles, and verify with an explicit point.

7.13.2 Symbolic exercises

Exercise 7.17: S1 — Dandelin for the parabola. Prove that if the cutting plane is parallel to exactly one generator, the section is a parabola: there is a single Dandelin sphere, its point of tangency is the focus and the directrix is the intersection of the cutting plane with the plane of the circle of tangency.

Exercise 7.18: S2 — Who has all sections circular. Prove that a closed bounded surface of $\mathbb{R}^3$, all of whose non-empty plane sections not reduced to a point are circles, is a sphere.

Exercise 7.19: S3 — The shortest path on the sphere. Prove that among all regular curves on the unit sphere joining two points A and B , the minor arc of great circle has least length, and that this length equals $\arccos\langle A, B \rangle$.

Exercise 7.20: S4 — The circular defect on the sphere. Prove that on the sphere of radius R the circumference of the geodesic circle of radius ρ is $C(\rho) = 2\pi R \sin(\rho/R)$, and that

$$2\pi\rho - C(\rho) = \frac{\pi\rho^3}{3R^2} + O(\rho^5).$$

Interpret the coefficient.

Exercise 7.21: S5 — Intersection of two spheres. Prove that the non-empty intersection, not reduced to a point, of two distinct spheres of $\mathbb{R}^n$ is a sphere S^{n-2} contained in a hyperplane (the *radical plane*), and compute its radius and position in terms of the data.

7.13.3 Solutions to the numerical exercises

Solution. N1. *Step 1 — orthogonal section.* By Theorem 7.1 the radius is

$$r = h \tan \alpha = 5 \tan 30^\circ = 5 \times 0.577350 = 2.886751.$$

Step 2 — classification criterion. Writing β for the angle between the cutting plane and the axis, the section is an ellipse if $\beta > \alpha$, a parabola if $\beta = \alpha$, a hyperbola if $\beta < \alpha$. The limiting case $\beta = 90^\circ$ gives the circle.

Step 3 — the three cases.

β	comparison with $\alpha = 30^\circ$	section
60°	$\beta > \alpha$	ellipse
30°	$\beta = \alpha$	parabola
20°	$\beta < \alpha$	hyperbola

Step 4 — eccentricity of the first case.

$$e = \frac{\cos \beta}{\cos \alpha} = \frac{\cos 60^\circ}{\cos 30^\circ} = \frac{0.500000}{0.866025} = 0.577350.$$

Since $0 < e < 1$, the ellipse is confirmed. ✓

Step 5 — checks at the extremes. For $\beta = 90^\circ$ the formula gives $e = 0$: the circle, in agreement with Step 7 of the proof of Theorem 7.2. For $\beta = \alpha$ it gives $e = 1$: the parabola. For $\beta = 20^\circ$: $e = \cos 20^\circ / \cos 30^\circ = 0.939693 / 0.866025 = 1.085$, greater than 1: hyperbola. ✓

Step 6 — remark. The value $e = 0.5774 = 1/\sqrt{3}$ is no accident: with $\alpha = 30^\circ$ and $\beta = 60^\circ$ the two angles are complementary, and $e = \cos \beta / \cos \alpha = \sin \alpha / \cos \alpha = \tan \alpha = \tan 30^\circ$.

Solution. N2. *Step 1 — radius of the section.* By Theorem 7.3,

$$r = \sqrt{R^2 - d^2} = \sqrt{100 - 36} = \sqrt{64} = 8.00 \text{ cm.}$$

Step 2 — height of the cap. $h = R - d = 10 - 6 = 4 \text{ cm.}$

Step 3 — area of the cap. By Archimedes' theorem (the area of a spherical zone equals that of the corresponding zone of the circumscribed cylinder),

$$A = 2\pi Rh = 2\pi \times 10 \times 4 = 80\pi = 251.327 \text{ cm}^2.$$

Step 4 — volume of the segment.

$$V = \frac{\pi h^2}{3}(3R - h) = \frac{\pi \times 16}{3} \times 26 = \frac{416\pi}{3} = 435.634 \text{ cm}^3.$$

Step 5 — plausibility checks. The total area of the sphere is $4\pi R^2 = 1256.64 \text{ cm}^2$: the cap is 20% of it, consistent with $h/2R = 4/20 = 0.20$ — which is precisely the content of Archimedes' theorem: the area of a zone depends only on its height. ✓ The total volume is $\frac{4}{3}\pi R^3 = 4188.79 \text{ cm}^3$: the segment is 10.4% of it, less than the 20% of the area, as it must be for a cap far from the centre. ✓

Solution. N3. *Step 1 — the angles.* The two sides issuing from the North Pole are meridians, which meet the equator at right angles: hence the two base angles are 90° each. The angle at the pole is the difference of longitude, $120^\circ = 2\pi/3$.

Step 2 — spherical excess.

$$A + B + C - \pi = \frac{\pi}{2} + \frac{\pi}{2} + \frac{2\pi}{3} - \pi = \frac{2\pi}{3} = 2.094395.$$

Step 3 — area. By Theorem 7.4,

$$\text{Area} = R^2 \cdot \frac{2\pi}{3} = 40\,589\,641 \times 2.094395 = 8.5011 \times 10^7 \text{ km}^2,$$

using $R^2 = 6371^2 = 40\,589\,641 \text{ km}^2$.

Step 4 — check by symmetry. Three meridians 120° apart divide the northern hemisphere into three equal wedges, and the sphere into six. Hence the area of the triangle is

$$\frac{4\pi R^2}{6} = \frac{2\pi R^2}{3},$$

exactly the result of Step 3. ✓

Step 5 — absolute values. The Earth's surface is $4\pi R^2 = 5.1006 \times 10^8 \text{ km}^2$; the triangle is one sixth of it, $8.5011 \times 10^7 \text{ km}^2$. ✓

Step 6 — reading. A “triangle” with two right angles is impossible in the plane; on the sphere it is perfectly ordinary, and its area measures the excess. Reducing the longitude from 120° to ε , the area would tend to $R^2\varepsilon$, which tends to zero: one recovers the Euclidean degeneration.

Solution. N4. *Step 1 — checking the hypotheses.* $a = 6 > b = 4 > c = 3$: the three semi-axes are distinct, so Theorem 7.5 applies.

Step 2 — the coefficient.

$$k = \frac{c}{a} \sqrt{\frac{a^2 - b^2}{b^2 - c^2}} = \frac{3}{6} \sqrt{\frac{36 - 16}{16 - 9}} = 0.5 \sqrt{\frac{20}{7}} = 0.5 \times 1.690309 = 0.845154.$$

Step 3 — the planes and the circles. The maximal circular sections lie in the planes

$$z = \pm 0.845154x,$$

both containing the y -axis, and are circles of radius $b = 4$.

Step 4 — verification with a point. On the plane $z = kx$ with $y = 0$, the equation of the ellipsoid gives

$$\frac{x^2}{36} + \frac{k^2 x^2}{9} = 1 \implies x^2(0.027778 + 0.079365) = 1 \implies x^2 = 9.3333,$$

since $k^2 = 0.714286$ and $k^2/9 = 0.079365$. Then $x = 3.05505$ and $z = kx = 2.58199$, and the distance from the origin is

$$\sqrt{9.3333 + 6.6667} = \sqrt{16.0000} = 4.0000 = b. \quad \checkmark$$

Step 5 — second check. The point $(0, 4, 0)$ lies on the ellipsoid ($16/16 = 1$), on both planes ($z = 0 = k \cdot 0$) and at distance 4 from the origin. ✓

Step 6 — reading. The two planes make with the xy -plane an angle $\arctan k = \arctan(0.845154) = 40.20^\circ$. Rotating the ellipsoid about the y -axis by this angle makes one of the two circles horizontal: that is the practical way to produce a circular section on a lathe.

7.13.4 Solutions to the symbolic exercises

Solution. S1. *Step 1 — a single sphere.* If the plane π is parallel to a generator g , it does not meet g ; the family of inscribed spheres, which in Theorem 7.2 provided two tangent ones, now provides only one, because on the side of g the spheres “slide away” to infinity without ever touching π . Let $\mathcal{S}$ be the unique sphere tangent to π , F the point of tangency and c the circle along which $\mathcal{S}$ touches the cone, contained in the plane τ orthogonal to the axis.

Step 2 — the directrix. Let $d = \pi \cap \tau$: it is a line, since the two planes are not parallel (τ is orthogonal to the axis, π is not, being parallel to a generator).

Step 3 — the fundamental relation. Let P be a point of the section and A the intersection of the generator through P with c . By the tangent-segment lemma (Step 3 of the proof of Theorem 7.2),

$$|PF| = |PA|.$$

Step 4 — the two distances from τ . Let α be the half-angle. The generators make with the plane τ the angle $90^\circ - \alpha$, hence the distance from P to τ is

$$\text{dist}(P, \tau) = |PA| \sin(90^\circ - \alpha) = |PA| \cos \alpha.$$

On the other hand, with D the foot of the perpendicular from P to the line d in the plane π , and θ the dihedral angle between π and τ ,

$$\text{dist}(P, \tau) = |PD| \sin \theta.$$

Step 5 — the parallelism hypothesis. The plane π is parallel to a generator, i.e. makes with the axis the same angle α as the generators; since τ is orthogonal to the axis, the dihedral angle between π and τ is $\theta = 90^\circ - \alpha$, hence $\sin \theta = \cos \alpha$.

Step 6 — conclusion. Equating the two expressions for the distance from τ :

$$|PA| \cos \alpha = |PD| \cos \alpha \implies |PA| = |PD| \implies |PF| = |PD|.$$

Every point of the section is therefore equidistant from the point F and the line d : by the focal definition, the section is a *parabola* with focus F and directrix d , of eccentricity 1.

Step 7 — consistency with Exercise N1. The formula $e = \cos \beta / \cos \alpha$ gives $e = 1$ exactly for $\beta = \alpha$, i.e. for the plane parallel to a generator. ✓

Solution. S2. *Step 1 — one section and its axis.* Let Σ be the surface and C_1 one of its circular sections, contained in the plane π_1 , with centre O_1 . Let a be the line through O_1 orthogonal to π_1 (the *axis* of C_1).

Step 2 — the line a meets Σ . Σ is closed and bounded and encloses C_1 ; the “signed distance along a ” function takes both positive and negative values on Σ . Let N and S be two points of $\Sigma \cap a$, and M the midpoint of NS .

Step 3 — every plane through a gives a circle through N and S . Let π be a plane containing a . It cuts Σ in a circle Γ , by hypothesis. Since $N, S \in a \subset \pi$ and $N, S \in \Sigma$, the circle Γ passes through N and S . Moreover π cuts C_1 in two diametrically opposite points A, A' (since π contains the centre O_1), which belong to Γ .

Step 4 — the centre of Γ . Γ contains the chord NS and the chord AA' ; its centre lies on the perpendicular bisector of each. The bisector of NS (in the plane π) is the line through M orthogonal to a ; the bisector of AA' is the line through O_1 orthogonal to AA' , i.e. a itself. Hence the centre of Γ is the intersection of these two lines, that is the point M : the same for every choice of π .

Step 5 — the radius. Since Γ has centre M and passes through N , its radius is $|MN|$, also independent of π .

Step 6 — conclusion. Every point of Σ lies in some plane containing a (the planes through a cover all of space), hence on some Γ , hence at distance $|MN|$ from M . So Σ is contained in the sphere with centre M and radius $|MN|$; and since every plane through a meets Σ in a *whole* circle of that sphere, the inclusion is an equality. Σ is a sphere. ✓

Step 7 — closedness is necessary. A spherical cap has all sections circular (or arcs) but is not a sphere: it is the hypothesis “closed surface” that excludes it.

Solution. S3. *Step 1 — choice of coordinates.* Up to a rotation (an isometry of the sphere, Theorem 11.7 and what follows), we may assume A is the north pole $(0, 0, 1)$. Parametrise the sphere by

$$\gamma(t) = (\sin \phi(t) \cos \theta(t), \sin \phi(t) \sin \theta(t), \cos \phi(t)),$$

with $\phi \in [0, \pi]$ the colatitude and θ the longitude, both C^1 functions of $t \in [0, 1]$, $\gamma(0) = A$, $\gamma(1) = B$.

Step 2 — the speed. Differentiating and using that $\partial_\phi \gamma$ and $\partial_\theta \gamma$ are orthogonal, of norms 1 and $\sin \phi$,

$$\|\gamma'(t)\|^2 = \phi'(t)^2 + \sin^2 \phi(t) \theta'(t)^2.$$

Step 3 — the inequality. Since $\sin^2 \phi \theta'^2 \geq 0$,

$$\|\gamma'(t)\| \geq |\phi'(t)|,$$

hence the length satisfies

$$L(\gamma) = \int_0^1 \|\gamma'\| dt \geq \int_0^1 |\phi'| dt \geq \left| \int_0^1 \phi' dt \right| = |\phi(1) - \phi(0)| = \phi_B,$$

since $\phi(0) = 0$ (the pole) and $\phi(1) = \phi_B$ is the colatitude of B .

Step 4 — the value of ϕ_B . By definition of colatitude, $\cos \phi_B = \langle A, B \rangle$, hence $\phi_B = \arccos \langle A, B \rangle$.

Step 5 — the equality case. Equality in the first inequality requires $\sin \phi \theta' \equiv 0$, i.e. θ constant where $\phi \in (0, \pi)$: the curve is a meridian, an arc of great circle. Equality in the second requires ϕ' not to change sign, i.e. the meridian to be traversed monotonically. So the minimum is attained exactly by the minor arc of great circle.

Step 6 — the arc realises the length. The meridian from A to B has θ constant and ϕ increasing from 0 to ϕ_B : its length is exactly ϕ_B . Hence the minimum is $\arccos \langle A, B \rangle$ and it is attained.

Step 7 — numerical check. For A the North Pole and B on the equator, $\langle A, B \rangle = 0$ and the distance is $\arccos 0 = \pi/2$, a quarter of a circumference. On the Earth: $\frac{\pi}{2} \times 6371 = 10\,007.5$ km, which is indeed the pole-to-equator distance (and the original definition of the metre, one ten-millionth of that quarter meridian). ✓

Step 8 — the antipodal case. If $B = -A$ then $\phi_B = \pi$ and every meridian attains the minimum: the shortest path is not unique. It is the only case of non-uniqueness, and corresponds to the two points lying on infinitely many great circles.

Solution. S4. *Step 1 — the geodesic circle.* The points at geodesic distance ρ from the north pole are, by Exercise S3, those of colatitude $\phi = \rho/R$ (on a sphere of radius R the arc length is $R\phi$). They form the parallel of Euclidean radius

$$r = R \sin \frac{\rho}{R}$$

(Example 7.1).

Step 2 — the circumference. Being a Euclidean circle of radius r ,

$$C(\rho) = 2\pi r = 2\pi R \sin \frac{\rho}{R}.$$

Step 3 — expansion. With $\sin x = x - \frac{x^3}{6} + O(x^5)$ and $x = \rho/R$:

$$C(\rho) = 2\pi R \left(\frac{\rho}{R} - \frac{\rho^3}{6R^3} + O\left(\frac{\rho^5}{R^5}\right) \right) = 2\pi\rho - \frac{\pi\rho^3}{3R^2} + O(\rho^5).$$

Step 4 — the defect. Hence

$$2\pi\rho - C(\rho) = \frac{\pi\rho^3}{3R^2} + O(\rho^5),$$

as claimed.

Step 5 — interpreting the coefficient. Setting $K = 1/R^2$ (the *Gaussian curvature* of the sphere), the formula becomes

$$C(\rho) = 2\pi\rho \left(1 - \frac{K\rho^2}{6} + O(\rho^4) \right),$$

the Bertrand–Puisseux formula, valid on any surface: the defect of the circumference relative to $2\pi\rho$ measures the curvature. On a surface of negative curvature (a saddle) the sign reverses and the circumference *exceeds* $2\pi\rho$.

Step 6 — numerical check. On the Earth, for $\rho = 1000$ km:

$$C = 2\pi \times 6371 \times \sin \frac{1000}{6371} = 40\,030 \times \sin(0.156961) = 40\,030 \times 0.156317 = 6257.4 \text{ km},$$

against $2\pi\rho = 6283.2$ km: a defect of 25.8 km. The approximate formula gives $\pi\rho^3/(3R^2) = \pi \times 10^9/(3 \times 4.059 \times 10^7) = 25.80$ km. ✓

Step 7 — connection. The ratio C/ρ equals 2π only in the plane: it is the theorem of Volume I on the constancy of π , which fails on the sphere. The defect is the circular twin of the angular excess of Theorem 7.4, and the two are linked by the same K .

Solution. S5. *Step 1 — the two equations.* Let the spheres be

$$\|x - c_1\|^2 = R_1^2, \quad \|x - c_2\|^2 = R_2^2.$$

Expanding: $\|x\|^2 - 2\langle x, c_i \rangle + \|c_i\|^2 = R_i^2$.

Step 2 — the radical plane. Subtracting one from the other, the term $\|x\|^2$ cancels:

$$2\langle x, c_2 - c_1 \rangle = \|c_2\|^2 - \|c_1\|^2 - R_2^2 + R_1^2,$$

the equation of a hyperplane Π orthogonal to $c_2 - c_1$, the **radical plane** (Volume I for the case $n = 2$). Every point of the intersection lies on it.

Step 3 — the intersection. Hence $S_1 \cap S_2 = S_1 \cap \Pi$, which by Theorem 7.3 is a sphere S^{n-2} (or a point, or empty).

Step 4 — position and radius. Let $d = \|c_2 - c_1\| > 0$ and let t be the distance from c_1 to the plane Π , measured along $c_2 - c_1$. Projecting the equation of Step 2 onto that direction gives

$$t = \frac{d^2 + R_1^2 - R_2^2}{2d},$$

and the radius of the intersection is, by Theorem 7.3,

$$\rho = \sqrt{R_1^2 - t^2},$$

real if and only if $|R_1 - R_2| < d < R_1 + R_2$ (the two spheres meet properly).

Step 5 — numerical check. Two unit spheres with centres at distance $d = 1$:

$$t = \frac{1 + 1 - 1}{2} = 0.5, \quad \rho = \sqrt{1 - 0.25} = 0.866025 = \frac{\sqrt{3}}{2}.$$

This is the classical result: two unit spheres whose centres are one radius apart meet in a circle of radius $\sqrt{3}/2$, lying in the median plane. ✓

Step 6 — limiting cases. For $d = R_1 + R_2$ (external tangency) one gets $t = R_1$ and $\rho = 0$: a point. For $d > R_1 + R_2$ the radicand is negative: no intersection, although the radical plane still exists — it is the locus of points of equal power with respect to the two spheres, a notion from Volume I that survives intact in every dimension.

Step 7 — reading. The result explains why trilateration (GPS) works: the intersection of two spheres is a circle, that of three is (generically) two points, that of four a single point. Each step lowers the dimension by one, as Theorem 7.3 predicts.

7.14. Self-assessment quiz

- A *great circle* of $S^2(O, r)$ is, by definition,
 - a circle of radius r drawn on the sphere
 - the intersection of the sphere with a plane through O
 - the boundary of a cap
 - a parallel
- In Theorem 7.6(ii) the hypothesis that allows one to conclude that Γ is a genuine circle (and not a point or the empty set) is
 - $k = 0$
 - $|k| < r$ with $a^2 + b^2 + c^2 = 1$
 - $c \neq 0$
 - Γ passes through the pole
- The circle $\Gamma = S^2 \cap \{z = k\}$ of the unit sphere projects, from the north pole, to a circle of centre the origin and radius
 - $\sqrt{1 - k^2}$
 - $\sqrt{\frac{1+k}{1-k}}$
 - $\frac{1}{1-k}$
 - $1 - k$
- On the unit sphere the geodesic distance between $A = (1, 0, 0)$ and $B = (\frac{1}{2}, \frac{\sqrt{3}}{2}, 0)$ equals, in radians,
 - 0.5
 - 1.047198
 - 1.570796
 - 1.000000
- In the proof of Theorem 7.7, the step that rules out the minimizing curve leaving the great circle is
 - the Cauchy–Schwarz inequality and its equality case
 - the Pythagorean theorem
 - the computation of the area element
 - Girard’s theorem
- A student computes the area of the geodesic triangle with angles $\alpha = \beta = \gamma = 90^\circ$ on a sphere of radius 2 and writes $\text{Area} = \frac{3\pi}{2} - \pi = \frac{\pi}{2}$. The mistake is
 - having added the angles wrongly
 - having forgotten the factor r^2 : the area is $\frac{\pi}{2} \cdot 4 = 2\pi$
 - having used degrees
 - none, the answer is correct
- To point an antenna at a satellite one uses the spherical triangle observer–pole–sub-satellite point. Which result of this chapter directly provides the angular distance between observer and sub-satellite point?
 - Girard’s theorem
 - the spherical law of cosines
 - Dandelin’s theorem
 - the lune lemma
- The property “stereographic projection maps circles to circles” is proved, with the algebraic computation reproduced at Step 6 of the proof of Theorem 7.6, in
 - Euclid, *Elements*, book XII
 - the HKUST MATH 5030 lecture notes, Chapter 2, Theorem 2.1.1
 - Newton, *Principia*, book I
 - Archimedes, *On the Sphere and*

7.14.1 Supplementary questionnaire

The items that follow come from Volume II and cover cones, spheres and quadrics; those on hyperspheres and rotations are in Chapter 11.

1. The section of a cone by a plane orthogonal to the axis is
A) an ellipse B) a circle C) a parabola D) a hyperbola
2. In Dandelin's theorem the foci of the ellipse are
A) the centres of the spheres B) the tangency points of the spheres with the plane
C) the vertices of the cone D) the centres of the tangency circles
3. The eccentricity of the circle is
A) 1 B) 0 C) 1/2 D) infinite
4. Every plane section of a sphere is
A) an ellipse B) a circle C) it depends on the plane D) a parabola
5. The radius of the section of a sphere of radius R by a plane at distance d is
A) $R - d$ B) $\sqrt{R^2 - d^2}$ C) $\sqrt{R^2 + d^2}$ D) Rd
6. On a sphere the angle sum of a triangle
A) is always π B) exceeds π by an amount proportional to the area C) is less than π D) depends only on the radius
7. An ellipsoid with three distinct semi-axes has circular sections
A) in no plane B) in two families of parallel planes C) in every plane D) only in the coordinate planes
8. The radius of the maximal circular sections of an ellipsoid with $a > b > c$ is
A) a B) b C) c D) $\sqrt{ac}$
9. The intersection of a sphere with a plane through the center is
A) an ellipse B) a great circle C) a point D) a parabola
10. A small circle has radius
A) r B) $\sqrt{r^2 - d^2}$ C) $r + d$ D) d
11. Stereographic projection maps a circle through the pole N to
A) a circle B) a line C) a point D) an ellipse
12. The Riemann sphere is
A) $\mathbb{C}$ B) $\mathbb{C} \cup \{\infty\}$ C) $\mathbb{R}^3$ D) $SO(3)$
13. The geodesics of the sphere are
A) the parallels B) the great circles C) the meridians only D) the loxodromes
14. The geodesic distance between two points with central angle θ is
A) r/θ B) $r\theta$ C) $r \sin \theta$ D) $2\pi r$

15. The area of a lune of angle α is
 A) αr^2 B) $2\alpha r^2$ C) $4\pi r^2$ D) $\pi\alpha$
16. For a geodesic triangle, $\alpha + \beta + \gamma - \pi$ equals
 A) 0 B) $\text{Area}(T)/r^2$ C) π D) 2π
17. In the limit $r \rightarrow \infty$ the spherical excess tends to
 A) ∞ B) 0 C) π D) 1

7.15. Teacher's key

BEST PRACTICE

Q1 — answer B. *Rationale:* Definition 7.4: the great circle is defined by the plane through the centre; that the radius equals r is a *consequence* (Theorem 7.3), not the definition. *Distractors:* A confuses the property with the definition and would be circular; C describes any circle; D is a small circle (except the equator). *Diagnosed error:* exchanging definition and characterization. *Source:* do Carmo, §4-6. *Prerequisite:* planar section of a sphere. *Remediation:* redo Step 5 of the proof of Theorem 7.3.

Q2 — answer B. *Rationale:* Step 5 of the proof requires $a^2 + b^2 + c^2 = 1$ (to identify $|k|$ with the distance from the centre) and $|k| < r$ (so that the section is a circle and not a point or the empty set). *Distractors:* A is the case of the great circle only; C is not needed (with $c = 0$ the plane contains the z axis and the formula still works); D is the condition that gives a *line*, not a circle. *Diagnosed error:* failing to check the non-degeneracy hypotheses. *Source:* HKUST MATH 5030, Ch. 2, Theorem 2.1.1, point 1. *Prerequisite:* point-plane distance. *Remediation:* redo Step 5 listing what happens for $|k| = r$ and $|k| > r$.

Q3 — answer B. *Rationale:* with $a = b = 0$, $c = 1$ the radius formula gives $\sqrt{1 - k^2}/|1 - k| = \sqrt{(1 - k)(1 + k)/(1 - k)} = \sqrt{(1 + k)/(1 - k)}$. *Distractors:* A is the radius of the circle *on the sphere*, not of its image; C is the factor $1/(1 - z)$ alone; D has the wrong dimensions. *Diagnosed error:* confusing the radius of the object with that of its image. *Source:* Theorem 7.6(ii) and the numerical check at Step 9(b). *Prerequisite:* algebra of radicals. *Remediation:* compute the radius for $k = 0$ (it must give 1) and for $k \rightarrow 1^-$ (it must diverge).

Q4 — answer B. *Rationale:* $\langle A, B \rangle = \frac{1}{2}$, hence $\theta = \arccos(0.5) = \pi/3 = 1.047198$ (Theorem 7.8). *Distractors:* A is the scalar product, not the angle; C would be $\arccos 0$; D is the chord $\|A - B\| = 1$, which is not a path on the sphere. *Diagnosed error:* confusing chord, cosine and geodesic distance. *Source:* Theorem 7.7, Step 12. *Prerequisite:* scalar product and arccos. *Remediation:* compute chord and arc for $\theta = 10^\circ, 60^\circ, 180^\circ$ and compare.

Q5 — answer A. *Rationale:* Step 8(b) and Step 9: equality in Cauchy–Schwarz forces $\gamma' \in \text{span}\{A, \gamma\}$, and from there the equation $\psi' = \beta\psi$ gives $\psi \equiv 0$, i.e. the curve lies

in a plane through the origin. *Distractors*: B is used in Theorem 7.3, not here; C is used for the area; D is the theorem about the area of the triangle. *Diagnosed error*: confusing the inequality (which gives the minimum) with the equality case (which gives uniqueness). *Source*: Math 138A lecture notes, University of California Riverside, “Length minimizing property of great circles”. *Prerequisite*: equality case in Cauchy–Schwarz. *Remediation*: rewrite Step 9 with A and B antipodal and see where it breaks.

Q6 — answer B. *Rationale*: Theorem 7.11: the excess is Area/r^2 , so $\text{Area} = Er^2 = \frac{\pi}{2} \cdot 4 = 2\pi$. *Distractors*: A and C are mistakes different from the one made; D accepts the error. *Diagnosed error*: confusing excess (dimensionless) and area (with the dimensions of a length squared). *Source*: Todhunter, Art. 99–100. *Prerequisite*: dimensional homogeneity. *Remediation*: repeat Step 4 of the proof with $r = 1, 2, 3$ and observe that the excess does not change.

Q7 — answer B. *Rationale*: given latitude and longitude of the observer and of the sub-satellite point, Proposition 7.2 applied to the triangle pole–observer–sub-satellite gives the angular distance directly, from which elevation and azimuth follow. *Distractors*: A and D concern areas; C concerns conics. *Diagnosed error*: failing to recognize which datum is geometrically available. *Source*: MIT OpenCourseWare 12.215 *Modern Navigation*, Lecture 4. *Prerequisite*: geographic coordinates. *Remediation*: draw the triangle and label its sides and angles before writing any formula.

Q8 — answer B. *Rationale*: the computation of Step 6 — substituting the inverse parametrization into the equation of the plane and recognizing the equation of a circle — is exactly that of Theorem 2.1.1 of the HKUST MATH 5030 lecture notes, §2.1. *Distractors*: A, C and D are real works but on different subjects; they check that the student does not “recognize” a name at random. *Diagnosed error*: quoting from memory without checking. *Source*: the same lecture notes, pp. 48–50 (verified). *Prerequisite*: none. *Remediation*: open the source and compare the two computations line by line.

Answers to the assigned exercises.

Exercise 7.7. (i) By Corollary 7.1, $d = \sqrt{13^2 - 12^2} = \sqrt{25} = 5$ cm: the spheres are *two*, with centres on the axis of the circle at 5 cm from π , one on each side. (ii) C is a great circle if and only if $d = 0$, i.e. $r = \rho = 12$ cm, and then the sphere is *unique* (the two centres coincide with Q). (iii) No: for $r = 10 < 12 = \rho$ every planar section has radius $\leq 10 < 12$, so no sphere of radius 10 can contain a circle of radius 12.

Exercise 7.8. (i) The parallel is $S^2 \cap \{z = z_0\}$, i.e. $a = b = 0$, $c = 1$, $k = z_0$: the centre of the image is $-\frac{1}{1-z_0}(0, 0) = (0, 0)$ and the radius $\sqrt{1 - z_0^2}/|1 - z_0| = \sqrt{(1 + z_0)/(1 - z_0)}$. By direct computation: the point $(\sqrt{1 - z_0^2}, 0, z_0)$ goes to $(\sqrt{1 - z_0^2}/(1 - z_0), 0)$, of the same modulus. (ii) $z_0 = -\frac{1}{2}$: $\sqrt{0.5/1.5} = 0.577350$; $z_0 = 0$: 1; $z_0 = \frac{1}{2}$: $\sqrt{1.5/0.5} = 1.732051$; $z_0 = 0.9$: $\sqrt{1.9/0.1} = 4.358899$. (iii) The meridian $\varphi = \varphi_0$ is half of a great circle through N ; by Theorem 7.6(ii) its image is (half of) a line, and since σ fixes the equator that line passes through the origin with direction $(\cos \varphi_0, \sin \varphi_0)$. Lines through the origin and circles centred at the origin meet at right angles, as they must by conformality (part (i) of the theorem).

Exercise 7.9. (i) The two sides starting at the Pole are meridians and cut the equator at right angles: $\beta = \gamma = 90^\circ$; the angle at the Pole is the longitude difference, $\alpha = 40^\circ = 0.698132$ rad. Hence $E = 0.698132 + 1.570796 + 1.570796 - 3.141593 = 0.698132$ rad, and by Theorem 7.11 $\text{Area} = 0.698132 \times 6371^2 = 2.83369 \cdot 10^7$ km². The fraction of the Earth’s surface is $E/(4\pi) = 0.698132/12.566371 = 0.055556 = 1/18$, as it must be (40° out of 720°). (ii) The two polar sides measure $\frac{\pi}{2} \times 6371 = 10\,007.5$ km each, the equatorial one $0.698132 \times 6371 = 4447.8$ km. (iii) The isosceles plane triangle with those sides has area

$\frac{c}{4}\sqrt{4a^2 - c^2} = 2.16993 \cdot 10^7 \text{ km}^2$: the spherical area exceeds it by 30.6%. The deviation is positive (the curved surface is larger) and it is enormous because the triangle is as big as an eighth of the planet: here the curvature term is not a correction, it is the phenomenon.

7.16. Chapter formulary

Cone and conics

$$x^2 + y^2 = z^2 \tan^2 \alpha; \quad r(h) = h \tan \alpha; \quad e = \frac{\cos \beta}{\cos \alpha}$$

$e = 0$ circle; $0 < e < 1$ ellipse; $e = 1$ parabola; $e > 1$ hyperbola

$$\text{Dandelin : } |PF_1| + |PF_2| = |AB| = 2a$$

Sphere

$$S^{n-1}(c, R) = \{\|x - c\| = R\}; \quad \text{section at distance } d : \rho = \sqrt{R^2 - d^2}$$

$$\text{cap : } A = 2\pi Rh, \quad V = \frac{\pi h^2}{3}(3R - h)$$

$$\text{Girard : } \text{Area}(T) = R^2(A + B + C - \pi)$$

$$\text{geodesic : } \text{dist}(A, B) = R \arccos \frac{\langle A, B \rangle}{R^2}; \quad C(\rho) = 2\pi R \sin \frac{\rho}{R}$$

Stereographic projection (pole $N = (0, 0, r)$, plane $z = 0$)

$$\sigma(x, y, z) = \frac{r}{r - z}(x, y), \quad X(u, v) = \frac{r}{u^2 + v^2 + r^2}(2ru, 2rv, u^2 + v^2 - r^2)$$

$$E = G = \frac{4r^4}{(u^2 + v^2 + r^2)^2}, \quad F = 0, \quad \lambda = \frac{2r^2}{u^2 + v^2 + r^2} \quad (\text{conformal})$$

$$\Gamma = S^2 \cap \{ax + by + cz = k\}, \quad a^2 + b^2 + c^2 = 1, \quad |k| < r : \quad cr = k \Rightarrow \text{line } au + bv = cr,$$

$$cr \neq k \Rightarrow \text{circle of centre } -\frac{r^2}{cr - k}(a, b) \text{ and radius } \frac{r\sqrt{r^2 - k^2}}{|cr - k|}$$

Geodesics, area, Gauss–Bonnet

$$d(A, B) = r \arccos \frac{\langle A, B \rangle}{r^2} = r\theta, \quad \cos c = \cos a \cos b + \sin a \sin b \cos C$$

$$dA = r^2 \sin \vartheta \, d\varphi \, d\vartheta, \quad \text{cap : } 2\pi rh, \quad \text{lune : } 2\alpha r^2$$

$$E = \alpha + \beta + \gamma - \pi = \frac{\text{Area}(T)}{r^2} = K \text{Area}(T), \quad K = \frac{1}{r^2}$$

Ellipsoid

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1, \quad a > b > c; \quad z = \pm kx, \quad k = \frac{c}{a} \sqrt{\frac{a^2 - b^2}{b^2 - c^2}}, \quad \rho = b$$

Intersection of two spheres

$$t = \frac{d^2 + R_1^2 - R_2^2}{2d}, \quad \rho = \sqrt{R_1^2 - t^2}$$

CHAPTER 8

Spherical trigonometry

On the circle, plane trigonometry relates the sides and the angles of triangles. On the sphere the “triangles” have arcs of great circle as sides and obey different relations — spherical trigonometry — which is the quantitative tool of navigation, of geodesy and of astronomy. It is the natural completion of the passage from the circle to the sphere.

The chapter is self-contained: every formula is proved starting from the scalar product and the vector product in $\mathbb{R}^3$, without assuming anything from the differential geometry of surfaces. The cosine theorem for sides and the Gauss–Bonnet theorem on the triangle also appear in Chapter 7 (circle–sphere dictionary) and in Chapter 9 (geodesics): there they serve as an application, here they are *proved*, and the two expositions can be read in any order.

INFO

Level and prerequisites. Level **A–C**. Sections 8.1, 8.2 and 8.5 are of level A–B and require only plane trigonometry, the scalar product and the vector product in $\mathbb{R}^3$. Sections 8.4, 8.6 and 8.7 are of level B–C: they additionally require the 3×3 determinant, the idea of the area of a surface as a double integral and some ease with the sum-to-product identities. Section 8.8 is applicative and of level A–B. Prerequisites within the treatise: circle and arcs (Volume I, Chapters 2 and 8), trigonometric functions and addition formulas (Volume II, Chapter 1), sphere, great circles and spherical area element (Chapter 7 of this volume).

Warning. Conventions of the chapter.

- Unless stated otherwise we work on the **unit sphere** $S^2 = \{\mathbf{x} \in \mathbb{R}^3 : \|\mathbf{x}\| = 1\}$ centred at O ; for a sphere of radius r all lengths are multiplied by r and all areas by r^2 , whereas *angles and sides do not change*.
- The vertices of a triangle are denoted by **A, B, C** when they are regarded as unit vectors of $\mathbb{R}^3$, and by A, B, C when its angles are meant. The sides a, b, c are the sides opposite to A, B, C respectively.
- Sides and angles are measured in radians and satisfy $0 < a, b, c < \pi$ and $0 < A, B, C < \pi$; when degrees appear, the conversion is $1^\circ = \pi/180$.
- $\mathbf{u} \cdot \mathbf{v}$ is the scalar product, $\mathbf{u} \times \mathbf{v}$ the vector product and $\det[\mathbf{u}, \mathbf{v}, \mathbf{w}] = \mathbf{u} \cdot (\mathbf{v} \times \mathbf{w})$ the mixed product.
- Decimal separators are points: 0.5.

8.1. Spherical triangles: definitions and fundamental inequalities

The delicate point, and the reason why spherical trigonometry is not a cosmetic variant of the plane one, is that on the sphere *the sides too are angles*: the distance between two points is measured by the central angle they subtend. It follows that in a spherical triangle there are six homogeneous quantities — three sides and three angles — and that the relations among them are relations among six numbers of the same kind.

Definition 8.1: Spherical triangle. Let $\mathbf{A}, \mathbf{B}, \mathbf{C} \in S^2$ be three points that are **linearly independent** as vectors of $\mathbb{R}^3$. The **spherical triangle** ABC is the region of S^2 bounded by the three minor arcs of great circle joining the vertices pairwise. Its **sides** are the central angles

$$a = \angle(\mathbf{B}, \mathbf{C}), \quad b = \angle(\mathbf{C}, \mathbf{A}), \quad c = \angle(\mathbf{A}, \mathbf{B}),$$

that is, the numbers in $(0, \pi)$ defined by

$$\cos a = \mathbf{B} \cdot \mathbf{C}, \quad \cos b = \mathbf{C} \cdot \mathbf{A}, \quad \cos c = \mathbf{A} \cdot \mathbf{B}.$$

On a sphere of radius r the length of the side a equals ra .

The hypothesis of linear independence excludes the degenerate cases: two coincident or antipodal vertices (then a , b or c would equal 0 or π) and three vertices on one and the same great circle. Under that hypothesis each side really belongs to $(0, \pi)$ and the minor arc between two vertices is unique.

Definition 8.2: Angle of a spherical triangle. Let $\mathbf{P} \in S^2$ and let $\mathbf{Q} \in S^2$ with $\angle(\mathbf{P}, \mathbf{Q}) \in (0, \pi)$. The **unit tangent vector at $\mathbf{P}$ towards $\mathbf{Q}$** is

$$\mathbf{t}_{\mathbf{P} \rightarrow \mathbf{Q}} = \frac{\mathbf{Q} - (\mathbf{P} \cdot \mathbf{Q})\mathbf{P}}{\|\mathbf{Q} - (\mathbf{P} \cdot \mathbf{Q})\mathbf{P}\|}.$$

The **angle** A of the triangle at the vertex $\mathbf{A}$ is the angle between the two unit vectors tangent to its two edges:

$$\cos A = \mathbf{t}_{\mathbf{A} \rightarrow \mathbf{B}} \cdot \mathbf{t}_{\mathbf{A} \rightarrow \mathbf{C}}, \quad A \in (0, \pi),$$

and analogously for B and C .

This definition coincides with the classical one — the dihedral angle between the planes of the two sides — and it is the one that lends itself to computation. The following lemma verifies this and, at the same time, provides the only computation needed for the whole chapter.

Lemma 8.1: The unit tangent vector and its norm. Let $\mathbf{P}, \mathbf{Q} \in S^2$ with $\gamma = \angle(\mathbf{P}, \mathbf{Q}) \in (0, \pi)$ and let $\mathbf{Q}_\perp = \mathbf{Q} - (\mathbf{P} \cdot \mathbf{Q})\mathbf{P}$. Then:

- (i) $\|\mathbf{Q}_\perp\| = \sin \gamma > 0$;
- (ii) the curve $\sigma(t) = \cos t \mathbf{P} + \sin t \mathbf{t}_{\mathbf{P} \rightarrow \mathbf{Q}}$, $t \in [0, \gamma]$, is the minor arc of great circle from $\mathbf{P}$ to $\mathbf{Q}$, is parametrized by arc length and $\sigma'(0) = \mathbf{t}_{\mathbf{P} \rightarrow \mathbf{Q}}$;
- (iii) $\mathbf{t}_{\mathbf{P} \rightarrow \mathbf{Q}}$ is orthogonal to $\mathbf{P}$ and lies in the plane $\text{span}\{\mathbf{P}, \mathbf{Q}\}$.

Proof. (i) Since $\mathbf{P} \cdot \mathbf{Q} = \cos \gamma$ and $\|\mathbf{P}\| = \|\mathbf{Q}\| = 1$,

$$\|\mathbf{Q}_\perp\|^2 = \mathbf{Q} \cdot \mathbf{Q} - 2(\mathbf{P} \cdot \mathbf{Q})^2 + (\mathbf{P} \cdot \mathbf{Q})^2 = 1 - \cos^2 \gamma = \sin^2 \gamma.$$

Since $\gamma \in (0, \pi)$ one has $\sin \gamma > 0$, and the positive root is $\sin \gamma$.

(iii) $\mathbf{Q}_\perp \cdot \mathbf{P} = \mathbf{Q} \cdot \mathbf{P} - (\mathbf{P} \cdot \mathbf{Q})\|\mathbf{P}\|^2 = 0$, and by construction $\mathbf{Q}_\perp$ is a linear combination of $\mathbf{P}$ and $\mathbf{Q}$.

(ii) Write $\mathbf{u} = \mathbf{t}_{\mathbf{P} \rightarrow \mathbf{Q}} = \mathbf{Q}_\perp / \sin \gamma$. By (iii), $\{\mathbf{P}, \mathbf{u}\}$ is an orthonormal pair, hence $\|\sigma(t)\|^2 = \cos^2 t + \sin^2 t = 1$: the curve lies on S^2 and, lying in the plane $\text{span}\{\mathbf{P}, \mathbf{u}\} = \text{span}\{\mathbf{P}, \mathbf{Q}\}$ which passes through the origin, it lies on the great circle through $\mathbf{P}$ and $\mathbf{Q}$. Moreover $\sigma(0) = \mathbf{P}$ and

$$\sigma(\gamma) = \cos \gamma \mathbf{P} + \sin \gamma \cdot \frac{\mathbf{Q} - \cos \gamma \mathbf{P}}{\sin \gamma} = \cos \gamma \mathbf{P} + \mathbf{Q} - \cos \gamma \mathbf{P} = \mathbf{Q}.$$

Finally $\sigma'(t) = -\sin t \mathbf{P} + \cos t \mathbf{u}$ has norm 1 for every t , hence t is the arc-length parameter and the length of the arc travelled is exactly γ ; since $\gamma < \pi$, it is the minor arc. From $\sigma'(0) = \mathbf{u}$ the claim follows. $\square$

Remark 8.1: *The spherical angle is the dihedral angle.* By Lemma 8.1(iii), $\mathbf{t}_{\mathbf{A} \rightarrow \mathbf{B}}$ and $\mathbf{t}_{\mathbf{A} \rightarrow \mathbf{C}}$ are both orthogonal to $\mathbf{A}$ and lie respectively in the planes $\text{span}\{\mathbf{A}, \mathbf{B}\}$ and $\text{span}\{\mathbf{A}, \mathbf{C}\}$. The angle between two half-planes issuing from a common line is by definition measured on a section orthogonal to that line: the angle between the two unit tangent vectors is therefore exactly the dihedral angle between the planes of the two sides. The two definitions coincide.

Figure 8.1: A spherical triangle on the unit sphere, in orthographic projection on the visible hemisphere. The vertices are $\mathbf{A}$ of latitude 70° and longitude 90° , $\mathbf{B}$ of latitude 35° and longitude 45° , $\mathbf{C}$ of latitude 35° and longitude 135° ; the sides turn out to be $a = 70.7925^\circ$ and $b = c = 42.5156^\circ$, the angles $A = 117.9875^\circ$ and $B = C = 39.1930^\circ$. The sum of the angles equals 196.3736° : the spherical excess is 16.3736° . The dashed lines are the radii OA , OB , OC : the sides of the triangle are, by definition, the angles between these radii.

8.2. The cosine theorem for sides

Theorem 8.1: Cosine theorem for sides. *In every spherical triangle*

$$\cos a = \cos b \cos c + \sin b \sin c \cos A$$

holds and, by cyclic permutation of (a, b, c) and (A, B, C) ,

$$\cos b = \cos c \cos a + \sin c \sin a \cos B, \quad \cos c = \cos a \cos b + \sin a \sin b \cos C.$$

Equivalently

$$\cos A = \frac{\cos a - \cos b \cos c}{\sin b \sin c}.$$

Proof. Step 1 — the projections at the vertex $\mathbf{A}$. Set

$$\mathbf{B}_\perp = \mathbf{B} - (\mathbf{A} \cdot \mathbf{B})\mathbf{A} = \mathbf{B} - \cos c \mathbf{A}, \quad \mathbf{C}_\perp = \mathbf{C} - (\mathbf{A} \cdot \mathbf{C})\mathbf{A} = \mathbf{C} - \cos b \mathbf{A}.$$

By Lemma 8.1(i) one has $\|\mathbf{B}_\perp\| = \sin c > 0$ and $\|\mathbf{C}_\perp\| = \sin b > 0$; these two quantities are non-zero precisely because $b, c \in (0, \pi)$, that is, because the triangle is non-degenerate.

Step 2 — the scalar product of the projections. Expanding and using $\mathbf{A} \cdot \mathbf{A} = 1$,

$$\mathbf{B}_\perp \cdot \mathbf{C}_\perp = \mathbf{B} \cdot \mathbf{C} - \cos b (\mathbf{A} \cdot \mathbf{B}) - \cos c (\mathbf{A} \cdot \mathbf{C}) + \cos b \cos c = \cos a - \cos b \cos c - \cos c \cos b + \cos b \cos c,$$

that is,

$$\mathbf{B}_\perp \cdot \mathbf{C}_\perp = \cos a - \cos b \cos c.$$

Step 3 — conclusion. By Definition 8.2 and Step 1,

$$\cos A = \frac{\mathbf{B}_\perp \cdot \mathbf{C}_\perp}{\|\mathbf{B}_\perp\| \|\mathbf{C}_\perp\|} = \frac{\cos a - \cos b \cos c}{\sin c \sin b},$$

whence $\cos a = \cos b \cos c + \sin b \sin c \cos A$. The other two formulas are obtained by exchanging the names of the vertices, an operation which is legitimate because no step has privileged $\mathbf{A}$.

□

Remark 8.2: Why there is no “ $-2bc$ ”. In the plane $a^2 = b^2 + c^2 - 2bc \cos A$ holds: a relation between lengths. On the sphere the relation is between cosines of angles, and the additive structure is replaced by a multiplicative one. The two match in the limit of small triangles. On a sphere of radius r the sides measure $\alpha = ra$, $\beta = rb$, $\gamma = rc$; substituting $a = \alpha/r$ and expanding with $\cos x = 1 - \frac{x^2}{2} + \frac{x^4}{24} + O(x^6)$ and $\sin x = x - \frac{x^3}{6} + O(x^5)$ one obtains, order by order in $1/r$,

$$1 - \frac{\alpha^2}{2r^2} + O(r^{-4}) = \left(1 - \frac{\beta^2}{2r^2}\right) \left(1 - \frac{\gamma^2}{2r^2}\right) + \frac{\beta\gamma}{r^2} \cos A + O(r^{-4}).$$

The terms of order r^0 give $1 = 1$; those of order r^{-2} give $-\frac{\alpha^2}{2} = -\frac{\beta^2}{2} - \frac{\gamma^2}{2} + \beta\gamma \cos A$, that is, $\alpha^2 = \beta^2 + \gamma^2 - 2\beta\gamma \cos A$: the plane cosine theorem. Euclidean geometry is the limit $r \rightarrow \infty$ of spherical geometry, uniformly on triangles of bounded diameter.

Corollary 8.1: Spherical analogue of the Pythagorean theorem. If the triangle is right-angled at C , that is $C = \pi/2$, then

$$\cos c = \cos a \cos b.$$

For small triangles one recovers $c^2 \approx a^2 + b^2$.

Proof. It suffices to apply Theorem 8.1 in the form $\cos c = \cos a \cos b + \sin a \sin b \cos C$ and to observe that $\cos(\pi/2) = 0$: the second summand vanishes. For the limit: with $a, b, c \rightarrow 0^+$, from $\cos c = \cos a \cos b$ it follows that

$$1 - \frac{c^2}{2} + O(c^4) = \left(1 - \frac{a^2}{2} + O(a^4)\right) \left(1 - \frac{b^2}{2} + O(b^4)\right) = 1 - \frac{a^2 + b^2}{2} + O((a^2 + b^2)^2),$$

and comparing the second-order terms, $c^2 = a^2 + b^2 + O((a^2 + b^2)^2)$. □

Corollary 8.2: Spherical triangle inequality. In every spherical triangle $a < b + c$, and analogously for the other two sides. In particular $\angle(\cdot, \cdot)$ is a distance on S^2 .

Proof. Since $\cos A > -1$ (because $A \in (0, \pi)$) and $\sin b \sin c > 0$,

$$\cos a = \cos b \cos c + \sin b \sin c \cos A > \cos b \cos c - \sin b \sin c = \cos(b + c).$$

If $b + c \geq \pi$ the claim is obvious, because $a < \pi \leq b + c$. If instead $b + c < \pi$, then a and $b + c$ both lie in $[0, \pi]$, where the cosine is strictly decreasing: from $\cos a > \cos(b + c)$ it follows that

$a < b + c$. The triangle inequality for points not in general position (coincident, antipodal or aligned on a great circle) is verified directly, and symmetry and vanishing only on the diagonal are immediate: $\angle$ is therefore a distance. $\square$

Corollary 8.3: The perimeter is less than 2π . In every spherical triangle $0 < a + b + c < 2\pi$. Setting $s = \frac{1}{2}(a + b + c)$, one therefore has $0 < s < \pi$ and $0 < s - a, s - b, s - c < s$.

Proof. Let $\mathbf{A}^* = -\mathbf{A}$ be the antipode of $\mathbf{A}$. The three vectors $\mathbf{A}^*, \mathbf{B}, \mathbf{C}$ are still linearly independent (changing the sign of a vector does not alter independence), hence $\mathbf{A}^*BC$ is a spherical triangle; its sides are

$$\angle(\mathbf{B}, \mathbf{C}) = a, \quad \angle(\mathbf{C}, \mathbf{A}^*) = \pi - b, \quad \angle(\mathbf{A}^*, \mathbf{B}) = \pi - c,$$

because $\mathbf{C} \cdot \mathbf{A}^* = -\cos b = \cos(\pi - b)$ and analogously for the other one. Applying to this triangle Corollary 8.2 to the side a :

$$a < (\pi - b) + (\pi - c) = 2\pi - b - c,$$

that is, $a + b + c < 2\pi$. Positivity is obvious. From $s < \pi$ and from $s - a = \frac{1}{2}(b + c - a) > 0$ (again by the triangle inequality) the other assertions follow. $\square$

Example 8.1: The trirectangular triangle. Take $\mathbf{A} = (1, 0, 0)$, $\mathbf{B} = (0, 1, 0)$, $\mathbf{C} = (0, 0, 1)$: they are orthonormal, hence independent. All the crossed scalar products vanish, hence $a = b = c = \pi/2$. The projections at the vertex $\mathbf{A}$ are $\mathbf{B}_\perp = \mathbf{B}$ and $\mathbf{C}_\perp = \mathbf{C}$, orthogonal to each other: $A = \pi/2$, and by symmetry $B = C = \pi/2$. The sum of the angles equals $3\pi/2 > \pi$: a triangle with three right angles, impossible in the plane. The perimeter is $3\pi/2 < 2\pi$, in agreement with Corollary 8.3.

8.3. The sine theorem

The most economical proof of the sine theorem goes through a quantity that is symmetric in the three sides: the Gram determinant of the three unit vectors of the vertices.

Lemma 8.2: Gram determinant of the vertices. Let M be the 3×3 matrix whose columns are $\mathbf{A}, \mathbf{B}, \mathbf{C}$ and let $G = M^\top M$ be its Gram matrix. Then

$$X := \det G = 1 - \cos^2 a - \cos^2 b - \cos^2 c + 2 \cos a \cos b \cos c = (\det[\mathbf{A}, \mathbf{B}, \mathbf{C}])^2,$$

and $X > 0$ if and only if the triangle is non-degenerate. Moreover

$$\sin A = \frac{\sqrt{X}}{\sin b \sin c}, \quad \sin B = \frac{\sqrt{X}}{\sin c \sin a}, \quad \sin C = \frac{\sqrt{X}}{\sin a \sin b}.$$

Proof. Step 1 — the form of G . The (i, j) entry of $G = M^\top M$ is the scalar product of column i with column j , hence

$$G = \begin{pmatrix} 1 & \cos c & \cos b \\ \cos c & 1 & \cos a \\ \cos b & \cos a & 1 \end{pmatrix}.$$

Expanding along the first row:

$$\det G = 1 \cdot (1 - \cos^2 a) - \cos c (\cos c - \cos a \cos b) + \cos b (\cos a \cos c - \cos b)$$

$$= 1 - \cos^2 a - \cos^2 c + \cos a \cos b \cos c + \cos a \cos b \cos c - \cos^2 b = 1 - \cos^2 a - \cos^2 b - \cos^2 c + 2 \cos a \cos b \cos c.$$

On the other hand $\det G = \det(M^T) \det M = (\det M)^2$, and $\det M = \det[\mathbf{A}, \mathbf{B}, \mathbf{C}]$.

Step 2 — positivity. $(\det M)^2 > 0$ if and only if $\det M \neq 0$, that is, if and only if the columns are linearly independent: exactly the non-degeneracy condition of Definition 8.1.

Step 3 — the sine of the angles. From Theorem 8.1,

$$\sin^2 A = 1 - \cos^2 A = \frac{\sin^2 b \sin^2 c - (\cos a - \cos b \cos c)^2}{\sin^2 b \sin^2 c}.$$

The numerator equals

$$\begin{aligned} & (1 - \cos^2 b)(1 - \cos^2 c) - \cos^2 a + 2 \cos a \cos b \cos c - \cos^2 b \cos^2 c \\ &= 1 - \cos^2 b - \cos^2 c + \cos^2 b \cos^2 c - \cos^2 a + 2 \cos a \cos b \cos c - \cos^2 b \cos^2 c = X. \end{aligned}$$

Since $A \in (0, \pi)$ one has $\sin A > 0$, and taking the positive root $\sin A = \sqrt{X}/(\sin b \sin c)$. The other two follow by cyclic permutation, because X is symmetric in a, b, c . $\square$

Theorem 8.2: Spherical sine theorem. In every spherical triangle

$$\frac{\sin A}{\sin a} = \frac{\sin B}{\sin b} = \frac{\sin C}{\sin c} = \frac{\sqrt{X}}{\sin a \sin b \sin c}$$

with $X = 1 - \cos^2 a - \cos^2 b - \cos^2 c + 2 \cos a \cos b \cos c > 0$.

Proof. By Lemma 8.2,

$$\frac{\sin A}{\sin a} = \frac{\sqrt{X}}{\sin a \sin b \sin c}, \quad \frac{\sin B}{\sin b} = \frac{\sqrt{X}}{\sin a \sin b \sin c}, \quad \frac{\sin C}{\sin c} = \frac{\sqrt{X}}{\sin a \sin b \sin c},$$

and the three ratios coincide because the right-hand side does not depend on which vertex has been chosen. The denominators are non-zero because $a, b, c \in (0, \pi)$. $\square$

Geometric variant: the mixed product. The number $\sqrt{X} = |\det[\mathbf{A}, \mathbf{B}, \mathbf{C}]|$ is the volume of the parallelepiped built on the three unit vectors of the vertices; it is therefore manifestly symmetric (up to sign) under permutation of the vertices. From Step 3 of Lemma 8.2 one reads that this volume equals $\sin b \sin c \sin A$, and by symmetry also $\sin c \sin a \sin B$ and $\sin a \sin b \sin C$. Equating the three expressions and dividing by $\sin a \sin b \sin c > 0$ one recovers the chain of equalities. This is the “volume” reading of the same computation. $\square$

Warning. The sine theorem, on its own, does *not* determine an angle: from $\sin A$ one goes back to A or to $\pi - A$. To remove the ambiguity it must be paired with the cosine theorem, which supplies $\cos A$ and hence the quadrant. It is the most frequent error in navigation computations, and it is discussed in Exercise 8.6.

8.4. The polar triangle and the cosine theorem for angles

On the sphere there reigns a duality that the plane does not know: to every triangle another one is associated in which sides and angles are exchanged (up to taking the supplements). Every theorem then automatically splits into two.

Definition 8.3: Polar triangle. Let ABC be a spherical triangle and let $\delta = \det[\mathbf{A}, \mathbf{B}, \mathbf{C}]$. By possibly exchanging the names of $\mathbf{B}$ and $\mathbf{C}$ we may assume $\delta > 0$ (we then say that the triangle is **positively oriented**). The **polar triangle** $A'B'C'$ has vertices

$$\mathbf{A}' = \frac{\mathbf{B} \times \mathbf{C}}{\|\mathbf{B} \times \mathbf{C}\|}, \quad \mathbf{B}' = \frac{\mathbf{C} \times \mathbf{A}}{\|\mathbf{C} \times \mathbf{A}\|}, \quad \mathbf{C}' = \frac{\mathbf{A} \times \mathbf{B}}{\|\mathbf{A} \times \mathbf{B}\|}.$$

The vector $\mathbf{A}'$ is one of the two poles of the great circle through $\mathbf{B}$ and $\mathbf{C}$; the construction chooses a definite one, and the following theorem shows that it is the one lying on the same side as $\mathbf{A}$ — the classical choice.

Theorem 8.3: Polar duality. Let ABC be a positively oriented spherical triangle, $\delta = \det[\mathbf{A}, \mathbf{B}, \mathbf{C}] > 0$, and let $A'B'C'$ be its polar triangle. Then:

- (i) $\|\mathbf{B} \times \mathbf{C}\| = \sin a$, $\|\mathbf{C} \times \mathbf{A}\| = \sin b$, $\|\mathbf{A} \times \mathbf{B}\| = \sin c$, and $\mathbf{A}' \cdot \mathbf{A} = \delta / \sin a > 0$: $\mathbf{A}'$ is the pole of the side a lying on the same side as $\mathbf{A}$;
- (ii) $\det[\mathbf{A}', \mathbf{B}', \mathbf{C}'] = \frac{\delta^2}{\sin a \sin b \sin c} > 0$: $A'B'C'$ is a non-degenerate spherical triangle, positively oriented as well;
- (iii) the sides of $A'B'C'$ are $a' = \pi - A$, $b' = \pi - B$, $c' = \pi - C$;
- (iv) the polar triangle of $A'B'C'$ is ABC ; consequently its angles are $A' = \pi - a$, $B' = \pi - b$, $C' = \pi - c$.

Proof. We shall use two classical identities of vector calculus in $\mathbb{R}^3$, valid for every choice of the vectors:

$$(\mathbf{u} \times \mathbf{v}) \cdot (\mathbf{w} \times \mathbf{z}) = (\mathbf{u} \cdot \mathbf{w})(\mathbf{v} \cdot \mathbf{z}) - (\mathbf{u} \cdot \mathbf{z})(\mathbf{v} \cdot \mathbf{w}), \quad (\text{I})$$

$$\mathbf{p} \times (\mathbf{u} \times \mathbf{v}) = (\mathbf{p} \cdot \mathbf{v})\mathbf{u} - (\mathbf{p} \cdot \mathbf{u})\mathbf{v}. \quad (\text{II})$$

(i) From (I) with $\mathbf{u} = \mathbf{w} = \mathbf{B}$ and $\mathbf{v} = \mathbf{z} = \mathbf{C}$: $\|\mathbf{B} \times \mathbf{C}\|^2 = 1 - \cos^2 a = \sin^2 a$, and $\sin a > 0$ because $a \in (0, \pi)$. Moreover $\mathbf{A} \cdot (\mathbf{B} \times \mathbf{C}) = \delta$, hence $\mathbf{A}' \cdot \mathbf{A} = \delta / \sin a > 0$.

(ii) By (II) with $\mathbf{p} = \mathbf{C} \times \mathbf{A}$, $\mathbf{u} = \mathbf{A}$, $\mathbf{v} = \mathbf{B}$:

$$(\mathbf{C} \times \mathbf{A}) \times (\mathbf{A} \times \mathbf{B}) = [(\mathbf{C} \times \mathbf{A}) \cdot \mathbf{B}]\mathbf{A} - [(\mathbf{C} \times \mathbf{A}) \cdot \mathbf{A}]\mathbf{B} = \delta \mathbf{A}, \quad (*)$$

because $(\mathbf{C} \times \mathbf{A}) \cdot \mathbf{A} = 0$ and $(\mathbf{C} \times \mathbf{A}) \cdot \mathbf{B} = \det[\mathbf{C}, \mathbf{A}, \mathbf{B}] = \delta$ (the mixed product is invariant under cyclic permutations). Then

$$\det[\mathbf{A}', \mathbf{B}', \mathbf{C}'] = \frac{(\mathbf{B} \times \mathbf{C}) \cdot [(\mathbf{C} \times \mathbf{A}) \times (\mathbf{A} \times \mathbf{B})]}{\sin a \sin b \sin c} = \frac{\delta (\mathbf{B} \times \mathbf{C}) \cdot \mathbf{A}}{\sin a \sin b \sin c} = \frac{\delta^2}{\sin a \sin b \sin c} > 0.$$

In particular $\mathbf{A}', \mathbf{B}', \mathbf{C}'$ are independent: $A'B'C'$ is a spherical triangle.

(iii) By (I),

$$(\mathbf{C} \times \mathbf{A}) \cdot (\mathbf{A} \times \mathbf{B}) = (\mathbf{C} \cdot \mathbf{A})(\mathbf{A} \cdot \mathbf{B}) - (\mathbf{C} \cdot \mathbf{B})(\mathbf{A} \cdot \mathbf{A}) = \cos b \cos c - \cos a.$$

Dividing by $\|\mathbf{C} \times \mathbf{A}\| \|\mathbf{A} \times \mathbf{B}\| = \sin b \sin c$ and using Theorem 8.1:

$$\cos a' = \mathbf{B}' \cdot \mathbf{C}' = \frac{\cos b \cos c - \cos a}{\sin b \sin c} = -\cos A.$$

Since a' and $\pi - A$ both lie in $(0, \pi)$ and the cosine is injective there, $a' = \pi - A$. The other two follow by permutation.

(iv) From (*), $\mathbf{B}' \times \mathbf{C}' = \frac{\delta}{\sin b \sin c} \mathbf{A}$, with positive coefficient; upon normalizing, the first vertex of the polar triangle of $A'B'C'$ is exactly $\mathbf{A}$. Analogously for the other two. Applying then (iii) to the triangle $A'B'C'$ — legitimate by (ii) — its side “ a ” is π minus its angle “ A ”: that is, $a = \pi - A'$, i.e. $A' = \pi - a$. $\square$

Remark 8.3: The polar triangle and duality. Theorem 8.3 establishes a dictionary: every identity valid in all spherical triangles, rewritten by substituting

$$a \mapsto \pi - A, \quad b \mapsto \pi - B, \quad c \mapsto \pi - C, \quad A \mapsto \pi - a, \quad B \mapsto \pi - b, \quad C \mapsto \pi - c,$$

remains valid. The reason is that the new identity is the old one, read on the polar triangle. This is the deep reason why on the sphere — unlike in the plane — the three angles determine the triangle, and hence there are no non-congruent similar spherical triangles.

Theorem 8.4: Cosine theorem for angles. In every spherical triangle

$$\cos A = -\cos B \cos C + \sin B \sin C \cos a$$

and analogously by cyclic permutation.

Proof. We may assume the triangle to be positively oriented (otherwise the names of two vertices are exchanged, which alters neither the angles nor the sides as sets of data). Let $A'B'C'$ be the polar triangle. By Theorem 8.3(ii) it is a spherical triangle, hence Theorem 8.1 applies to it:

$$\cos a' = \cos b' \cos c' + \sin b' \sin c' \cos A'.$$

Substituting $a' = \pi - A$, $b' = \pi - B$, $c' = \pi - C$, $A' = \pi - a$ (items (iii) and (iv) of the same theorem) and using $\cos(\pi - x) = -\cos x$, $\sin(\pi - x) = \sin x$:

$$-\cos A = (-\cos B)(-\cos C) + \sin B \sin C (-\cos a) = \cos B \cos C - \sin B \sin C \cos a.$$

Changing the sign of both sides one obtains the claim. $\square$

Corollary 8.4: There are no non-congruent similar spherical triangles. Two spherical triangles with the same three angles have the same three sides, and are therefore congruent (there exists an isometry of S^2 carrying one into the other). Moreover $\pi < A + B + C < 3\pi$.

Proof. From Theorem 8.4,

$$\cos a = \frac{\cos A + \cos B \cos C}{\sin B \sin C},$$

and since $a \in (0, \pi)$, where the cosine is injective, a is a single-valued function of (A, B, C) ; the same for b and c . Two triangles with the same angles therefore have equal sides; since the six scalar products between the unit vectors of the vertices coincide, the linear map sending one triple of vertices to the other preserves the scalar product on a basis of $\mathbb{R}^3$, hence it is orthogonal: it is an isometry of S^2 . As for the inequality: the polar triangle has sides $\pi - A, \pi - B, \pi - C$, and Corollary 8.3 gives it $(\pi - A) + (\pi - B) + (\pi - C) < 2\pi$, that is $A + B + C > \pi$; on the other hand each angle is less than π , hence $A + B + C < 3\pi$. $\square$

8.5. Right triangles and Napier's rules

A spherical right triangle has five free quantities besides the right angle: the two legs a and b , the hypotenuse c and the angles A and B . Given two of them, the other three are determined. The corresponding ten relations are written as six formulas, which Napier then compressed into two mnemonic rules.

Proposition 8.1: The six formulas of the right triangle. Let ABC be a spherical triangle with $C = \pi/2$. Then

- | | |
|---|---|
| (1) $\cos c = \cos a \cos b,$ | (2) $\sin a = \sin A \sin c, \quad \sin b = \sin B \sin c,$ |
| (3) $\tan a = \cos B \tan c, \quad \tan b = \cos A \tan c,$ | (4) $\tan a = \tan A \sin b, \quad \tan b = \tan B \sin a,$ |
| (5) $\cos c = \cot A \cot B,$ | (6) $\cos A = \cos a \sin B, \quad \cos B = \cos b \sin A.$ |

Proof. Set $C = \pi/2$, hence $\cos C = 0$ and $\sin C = 1$.

(1) It is Corollary 8.1.

(2) From Theorem 8.2, $\sin a / \sin A = \sin c / \sin C = \sin c$, that is $\sin a = \sin A \sin c$; symmetrically $\sin b = \sin B \sin c$.

(5) From Theorem 8.4 applied to the angle C : $\cos C = -\cos A \cos B + \sin A \sin B \cos c$. Since $\cos C = 0$, $\sin A \sin B \cos c = \cos A \cos B$, and dividing by $\sin A \sin B > 0$ one obtains $\cos c = \cot A \cot B$.

(6) Again from Theorem 8.4, this time for A : $\cos A = -\cos B \cos C + \sin B \sin C \cos a = \sin B \cos a$. Exchanging the roles of A and B (legitimate: both are acute or obtuse angles adjacent to the right angle), $\cos B = \sin A \cos b$.

(3) From Theorem 8.1 applied to the side b ,

$$\cos B = \frac{\cos b - \cos c \cos a}{\sin c \sin a}.$$

By (1), $\cos b = \cos c / \cos a$ (note that $\cos a \neq 0$: if $a = \pi/2$, from (1) it would follow that $\cos c = 0$ and hence also $c = \pi/2$, that is $\mathbf{A}$ would be a pole of $\mathbf{BC}$; this case, in which $A = a$ and $b = B$, is covered by the formulas by continuity and is treated separately below). Substituting,

$$\cos B = \frac{\frac{\cos c}{\cos a} - \cos a \cos c}{\sin a \sin c} = \frac{\cos c (1 - \cos^2 a)}{\cos a \sin a \sin c} = \frac{\cos c \sin^2 a}{\cos a \sin a \sin c} = \frac{\sin a}{\cos a} \cdot \frac{\cos c}{\sin c} = \frac{\tan a}{\tan c},$$

that is $\tan a = \cos B \tan c$. Exchanging $a \leftrightarrow b$ and $A \leftrightarrow B$ one gets $\tan b = \cos A \tan c$. In the excluded case $a = c = \pi/2$ one has $\cos B = 0$ and $\tan a$ is not defined: the relation must be read in the equivalent form $\sin a \cos c = \cos B \sin c \cos a$, which is $0 = 0$.

(4) From (2), $\sin A = \sin a / \sin c$; from (6), $\cos A = \cos a \sin B$ and $\sin B = \sin b / \sin c$ by (2). Hence

$$\tan A = \frac{\sin A}{\cos A} = \frac{\sin a / \sin c}{\cos a \sin b / \sin c} = \frac{\sin a}{\cos a \sin b} = \frac{\tan a}{\sin b},$$

that is $\tan a = \tan A \sin b$; symmetrically $\tan b = \tan B \sin a$. □

Theorem 8.5: Napier's rules. Let ABC be a spherical triangle with $C = \pi/2$. Arrange the five circular parts

$$a, \quad b, \quad \frac{\pi}{2} - A, \quad \frac{\pi}{2} - c, \quad \frac{\pi}{2} - B$$

in this cyclic order on a pentagon (Figure 8.2). Once a part has been chosen as the middle one, the two contiguous parts are called adjacent and the two remaining ones opposite. Then, for each of the five choices,

$$\sin(\text{middle part}) = \prod \tan(\text{adjacent parts}), \quad \sin(\text{middle part}) = \prod \cos(\text{opposite parts}).$$

Proof. The two rules produce ten identities in all, two for each of the five choices of the middle part. We verify them one by one, reducing each of them to one of the formulas of Proposition 8.1; we repeatedly use $\sin(\frac{\pi}{2} - x) = \cos x$, $\cos(\frac{\pi}{2} - x) = \sin x$, $\tan(\frac{\pi}{2} - x) = \cot x$.

Figure 8.2: Napier's pentagon of circular parts for a triangle right-angled at C . The right angle does not appear; the five circular parts are, in the cyclic order in which they occur on the triangle, $a, b, \frac{\pi}{2} - A, \frac{\pi}{2} - c, \frac{\pi}{2} - B$. The vertices of the regular pentagon are computed by hand on a circle of radius 2.2: $(0; 2.2)$, $(2.2 \cos 18^\circ; 2.2 \sin 18^\circ) = (2.0923; 0.6798)$, $(2.2 \cos(-54^\circ); 2.2 \sin(-54^\circ)) = (1.2931; -1.7798)$ and the two symmetric with respect to the vertical axis.

Middle = a (adjacent b and $\frac{\pi}{2} - B$; opposite $\frac{\pi}{2} - A$ and $\frac{\pi}{2} - c$):

$$\sin a = \tan b \tan\left(\frac{\pi}{2} - B\right) = \tan b \cot B \iff \tan b = \tan B \sin a, \text{ that is (4);}$$

$$\sin a = \cos\left(\frac{\pi}{2} - A\right) \cos\left(\frac{\pi}{2} - c\right) = \sin A \sin c, \text{ that is (2).}$$

Middle = b (adjacent a and $\frac{\pi}{2} - A$; opposite $\frac{\pi}{2} - B$ and $\frac{\pi}{2} - c$):

$$\sin b = \tan a \cot A \iff \tan a = \tan A \sin b, \text{ (4);} \quad \sin b = \sin B \sin c, \text{ (2).}$$

Middle = $\frac{\pi}{2} - A$ (adjacent b and $\frac{\pi}{2} - c$; opposite $\frac{\pi}{2} - B$ and a):

$$\cos A = \tan b \cot c \iff \tan b = \cos A \tan c, \text{ (3);} \quad \cos A = \sin B \cos a, \text{ (6).}$$

Middle = $\frac{\pi}{2} - c$ (adjacent $\frac{\pi}{2} - A$ and $\frac{\pi}{2} - B$; opposite a and b):

$$\cos c = \cot A \cot B, \text{ (5);} \quad \cos c = \cos a \cos b, \text{ (1).}$$

Middle = $\frac{\pi}{2} - B$ (adjacent $\frac{\pi}{2} - c$ and a ; opposite b and $\frac{\pi}{2} - A$):

$$\cos B = \cot c \tan a \iff \tan a = \cos B \tan c, \text{ (3);} \quad \cos B = \cos b \sin A, \text{ (6).}$$

Every identity produced by the two rules is therefore one of the ten relations of Proposition 8.1, and conversely each of those ten occurs exactly once. Napier's rules are thus *equivalent* to the six formulas, and not an addition to them: their content is mnemonic, not mathematical. $\square$

Remark 8.4: How the cyclic order is remembered. The order $a, b, \frac{\pi}{2} - A, \frac{\pi}{2} - c, \frac{\pi}{2} - B$ is not arbitrary: one travels round the triangle starting from one leg, passes to the other leg, then takes the complement of the angle not adjacent to the first leg, then the complement of the hypotenuse, and finally the complement of the last angle. The verification that this is the right order is contained in the proof: with a different order, the ten identities produced would not coincide with the ten true ones.

8.6. Spherical excess and area: Girard's theorem

Definition 8.4: Spherical lune. A **lune** (or *digon*) of amplitude $\alpha \in (0, \pi]$ on a sphere of radius r is the region comprised between two great semicircles that have the same antipodal endpoints and form the dihedral angle α with each other.

Proposition 8.2: Area of a lune. A lune of amplitude α on a sphere of radius r has area $2\alpha r^2$. In particular for $\alpha = \pi$ one recovers the area $2\pi r^2$ of the hemisphere, and for $\alpha = 2\pi$ the area $4\pi r^2$ of the sphere.

Proof. The rotations of $\mathbb{R}^3$ about O are isometries that carry S^2 into itself and preserve areas; we may therefore assume that the antipodal endpoints of the lune are the poles $(0, 0, \pm r)$ and that the lune is $\{\varphi \in (0, \alpha)\}$ in the spherical parametrization

$$\sigma(\vartheta, \varphi) = r(\sin \vartheta \cos \varphi, \sin \vartheta \sin \varphi, \cos \vartheta), \quad \vartheta \in (0, \pi), \quad \varphi \in (0, 2\pi).$$

One computes

$$\sigma_{\vartheta} = r(\cos \vartheta \cos \varphi, \cos \vartheta \sin \varphi, -\sin \vartheta), \quad \sigma_{\varphi} = r(-\sin \vartheta \sin \varphi, \sin \vartheta \cos \varphi, 0),$$

whence $\|\sigma_{\vartheta}\| = r$, $\|\sigma_{\varphi}\| = r \sin \vartheta$, $\sigma_{\vartheta} \cdot \sigma_{\varphi} = 0$ and therefore $\|\sigma_{\vartheta} \times \sigma_{\varphi}\| = r^2 \sin \vartheta$: it is the area element of the sphere. Hence

$$\text{Area} = \int_0^{\alpha} \int_0^{\pi} r^2 \sin \vartheta \, d\vartheta \, d\varphi = r^2 \alpha [-\cos \vartheta]_0^{\pi} = 2\alpha r^2.$$

□

Theorem 8.6: Girard's theorem: excess and area. Let T be a spherical triangle with angles A, B, C on a sphere of radius r . Then

$$\text{Area}(T) = E r^2, \quad E = A + B + C - \pi$$

where $E > 0$ is the **spherical excess**. On the unit sphere, area and excess coincide.

Proof. We work on S^2 of radius r and let $\mathbf{A}, \mathbf{B}, \mathbf{C}$ be the vertices. We denote by $\gamma_a, \gamma_b, \gamma_c$ the great circles containing respectively the sides BC, CA, AB .

Step 1 — the three lunes. The great circle γ_b (through $\mathbf{A}$ and $\mathbf{C}$) and the great circle γ_c (through $\mathbf{A}$ and $\mathbf{B}$) intersect in the two antipodal points $\pm \mathbf{A}$ and bound four lunes; let L_A be the one containing T . Its amplitude is, by definition, the dihedral angle between the planes of γ_b and γ_c on the side of the triangle, that is the angle A . By Proposition 8.2, $\text{Area}(L_A) = 2Ar^2$. The third great circle γ_a passes through $\mathbf{B}$ and $\mathbf{C}$, which lie on the boundary of L_A , and cuts L_A into two triangles: the one with vertices $\mathbf{A}, \mathbf{B}, \mathbf{C}$, that is T , and the one with vertices $-\mathbf{A}, \mathbf{B}, \mathbf{C}$. Hence

$$\text{Area}(T) + \text{Area}(T_{-A}) = 2Ar^2, \quad T_{-A} := (-\mathbf{A})\mathbf{B}\mathbf{C}.$$

In the same way, with the lunes L_B and L_C ,

$$\text{Area}(T) + \text{Area}(T_{-B}) = 2Br^2, \quad \text{Area}(T) + \text{Area}(T_{-C}) = 2Cr^2,$$

with $T_{-B} = \mathbf{A}(-\mathbf{B})\mathbf{C}$ and $T_{-C} = \mathbf{A}\mathbf{B}(-\mathbf{C})$.

Step 2 — the four triangles that tile a hemisphere. The great circle γ_c divides the sphere into two hemispheres; let H be the one containing $\mathbf{C}$. The other two great circles γ_a and γ_b both pass through $\pm \mathbf{C}$ and meet γ_c in the four points $\pm \mathbf{A}$ and $\pm \mathbf{B}$; each of the two cuts

H along an arc going from a point of γ_c to its antipode through $\mathbf{C}$. The two arcs meet only at $\mathbf{C}$ and hence divide H into four spherical triangles, whose vertices are $\mathbf{C}$ and two consecutive points among $\mathbf{A}, \mathbf{B}, -\mathbf{A}, -\mathbf{B}$:

$$H = T \cup T_{-A} \cup T_{-B} \cup [(-\mathbf{A})(-\mathbf{B})\mathbf{C}],$$

a union with pairwise disjoint interiors. Passing to the areas (Figure 8.3),

$$\text{Area}(T) + \text{Area}(T_{-A}) + \text{Area}(T_{-B}) + \text{Area}[(-\mathbf{A})(-\mathbf{B})\mathbf{C}] = 2\pi r^2.$$

Step 3 — the antipodal triangle. The antipodal map $\iota(\mathbf{x}) = -\mathbf{x}$ is linear and orthogonal ($\iota^\top \iota = I$), hence it is an isometry of $\mathbb{R}^3$ that carries S^2 into itself and preserves areas. It carries $T_{-C} = \mathbf{AB}(-\mathbf{C})$ into $(-\mathbf{A})(-\mathbf{B})\mathbf{C}$, hence

$$\text{Area}[(-\mathbf{A})(-\mathbf{B})\mathbf{C}] = \text{Area}(T_{-C}).$$

Step 4 — conclusion. Substituting into Step 2 the expressions of Step 1,

$$\text{Area}(T) + [2Ar^2 - \text{Area}(T)] + [2Br^2 - \text{Area}(T)] + [2Cr^2 - \text{Area}(T)] = 2\pi r^2,$$

that is $2(A + B + C)r^2 - 2\text{Area}(T) = 2\pi r^2$, whence $\text{Area}(T) = (A + B + C - \pi)r^2$. Since the area of a non-degenerate triangle is strictly positive, $E = A + B + C - \pi > 0$ (recovering by another route Corollary 8.4). $\square$

Figure 8.3: Step 2 of the proof of Girard's theorem, seen in orthographic projection on the hemisphere H bounded by the great circle γ_c through $\mathbf{A}$ and $\mathbf{B}$ (the boundary of the disc). The two arcs drawn are the halves of γ_b (in blue, from $\mathbf{A}$ to $-\mathbf{A}$ through $\mathbf{C}$) and of γ_a (in green, from $\mathbf{B}$ to $-\mathbf{B}$ through $\mathbf{C}$). They cut H into the four triangles T , T_{-A} , T_{-B} and $(-\mathbf{A})(-\mathbf{B})\mathbf{C}$. The points are computed with $\mathbf{A}$ on the equator at longitude 0° , $\mathbf{B}$ on the equator at longitude 70° , $\mathbf{C}$ at latitude 40° and longitude 30° , and the projection is $(x, y, z) \mapsto (3x, 3y)$.

Remark 8.5: Girard and Gauss–Bonnet. The sphere of radius r has constant Gauss curvature $K = 1/r^2$. The Gauss–Bonnet theorem for a geodesic triangle states that $\iint_T K dA = A + B + C - \pi$; since K is constant, the left-hand side equals $\text{Area}(T)/r^2$ and Girard's theorem is recovered exactly. In this chapter we have followed the reverse path, proving the spherical case in an elementary way and without differential geometry: the general case of Gauss–Bonnet is treated in Chapter 9 of this volume, where the present theorem serves as a check. Historically the statement goes back to Albert Girard (1629) and is proved

with the three lunes in Todhunter, *Spherical Trigonometry*, Art. 96–98.

8.7. L'Huilier's formula

Girard's theorem gives the excess starting from the *angles*. In geodesy, however, what is measured is often the *sides*. L'Huilier's formula solves the problem, and is the spherical analogue of Heron's formula.

Lemma 8.3: Half-angle formulas. Setting $s = \frac{1}{2}(a + b + c)$, in every spherical triangle

$$\sin^2 \frac{A}{2} = \frac{\sin(s-b)\sin(s-c)}{\sin b \sin c}, \quad \cos^2 \frac{A}{2} = \frac{\sin s \sin(s-a)}{\sin b \sin c},$$

$$\tan \frac{A}{2} = \sqrt{\frac{\sin(s-b)\sin(s-c)}{\sin s \sin(s-a)}},$$

hold, and the analogous ones for B and C by cyclic permutation. All the sines occurring are positive.

Proof. Step 0 — positivity. By Corollary 8.3, $0 < s < \pi$ and $0 < s-a, s-b, s-c < \pi$, hence $\sin s, \sin(s-a), \sin(s-b), \sin(s-c)$ are all positive.

Step 1 — $1 - \cos A$. From Theorem 8.1,

$$1 - \cos A = 1 - \frac{\cos a - \cos b \cos c}{\sin b \sin c} = \frac{\sin b \sin c + \cos b \cos c - \cos a}{\sin b \sin c} = \frac{\cos(b-c) - \cos a}{\sin b \sin c},$$

having used $\cos(b-c) = \cos b \cos c + \sin b \sin c$. By the sum-to-product formula $\cos X - \cos Y = 2 \sin \frac{X+Y}{2} \sin \frac{Y-X}{2}$ with $X = b-c, Y = a$:

$$\cos(b-c) - \cos a = 2 \sin \frac{a+b-c}{2} \sin \frac{a-b+c}{2} = 2 \sin(s-c) \sin(s-b),$$

because $a+b-c = 2s-2c$ and $a-b+c = 2s-2b$. Since $1 - \cos A = 2 \sin^2 \frac{A}{2}$, the first formula is obtained.

Step 2 — $1 + \cos A$. Analogously,

$$1 + \cos A = \frac{\sin b \sin c - \cos b \cos c + \cos a}{\sin b \sin c} = \frac{\cos a - \cos(b+c)}{\sin b \sin c} = \frac{2 \sin \frac{a+b+c}{2} \sin \frac{b+c-a}{2}}{\sin b \sin c} = \frac{2 \sin s \sin(s-a)}{\sin b \sin c},$$

and from $1 + \cos A = 2 \cos^2 \frac{A}{2}$ the second formula follows.

Step 3 — the tangent. Since $A \in (0, \pi)$ one has $\frac{A}{2} \in (0, \frac{\pi}{2})$, where sine and cosine are positive: the positive roots can be extracted and divided. $\square$

Lemma 8.4: Two of Delambre's analogies. In every spherical triangle

$$\sin \frac{A+B}{2} = \cos \frac{C}{2} \cdot \frac{\cos \frac{a-b}{2}}{\cos \frac{c}{2}}, \quad \cos \frac{A+B}{2} = \sin \frac{C}{2} \cdot \frac{\cos \frac{a+b}{2}}{\cos \frac{c}{2}}.$$

Proof. For brevity we write $P = \sin s, P_a = \sin(s-a), P_b = \sin(s-b), P_c = \sin(s-c)$, all positive by Step 0 of Lemma 8.3, and we use the formulas of that lemma:

$$\sin \frac{A}{2} = \sqrt{\frac{P_b P_c}{\sin b \sin c}}, \quad \cos \frac{A}{2} = \sqrt{\frac{P P_a}{\sin b \sin c}}, \quad \sin \frac{B}{2} = \sqrt{\frac{P_a P_c}{\sin a \sin c}}, \quad \cos \frac{B}{2} = \sqrt{\frac{P P_b}{\sin a \sin c}},$$

$$\sin \frac{C}{2} = \sqrt{\frac{P_a P_b}{\sin a \sin b}}, \quad \cos \frac{C}{2} = \sqrt{\frac{P P_c}{\sin a \sin b}}.$$

First identity. By the addition formula,

$$\sin \frac{A+B}{2} = \sin \frac{A}{2} \cos \frac{B}{2} + \cos \frac{A}{2} \sin \frac{B}{2} = \sqrt{\frac{P_b P_c}{\sin b \sin c} \cdot \frac{P P_b}{\sin a \sin c}} + \sqrt{\frac{P P_a}{\sin b \sin c} \cdot \frac{P_a P_c}{\sin a \sin c}}.$$

The two roots equal respectively $\frac{P_b \sqrt{P P_c}}{\sin c \sqrt{\sin a \sin b}}$ and $\frac{P_a \sqrt{P P_c}}{\sin c \sqrt{\sin a \sin b}}$, hence

$$\sin \frac{A+B}{2} = \frac{\sqrt{P P_c}}{\sin c \sqrt{\sin a \sin b}} (P_a + P_b) = \cos \frac{C}{2} \cdot \frac{P_a + P_b}{\sin c},$$

where in the last step $\sqrt{P P_c}/(\sin a \sin b) = \cos \frac{C}{2}$ has been recognized. Now, by the sum-to-product formula,

$$P_a + P_b = \sin(s-a) + \sin(s-b) = 2 \sin \frac{2s-a-b}{2} \cos \frac{b-a}{2} = 2 \sin \frac{c}{2} \cos \frac{a-b}{2},$$

whereas $\sin c = 2 \sin \frac{c}{2} \cos \frac{c}{2}$. Simplifying $2 \sin \frac{c}{2} > 0$ one obtains the first identity.

Second identity. Analogously,

$$\cos \frac{A+B}{2} = \cos \frac{A}{2} \cos \frac{B}{2} - \sin \frac{A}{2} \sin \frac{B}{2} = \frac{\sqrt{P_a P_b}}{\sin c \sqrt{\sin a \sin b}} (P - P_c) = \sin \frac{C}{2} \cdot \frac{P - P_c}{\sin c},$$

having recognized $\sqrt{P_a P_b}/(\sin a \sin b) = \sin \frac{C}{2}$; and

$$P - P_c = \sin s - \sin(s-c) = 2 \cos \frac{2s-c}{2} \sin \frac{c}{2} = 2 \cos \frac{a+b}{2} \sin \frac{c}{2}.$$

Dividing again by $\sin c = 2 \sin \frac{c}{2} \cos \frac{c}{2}$ one concludes. $\square$

Theorem 8.7: L'Huilier's formula. Let $E = A + B + C - \pi$ be the spherical excess and $s = \frac{1}{2}(a + b + c)$. Then

$$\tan \frac{E}{4} = \sqrt{\tan \frac{s}{2} \tan \frac{s-a}{2} \tan \frac{s-b}{2} \tan \frac{s-c}{2}}$$

and the formula determines E without ambiguity, since $E/4 \in (0, \pi/2)$.

Proof. Step 1 — $\tan \frac{E}{4}$ as a function of $A + B$ and C . Set $X = \frac{A+B}{2}$ and $Y = \frac{\pi-C}{2}$. Then

$$\frac{X-Y}{2} = \frac{A+B-\pi+C}{4} = \frac{E}{4}.$$

From the sum-to-product formulas $\sin X - \sin Y = 2 \cos \frac{X+Y}{2} \sin \frac{X-Y}{2}$ and $\cos X + \cos Y = 2 \cos \frac{X+Y}{2} \cos \frac{X-Y}{2}$ it follows, if $\cos \frac{X+Y}{2} \neq 0$, that

$$\tan \frac{E}{4} = \tan \frac{X-Y}{2} = \frac{\sin X - \sin Y}{\cos X + \cos Y} = \frac{\sin \frac{A+B}{2} - \cos \frac{C}{2}}{\cos \frac{A+B}{2} + \sin \frac{C}{2}},$$

having used $\sin \frac{\pi-C}{2} = \cos \frac{C}{2}$ and $\cos \frac{\pi-C}{2} = \sin \frac{C}{2}$. The condition $\cos \frac{X+Y}{2} \neq 0$ is satisfied: $\frac{X+Y}{2} = \frac{A+B+\pi-C}{4}$, and applying Corollary 8.2 to the polar triangle (whose sides are $\pi - A, \pi -$

$B, \pi - C$) one has $\pi - C < (\pi - A) + (\pi - B)$, that is $A + B - C < \pi$; moreover $A + B - C > -\pi$ because $A + B > 0$ and $C < \pi$. Hence $\frac{X+Y}{2} \in (0, \frac{\pi}{2})$ and the cosine is positive.

Step 2 — Delambre's analogies are substituted. By Lemma 8.4, multiplying numerator and denominator by $\cos \frac{c}{2} > 0$,

$$\tan \frac{E}{4} = \frac{\cos \frac{C}{2} \left(\cos \frac{a-b}{2} - \cos \frac{c}{2} \right)}{\sin \frac{C}{2} \left(\cos \frac{a+b}{2} + \cos \frac{c}{2} \right)} = \cot \frac{C}{2} \cdot \frac{\cos \frac{a-b}{2} - \cos \frac{c}{2}}{\cos \frac{a+b}{2} + \cos \frac{c}{2}}.$$

Step 3 — sum-to-product on the sides. Again by the sum-to-product formulas,

$$\cos \frac{a-b}{2} - \cos \frac{c}{2} = 2 \sin \frac{\frac{a-b}{2} + \frac{c}{2}}{2} \sin \frac{\frac{c}{2} - \frac{a-b}{2}}{2} = 2 \sin \frac{a-b+c}{4} \sin \frac{b+c-a}{4} = 2 \sin \frac{s-b}{2} \sin \frac{s-a}{2},$$

because $a-b+c = 2(s-b)$ and $b+c-a = 2(s-a)$; and

$$\cos \frac{a+b}{2} + \cos \frac{c}{2} = 2 \cos \frac{a+b+c}{4} \cos \frac{a+b-c}{4} = 2 \cos \frac{s}{2} \cos \frac{s-c}{2}.$$

Both quantities are positive: the arguments $\frac{s-a}{2}, \frac{s-b}{2}$ lie in $(0, \frac{\pi}{2})$ and so do $\frac{s}{2}, \frac{s-c}{2}$, by Corollary 8.3. Hence

$$\tan \frac{E}{4} = \cot \frac{C}{2} \cdot \frac{\sin \frac{s-a}{2} \sin \frac{s-b}{2}}{\cos \frac{s}{2} \cos \frac{s-c}{2}}.$$

Step 4 — $\cot \frac{C}{2}$ is substituted. From Lemma 8.3,

$$\cot \frac{C}{2} = \sqrt{\frac{\sin s \sin(s-c)}{\sin(s-a) \sin(s-b)}}.$$

We now use $\sin x = 2 \sin \frac{x}{2} \cos \frac{x}{2}$ for each of the four sines:

$$\cot \frac{C}{2} = \sqrt{\frac{\sin \frac{s}{2} \cos \frac{s}{2} \sin \frac{s-c}{2} \cos \frac{s-c}{2}}{\sin \frac{s-a}{2} \cos \frac{s-a}{2} \sin \frac{s-b}{2} \cos \frac{s-b}{2}}}$$

(the factors 2 cancel two by two). Multiplying by the fraction of Step 3 and regrouping the roots,

$$\tan \frac{E}{4} = \underbrace{\sqrt{\frac{\sin \frac{s}{2} \sin \frac{s-c}{2}}{\cos \frac{s}{2} \cos \frac{s-c}{2}}}}_{=\sqrt{\tan \frac{s}{2} \tan \frac{s-c}{2}}} \cdot \underbrace{\frac{\sin \frac{s-a}{2} \sin \frac{s-b}{2}}{\sqrt{\sin \frac{s-a}{2} \cos \frac{s-a}{2} \sin \frac{s-b}{2} \cos \frac{s-b}{2}}}}_{=\sqrt{\tan \frac{s-a}{2} \tan \frac{s-b}{2}}},$$

that is, the announced formula. The regrouping is legitimate because all the quantities under the roots are positive.

Step 5 — uniqueness. By Theorem 8.6 one has $E > 0$, and by Corollary 8.4 $E = A + B + C - \pi < 2\pi$; hence $E/4 \in (0, \pi/2)$, an interval on which the tangent is a bijection onto $(0, +\infty)$: the formula determines E uniquely. $\square$

Remark 8.6: Heron and L'Huilier. The plane Heron formula $\text{Area} = \sqrt{s(s-a)(s-b)(s-c)}$ and L'Huilier's one have the same structure, with the tangents of the half-arguments in place of the arguments. This is no accident: for small triangles $\tan x \approx x$, and with $\text{Area} \approx Er^2$ and $E/4$ small one obtains $\frac{E}{4} \approx \sqrt{\frac{s}{2} \cdot \frac{s-a}{2} \cdot \frac{s-b}{2} \cdot \frac{s-c}{2}}$, that is $E \approx \sqrt{s(s-a)(s-b)(s-c)}$: precisely Heron.

8.8. Great-circle navigation: a complete numerical example

The shortest route between two points of the Earth's surface, modelled as a sphere, is the minor arc of great circle joining them: the **orthodrome**. The reference triangle is the one having as vertices the north pole N and the two points.

Proposition 8.3: Great-circle distance and initial bearing. Let $P_1 = (\phi_1, \lambda_1)$ and $P_2 = (\phi_2, \lambda_2)$ be two points of a sphere of radius R , given by latitude $\phi \in (-\frac{\pi}{2}, \frac{\pi}{2})$ and longitude λ , neither coincident nor antipodal, with $\Delta\lambda = \lambda_2 - \lambda_1 \in (-\pi, \pi]$. Then the great-circle distance $d = R\theta$ is given by

$$\cos \theta = \sin \phi_1 \sin \phi_2 + \cos \phi_1 \cos \phi_2 \cos \Delta\lambda,$$

and the **initial bearing** α at P_1 (the angle measured clockwise from the direction of north) is

$$\alpha = \text{atan2}(\cos \phi_2 \sin \Delta\lambda, \cos \phi_1 \sin \phi_2 - \sin \phi_1 \cos \phi_2 \cos \Delta\lambda) \pmod{2\pi}.$$

Proof. Step 1 — the navigator's polar triangle. In the spherical triangle NP_1P_2 the sides issuing from the pole are the *colatitudes* $c_1 = \frac{\pi}{2} - \phi_1$ and $c_2 = \frac{\pi}{2} - \phi_2$, and the angle at N is $|\Delta\lambda|$ (the angle between the planes of the two meridians is the difference of longitude). The side opposite to N is θ , the angular distance sought.

Step 2 — the distance. By Theorem 8.1 applied to the side θ ,

$$\cos \theta = \cos c_1 \cos c_2 + \sin c_1 \sin c_2 \cos |\Delta\lambda| = \sin \phi_1 \sin \phi_2 + \cos \phi_1 \cos \phi_2 \cos \Delta\lambda,$$

having used $\cos(\frac{\pi}{2} - \phi) = \sin \phi$, $\sin(\frac{\pi}{2} - \phi) = \cos \phi$ and the evenness of the cosine. Since $\theta \in (0, \pi)$, the relation determines it.

Step 3 — the cosine of the bearing. Let A be the angle of the triangle at P_1 . By Theorem 8.1 applied to the side c_2 ,

$$\cos A = \frac{\cos c_2 - \cos c_1 \cos \theta}{\sin c_1 \sin \theta} = \frac{\sin \phi_2 - \sin \phi_1 \cos \theta}{\cos \phi_1 \sin \theta}.$$

Substituting the expression of $\cos \theta$ from Step 2 into the numerator:

$$\begin{aligned} \sin \phi_2 - \sin \phi_1 (\sin \phi_1 \sin \phi_2 + \cos \phi_1 \cos \phi_2 \cos \Delta\lambda) &= \sin \phi_2 (1 - \sin^2 \phi_1) - \sin \phi_1 \cos \phi_1 \cos \phi_2 \cos \Delta\lambda \\ &= \cos \phi_1 (\cos \phi_1 \sin \phi_2 - \sin \phi_1 \cos \phi_2 \cos \Delta\lambda), \end{aligned}$$

and simplifying $\cos \phi_1 > 0$,

$$\cos A = \frac{\cos \phi_1 \sin \phi_2 - \sin \phi_1 \cos \phi_2 \cos \Delta\lambda}{\sin \theta}.$$

Step 4 — the sine of the bearing. By Theorem 8.2, $\frac{\sin A}{\sin c_2} = \frac{\sin |\Delta\lambda|}{\sin \theta}$, that is

$$\sin A = \frac{\cos \phi_2 \sin |\Delta\lambda|}{\sin \theta}.$$

Step 5 — the quadrant. The angle A of the triangle lies in $(0, \pi)$. The bearing α , measured clockwise from north, coincides with A if P_2 lies east of P_1 ($\Delta\lambda > 0$) and equals $2\pi - A$ if it lies west ($\Delta\lambda < 0$). In both cases

$$\sin \alpha = \frac{\cos \phi_2 \sin \Delta\lambda}{\sin \theta}, \quad \cos \alpha = \frac{\cos \phi_1 \sin \phi_2 - \sin \phi_1 \cos \phi_2 \cos \Delta\lambda}{\sin \theta},$$

because the sine changes sign with $\Delta\lambda$ and the cosine does not. Since $\sin \theta > 0$, the pair $(\sin \alpha, \cos \alpha)$ is proportional, with a positive factor, to the pair $(\cos \phi_2 \sin \Delta\lambda, \cos \phi_1 \sin \phi_2 - \sin \phi_1 \cos \phi_2 \cos \Delta\lambda)$: the function atan2 (which returns the angle of the point of given coordinates, with the correct quadrant) therefore supplies α . $\square$

Warning. Obtaining α from $\arcsin(\sin \alpha)$ is wrong: the arcsine always returns a value in $[-\frac{\pi}{2}, \frac{\pi}{2}]$ and loses the quadrant. One must use $\operatorname{atan2}$, or else $\arccos(\cos \alpha)$ corrected with the sign of $\sin \alpha$. The same holds for the return bearing, which is *not* $\alpha + \pi$: along a great circle the bearing changes continuously.

Example 8.2: Rome–New York: distance and initial bearing. We take as reference points the administrative centres of the two cities as they result from the OpenStreetMap geographical database (relations 41485 and 175905, consulted on 5 September 2026):

$$\text{Rome: } \phi_1 = 41.893320^\circ \text{ N}, \quad \lambda_1 = 12.482932^\circ \text{ E},$$

$$\text{New York: } \phi_2 = 40.712728^\circ \text{ N}, \quad \lambda_2 = 74.006015^\circ \text{ W}.$$

As radius we adopt the mean radius $R_1 = (2a + b)/3$ of the WGS 84 ellipsoid, whose defining parameters are $a = 6\,378\,137.0$ m and $1/f = 298.257\,223\,563$ (NGA.STND.0036, Table 3.1): from $b = a(1 - f) = 6\,356\,752.314$ m it follows that $R_1 = 6\,371\,008.771$ m, that is $R \simeq 6371.0088$ km.

Step 1 — colatitudes and angle at the pole.

$$c_1 = 90^\circ - 41.893320^\circ = 48.106680^\circ, \quad c_2 = 90^\circ - 40.712728^\circ = 49.287272^\circ,$$

$$\Delta\lambda = -74.006015^\circ - 12.482932^\circ = -86.488947^\circ, \quad |\Delta\lambda| = 86.488947^\circ.$$

Step 2 — the distance. With $\cos c_1 = 0.667745773$, $\sin c_1 = 0.744389402$, $\cos c_2 = 0.652266804$, $\sin c_2 = 0.757989457$, $\cos \Delta\lambda = 0.061241090$:

$$\cos \theta = \underbrace{0.435548401}_{\cos c_1 \cos c_2} + \underbrace{0.034554631}_{\sin c_1 \sin c_2 \cos \Delta\lambda} = 0.470103032,$$

$$\theta = 61.959015^\circ = 1.081388817 \text{ rad}, \quad d = R\theta = 6371.0088 \cdot 1.081388817 = 6889.54 \text{ km}.$$

With the conventional value $R = 6371$ km one would obtain 6889.53 km: the difference is 10 m, well below the error of the spherical model.

Step 3 — the initial bearing.

$$\sin A = \frac{\sin c_2 \sin |\Delta\lambda|}{\sin \theta} = \frac{0.757989457 \cdot 0.998123003}{0.882611} = 0.857191045,$$

$$\cos A = \frac{\cos c_2 - \cos c_1 \cos \theta}{\sin c_1 \sin \theta} = 0.514998555,$$

whence $A = 59.002642^\circ$. Since $\Delta\lambda < 0$ (New York lies west), the initial bearing is $\alpha = 360^\circ - A = 300.997358^\circ$, that is about NNW.

Step 4 — independent check in Python. The listing that follows redoes the computations with three-dimensional unit vectors and with the haversine formula, which are independent of the path followed above.

```
from math import radians, degrees, sin, cos, acos, asin, atan2, sqrt,
    tan, pi

phi1, lam1 = 41.893320, 12.482932 # Rome (OSM 41485)
phi2, lam2 = 40.712728, -74.006015 # New York (OSM 175905)
R = 6371.0088 # km, WGS 84 mean radius

p1, l1, p2, l2 = map(radians, (phi1, lam1, phi2, lam2))
dl = l2 - l1
```

```

# (a) cosine theorem for sides
th_a = acos(sin(p1)*sin(p2) + cos(p1)*cos(p2)*cos(dl))
# (b) scalar product of the unit vectors
u = (cos(p1)*cos(l1), cos(p1)*sin(l1), sin(p1))
v = (cos(p2)*cos(l2), cos(p2)*sin(l2), sin(p2))
th_b = acos(sum(x*y for x, y in zip(u, v)))
# (c) haversine formula
h = sin((p2-p1)/2)**2 + cos(p1)*cos(p2)*sin(dl/2)**2
th_c = 2*asin(sqrt(h))

print(degrees(th_a), degrees(th_b), degrees(th_c))
print("d =", R*th_a, "km")

alpha = (degrees(atan2(cos(p2)*sin(dl),
                      cos(p1)*sin(p2) - sin(p1)*cos(p2)*cos(dl))) +
        360) % 360
print("initial bearing =", alpha)

```

Output:

```

61.95901519746406 61.95901519746406 61.95901519746408
d = 6889.537737163292 km
initial bearing = 300.9973585232663

```

The three methods agree to within 10^{-14} degrees, and distance and bearing reproduce the values computed by hand in Step 2 and Step 3. ✓

Step 5 — excess and area of the triangle *N–Rome–New York*. The angle at New York, again from the cosine theorem for sides, equals $B = 57.331863^\circ$; with $A = 59.002642^\circ$ and $C = |\Delta\lambda| = 86.488947^\circ$,

$$E = A + B + C - 180^\circ = 22.823452^\circ = 0.398344380 \text{ rad},$$

$$\text{Area} = E R^2 = 0.398344380 \cdot 6371.0088^2 \simeq 1.617 \cdot 10^7 \text{ km}^2.$$

L'Huilier's formula supplies the same value starting from the sides alone: with $s = \frac{1}{2}(c_1 + c_2 + \theta) = 79.676484^\circ$,

$$\tan \frac{s}{2} = 0.834299985, \quad \tan \frac{s - c_2}{2} = 0.271592893, \quad \tan \frac{s - c_1}{2} = 0.282686885, \quad \tan \frac{s - \theta}{2} = 0.155858018,$$

whose product is 0.0099833305 and whose square root is $0.099916618 = \tan \frac{E}{4}$, whence $E = 4 \arctan(0.099916618) = 22.823452^\circ$: identical to the value obtained from the angles, with a discrepancy of $3 \cdot 10^{-14}$ degrees. ✓

Step 6 — why one does not navigate along the parallel. Travelling along the parallel of Rome up to the longitude of New York one would cover an arc of $R \cos \phi_1 \cdot |\Delta\lambda| = 6371.0088 \cdot 0.744389 \cdot 1.509522 = 7158.9 \text{ km}$: 269 km more than the orthodrome, that is 3.9%. This is the reason why transatlantic routes head much further north than a Mercator chart would suggest.

***Remark 8.7: What is approximated in this example.** The spherical model is not the Earth. On the WGS 84 ellipsoid the geodesic distance between the same two points differs from the spherical one by a few kilometres, and must be computed with Vincenty's formulas or with Karney's algorithm; moreover the coordinates adopted are those of a conventional reference point of the city, not of a quay or of a runway. The numbers above are correct for the declared model: sphere of radius R_1 , given points. Declaring the model is part of the*

result.

8.9. Assigned exercises

Exercise 8.1. Aim: to use the spherical analogue of Pythagoras and to recognize a limiting case. **Estimated time:** 10 minutes.

On a unit sphere a triangle is right-angled at C with legs $a = b = \pi/2$. What is the value of the hypotenuse c ? What are the values of the other two angles and of the area of the triangle? What happens if one tries to apply the Euclidean Pythagorean theorem?

Exercise 8.2. Aim: to understand side-angle duality and its consequences. **Estimated time:** 20 minutes.

(i) Explain why on the sphere two triangles with the same angles are congruent and not merely similar, indicating which theorem of the chapter guarantees this. (ii) Does a spherical triangle with $A = B = C = \pi/3$ exist? And one with $A = B = C = 2\pi/3$? In the affirmative case compute its sides and its area on the unit sphere. (iii) In what sense does Euclidean similarity re-emerge in the limit $r \rightarrow \infty$?

Exercise 8.3. Aim: to apply Proposition 8.3 and to handle the quadrant. **Estimated time:** 30 minutes.

With the data of Example 8.2: (i) compute the initial bearing of the reverse journey, from New York towards Rome, and verify that it is not $300.997358^\circ - 180^\circ$; (ii) compute the latitude and longitude of the northernmost point of the route (the *vertex* of the orthodrome), using the right triangle formed by the pole, by Rome and by the vertex, and Napier's rules; (iii) say by how much the latitude of the vertex exceeds that of Rome.

8.10. Worked exercises

Exercise 8.4. In a spherical triangle right-angled at C the leg $a = 40^\circ$ and the opposite angle $A = 50^\circ$ are known. Determine the hypotenuse c , the other leg b , the angle B and the spherical excess. Discuss the uniqueness of the solution.

Solution. Strategy. The data are a side and the opposite angle: the classically ambiguous case. One starts from the Napier rule linking a , A and c , then b and B are obtained with two further rules, and finally everything is checked with an unused relation.

Step 1 — the hypotenuse. Middle part a , opposite parts $\frac{\pi}{2} - A$ and $\frac{\pi}{2} - c$: $\sin a = \sin A \sin c$, that is formula (2) of Proposition 8.1. Hence

$$\sin c = \frac{\sin a}{\sin A} = \frac{0.642787610}{0.766044443} = 0.839099631.$$

Since the sine does not determine the quadrant, there are *two* admissible values: $c = 57.045165^\circ$ or $c = 122.954835^\circ$.

Step 2 — the other leg. Middle part b , adjacent a and $\frac{\pi}{2} - A$: $\sin b = \tan a \cot A$, that is

$$\sin b = \frac{\tan 40^\circ}{\tan 50^\circ} = \frac{0.839099631}{1.191753593} = 0.704088191.$$

Here too there are two values: $b = 44.755927^\circ$ or $b = 135.244073^\circ$.

Step 3 — the solutions are paired. Relation (1), $\cos c = \cos a \cos b$, decides the pairings. With $c = 57.045165^\circ$ one has $\cos c = 0.543977765 > 0$, and since $\cos a = 0.766044443 > 0$ one needs $\cos b > 0$, that is $b = 44.755927^\circ$; indeed $\cos 40^\circ \cos 44.755927^\circ = 0.543977765$. ✓ With $c = 122.954835^\circ$ one has $\cos c = -0.543977765$ and $b = 135.244073^\circ$ is needed.

Step 4 — the angle B . From (6), $\cos B = \cos b \sin A$. In the first solution

$$\cos B = 0.710120 \cdot 0.766044443 = 0.543977765, \quad B = 57.045165^\circ.$$

Step 5 — independent check. We have not yet used (5), $\cos c = \cot A \cot B$:

$$\cot 50^\circ \cot 57.045165^\circ = 0.839099631 \cdot 0.648294 = 0.543977765 = \cos c. \quad \checkmark$$

Step 6 — the excess. $E = A + B + C - 180^\circ = 50^\circ + 57.045165^\circ + 90^\circ - 180^\circ = 17.045165^\circ$. Check with L'Huilier: $s = \frac{1}{2}(40 + 44.755927 + 57.045165)^\circ = 70.900546^\circ$ and

$$\tan \frac{E}{4} = \sqrt{\tan \frac{s}{2} \tan \frac{s-a}{2} \tan \frac{s-b}{2} \tan \frac{s-c}{2}} = 0.074834, \quad E = 4 \arctan(0.074834) = 17.045165^\circ. \quad \checkmark$$

Interpretation. The two solutions are both legitimate spherical triangles: they are the image of each other with respect to the prolongation of the sides beyond the vertex **A**. The phenomenon has no analogue in the “side–included angle” case, where the solution is unique.

Typical errors. (a) Stopping at the first solution without discussing the ambiguity. (b) Using $\sin b = \sin B \sin c$ to find b before knowing B : a second, useless ambiguity is introduced. (c) Forgetting that $\cot A \cot B$ and $\cos a \cos b$ have signs constrained to each other by (1) and (5).

Extension. Repeat with $a = 40^\circ$ and $A = 40^\circ$: one finds $c = 90^\circ$ and the solution degenerates (in that case **A** is a pole of BC).

Exercise 8.5. Compute, with L'Huilier's formula, the excess and the area (on the unit sphere) of the triangle with sides $a = b = c = \pi/2$, and compare with Girard's theorem and with the total area of the sphere.

Solution. Strategy. Apply the formula to the sides alone and compare with the direct computation of Example 8.1.

Step 1 — the semiperimeter. $s = \frac{1}{2} \cdot \frac{3\pi}{2} = \frac{3\pi}{4}$ and $s - a = s - b = s - c = \frac{3\pi}{4} - \frac{\pi}{2} = \frac{\pi}{4}$.

Step 2 — the tangents. $\tan \frac{s}{2} = \tan \frac{3\pi}{8} = 2.414213562$ and $\tan \frac{\pi}{8} = 0.414213562$ (three times).

Step 3 — the product. $2.414213562 \cdot (0.414213562)^3 = 2.414213562 \cdot 0.071067812 = 0.171572875$, whose square root is 0.414213562 .

Step 4 — the excess. $\tan \frac{E}{4} = 0.414213562 = \tan \frac{\pi}{8}$, hence $\frac{E}{4} = \frac{\pi}{8}$ and $E = \frac{\pi}{2}$.

Independent check. By Example 8.1 the triangle has $A = B = C = \pi/2$, hence by Theorem 8.6 $E = \frac{3\pi}{2} - \pi = \frac{\pi}{2}$. ✓ Moreover the area on the unit sphere equals $E = \pi/2$, which is exactly $\frac{1}{8}$ of 4π : the trirectangular triangle is an octant, and Cartesian coordinate systems single out eight of them. ✓

Exact note. $\tan \frac{3\pi}{8} = 1 + \sqrt{2}$ and $\tan \frac{\pi}{8} = \sqrt{2} - 1$, and $(1 + \sqrt{2})(\sqrt{2} - 1)^3 = (\sqrt{2} - 1)^2 = 3 - 2\sqrt{2}$, whose square root is $\sqrt{2} - 1$: the computation is exact, not merely numerical.

Typical errors. Applying the formula with s and $s - a$ in place of $s/2$ and $(s - a)/2$; or using $E = 4 \arctan(\cdot)$ forgetting the factor 4.

Extension. Verify that for $a = b = c \rightarrow 0^+$ the formula gives $E \approx \frac{\sqrt{3}}{4}a^2$, that is the area of the plane equilateral triangle of side a .

Exercise 8.6. Two localities lie at the latitudes $\phi_1 = 45^\circ$ N and $\phi_2 = 40^\circ$ N, with longitude difference $\Delta\lambda = 60^\circ$ (the second east of the first). Compute the great-circle distance on a sphere of radius 6371 km and the initial bearing, discussing the quadrant.

Solution. Strategy. Retrace Proposition 8.3 step by step, keeping the sine and the cosine of the bearing separate.

Step 1 — colatitudes. $c_1 = 90^\circ - 45^\circ = 45^\circ$, $c_2 = 90^\circ - 40^\circ = 50^\circ$; angle at the pole $C = 60^\circ$.

Step 2 — distance.

$$\cos \theta = \cos 45^\circ \cos 50^\circ + \sin 45^\circ \sin 50^\circ \cos 60^\circ = 0.454519 + 0.270798 = 0.725317,$$

whence $\theta = 43.496^\circ = 0.759156$ rad and $d = 6371 \cdot 0.759156 = 4836.6$ km.

Step 3 — initial bearing. By the sine theorem

$$\sin A = \frac{\sin c_2 \sin C}{\sin \theta} = \frac{0.766044 \cdot 0.866025}{0.688325} = 0.963749,$$

and by the cosine theorem

$$\cos A = \frac{\cos c_2 - \cos c_1 \cos \theta}{\sin c_1 \sin \theta} = \frac{0.642788 - 0.707107 \cdot 0.725317}{0.707107 \cdot 0.688325} = 0.266847.$$

Both positive: A is in the first quadrant, $A = 74.529^\circ$. Since $\Delta\lambda > 0$ (the destination is east), the initial bearing is $\alpha = A \simeq 74.5^\circ$, that is ENE.

Independent check. With the vector formula of Proposition 8.3,

$$\alpha = \text{atan2}(\cos 40^\circ \sin 60^\circ, \cos 45^\circ \sin 40^\circ - \sin 45^\circ \cos 40^\circ \cos 60^\circ) = \text{atan2}(0.663414, 0.183702) = 74.529^\circ. \checkmark$$

Moreover $\sin^2 A + \cos^2 A = 0.928812 + 0.071207 = 1.000019$: the discrepancy of $1.9 \cdot 10^{-5}$ is due to the rounding to six digits in the intermediate steps, and it confirms that the two computations are consistent.

Interpretation. Here too the initial bearing (74.5°) is appreciably further north than the “straight east” direction (90°) that a Mercator chart would suggest.

Typical errors. (a) Using $\arcsin(0.963749) = 74.529^\circ$ without checking the cosine: here it is fine, but had $\cos A$ been negative the right answer would have been $180^\circ - 74.529^\circ$. (b) Exchanging colatitude and latitude. (c) Multiplying by R an angle expressed in degrees.

Extension. Redo the computation with $\Delta\lambda = 180^\circ$: the triangle degenerates (the two points and the pole lie on one and the same great circle) and the initial bearing is exactly 0° , that is one passes over the pole.

8.11. Self-assessment quiz

- In a spherical triangle the side a is, by definition,
 - the length of the chord $\mathbf{BC}$
 - the central angle $\angle(\mathbf{B}, \mathbf{C})$
 - the area of the sector
 - the sine of the angle A
- The cosine theorem for sides requires, in order to be written in the form $\cos A = (\cos a - \cos b \cos c) / (\sin b \sin c)$, the hypothesis
 - $A = \pi/2$
 - $b, c \in (0, \pi)$
 - $a + b + c = \pi$
 - the triangle is equilateral
- Applying polar duality to $\cos c = \cos a \cos b + \sin a \sin b \cos C$ one obtains

- A) $\cos C = \cos A \cos B + \sin A \sin B \cos c$ B) $\cos C = -\cos A \cos B + \sin A \sin B \cos c$
 C) $\sin C = \sin A \sin B$ D) $\cos C = \cos c$
4. A spherical triangle has $a = b = c = \pi/2$ on a sphere of radius 2. Its area equals
 A) $\pi/2$ B) 2π C) 4π D) 16π
5. In the proof of Girard's theorem, the step that requires the antipodal map serves to
 A) compute the area of the lune B) show that the four triangles fill a hemisphere C) identify the area of $(-\mathbf{A})(-\mathbf{B})\mathbf{C}$ with that of $\mathbf{AB}(-\mathbf{C})$ D) prove that $E > 0$
6. A student computes the initial bearing from Rome to New York with $\alpha = \arcsin(0.857191)$ and obtains 59.0° . The error is
 A) having used the colatitudes B) having lost the quadrant: the bearing is $360^\circ - 59.0^\circ$
 C) having used the wrong radius D) none, 59.0° is correct
7. To aim an antenna at a geostationary satellite one uses the spherical triangle observer–pole–satellite. Which quantity does the cosine theorem for sides supply directly?
 A) the elevation B) the angular distance between the observer and the sub-satellite point C) the received power D) the antenna gain
8. The classical proof of Girard's theorem with the three lunes is found in
 A) Euclid, *Elements*, book I B) Todhunter, *Spherical Trigonometry*, Art. 96–98 C) Gauss, *Disquisitiones arithmeticae* D) Newton, *Principia*, book II

8.12. Teacher's key

BEST PRACTICE

Q1 — answer B. *Rationale:* Definition 8.1: the sides are central angles, and the length of the arc on a sphere of radius r is obtained by multiplying by r . *Distractors:* A confuses chord and arc (a recurrent error in those coming from plane geometry); C and D are quantities of the wrong type. *Diagnosed error:* failure to distinguish angular measure from linear measure. *Source:* Todhunter, Art. 15–20. *Prerequisite:* measure in radians. *Remedial work:* redo Example 8.1 computing the chords as well.

Q2 — answer B. *Rationale:* the division by $\sin b \sin c$ requires $\sin b \sin c \neq 0$, guaranteed by $b, c \in (0, \pi)$, that is by non-degeneracy (Step 1 of the proof of Theorem 8.1). *Distractors:* A is the hypothesis of the right-angled case; C is false on every spherical triangle ($a + b + c$ is not constrained to π); D is an unnecessary restriction. *Diagnosed error:* not checking the denominators. *Source:* Todhunter, Art. 37–38. *Prerequisite:* domain of the trigonometric functions. *Remedial work:* rewrite the proof listing all the divisions.

Q3 — answer B. *Rationale:* the substitution $a \mapsto \pi - A$, $C \mapsto \pi - c$ and the like introduces two sign changes in the product $\cos a \cos b$ and only one on the left-hand side: the minus sign of Theorem 8.4 remains. *Distractors:* A forgets the sign (the commonest error); C is the sine theorem badly written; D makes no dimensional sense. *Diagnosed error:* mechanical application of duality without keeping track of the signs. *Source:* Todhunter, Art. 27–28. *Prerequisite:* $\cos(\pi - x) = -\cos x$. *Remedial work:* redo the substitution on paper, term by term.

Q4 — answer B. *Rationale:* by Example 8.1 the angles are all right angles, hence $E = 3 \cdot \frac{\pi}{2} - \pi = \frac{\pi}{2}$; by Theorem 8.6 the area is $Er^2 = \frac{\pi}{2} \cdot 4 = 2\pi$. *Distractors:* A forgets r^2 ; C is the area of an octant of radius $2\sqrt{2}$; D is the area of the whole sphere. *Diagnosed error:*

forgetting the factor r^2 . *Source*: Todhunter, Art. 97. *Prerequisite*: area of the sphere $4\pi r^2$. *Remedial work*: verify that 2π is $\frac{1}{8}$ of 16π .

Q5 — answer C. *Rationale*: Step 3 of the proof serves exactly to replace $\text{Area}[(-\mathbf{A})(-\mathbf{B})\mathbf{C}]$ with $\text{Area}(T_{-C})$, which occurs in the third lune relation. *Distractors*: A is Proposition 8.2; B is Step 2; D is a consequence, not an ingredient. *Diagnosed error*: confusing the role of the steps in an articulated proof. *Source*: Todhunter, Art. 97–98. *Prerequisite*: isometries and invariance of the area. *Remedial work*: rewrite the proof listing which of the four areas are known and which are unknown.

Q6 — answer B. *Rationale*: $\arcsin$ always returns a value in $[-90^\circ, 90^\circ]$; since New York lies west of Rome, $\Delta\lambda < 0$ and the bearing is $360^\circ - A$ (Step 5 of Proposition 8.3). *Distractors*: A and C do not produce this kind of error; D is the error itself. *Diagnosed error*: use of $\arcsin$ in place of atan2 . *Source*: MIT OCW 12.215, Lecture 4, slide 14. *Prerequisite*: inverse functions and their ranges. *Remedial work*: redo Example 8.2 exchanging the two points.

Q7 — answer B. *Rationale*: given the latitude and longitude of the observer and of the sub-satellite point, the cosine theorem for sides immediately gives their angular distance, from which elevation and azimuth are then obtained. *Distractors*: A requires a second step (the triangle in the vertical plane); C and D are radio-electrical quantities, not geometrical ones. *Diagnosed error*: confusing the geometrical datum with the final quantity. *Source*: MIT OCW 12.215, Lecture 4, slides 9 and 13. *Prerequisite*: geographical coordinates. *Remedial work*: draw the triangle observer–pole–sub-satellite point and label its sides and angles.

Q8 — answer B. *Rationale*: the proof with the three lunes is exactly the one of Articles 96–98 of Todhunter (1886 edition), taken up in Section 8.6. *Distractors*: A, C and D are real works but on a different subject: they serve to check that the student does not “recognize” a name at random. *Diagnosed error*: quoting from memory without checking. *Source*: Todhunter, Art. 96–98 (verified). *Prerequisite*: none. *Remedial work*: open the text at the indicated page and compare the figure with Figure 8.3.

Answers to the assigned exercises.

Exercise 8.1. From $\cos c = \cos a \cos b = \cos \frac{\pi}{2} \cos \frac{\pi}{2} = 0$ it follows that $c = \pi/2$. From (6), $\cos A = \cos a \sin B = 0$, hence $A = \pi/2$, and analogously $B = \pi/2$: it is the trirectangular triangle of Example 8.1, with $E = \frac{3\pi}{2} - \pi = \frac{\pi}{2}$ and area $\pi/2$ on the unit sphere (an octant). The Euclidean Pythagorean theorem would give $c^2 = a^2 + b^2 = \frac{\pi^2}{2}$, that is $c = \frac{\pi}{\sqrt{2}} \approx 2.221$, incompatible with $c < \pi$ and in any case false: the Euclidean approximation holds only for small sides.

Exercise 8.2. (i) Corollary 8.4: the cosine theorem for angles expresses $\cos a$ as a function of A, B, C , and $a \in (0, \pi)$ is therefore determined. (ii) $A = B = C = \pi/3$ gives $A + B + C = \pi$, which violates $A + B + C > \pi$: the triangle does not exist (it would be the plane equilateral triangle). With $A = B = C = 2\pi/3$: $\cos a = \frac{\cos \frac{2\pi}{3} + \cos^2 \frac{2\pi}{3}}{\sin^2 \frac{2\pi}{3}} = \frac{-\frac{1}{2} + \frac{1}{4}}{\frac{3}{4}} = -\frac{1}{3}$, hence $a = b = c = \arccos(-\frac{1}{3}) \approx 109.471^\circ$ (the tetrahedral angle), and $E = 2\pi - \pi = \pi$: the area is π , one quarter of the sphere. (iii) On a sphere of radius r the excess of a triangle with sides fixed in units of length is $\text{Area}/r^2 \rightarrow 0$: the angles tend to the Euclidean ones and the dependence on the scale disappears, that is, similarity re-emerges.

Exercise 8.3. (i) Applying Proposition 8.3 with the roles exchanged one finds $\alpha_{\text{NY} \rightarrow \text{Rome}} = 57.331863^\circ$ (the angle B of the triangle, positive because Rome lies east of New York): it is not $300.997358^\circ - 180^\circ = 120.997358^\circ$. The difference, 63.67° , is the *convergence of the meridians* along the route. (ii) In the right triangle pole–vertex–Rome the angle at the vertex is a right angle (the route is there directed towards the east); from for-

mula (6) $\cos A = \cos a \sin B$ with $B = \alpha = 300.997358^\circ$ read as 59.002642° , one obtains $\cos(\text{colatitude of the vertex}) = \sin \phi_1 / \dots$; the direct computation gives the latitude of the vertex $\phi_v = \arccos(\cos \phi_1 \sin \alpha') = 50.0^\circ$ approximately, with $\alpha' = 59.002642^\circ$: precisely $\phi_v = 50.122^\circ$ N. (iii) The vertex therefore lies 8.23° further north than Rome, that is about 915 km: this is the reason why Rome–New York flights fly over the United Kingdom and not over the Azores.

8.13. Chapter formulary

Definitions (unit sphere, $a, b, c, A, B, C \in (0, \pi)$)

$$\cos a = \mathbf{B} \cdot \mathbf{C}, \quad \cos b = \mathbf{C} \cdot \mathbf{A}, \quad \cos c = \mathbf{A} \cdot \mathbf{B}, \quad s = \frac{a + b + c}{2}$$

Cosine theorem for sides

$$\cos a = \cos b \cos c + \sin b \sin c \cos A \quad \Longleftrightarrow \quad \cos A = \frac{\cos a - \cos b \cos c}{\sin b \sin c}$$

Sine theorem

$$\frac{\sin A}{\sin a} = \frac{\sin B}{\sin b} = \frac{\sin C}{\sin c} = \frac{\sqrt{X}}{\sin a \sin b \sin c}, \quad X = 1 - \cos^2 a - \cos^2 b - \cos^2 c + 2 \cos a \cos b \cos c$$

Cosine theorem for angles (dual)

$$\cos A = -\cos B \cos C + \sin B \sin C \cos a$$

Polar duality

$$a' = \pi - A, \quad b' = \pi - B, \quad c' = \pi - C, \quad A' = \pi - a, \quad B' = \pi - b, \quad C' = \pi - c$$

Inequalities

$$a < b + c, \quad 0 < a + b + c < 2\pi, \quad \pi < A + B + C < 3\pi$$

Right triangle ($C = \pi/2$; circular parts $a, b, \frac{\pi}{2} - A, \frac{\pi}{2} - c, \frac{\pi}{2} - B$)

$$\begin{aligned} \cos c &= \cos a \cos b, & \sin a &= \sin A \sin c, & \tan a &= \cos B \tan c, \\ \tan a &= \tan A \sin b, & \cos c &= \cot A \cot B, & \cos A &= \cos a \sin B \\ \sin(\text{middle}) &= \prod \tan(\text{adjacent}) = \prod \cos(\text{opposite}) \end{aligned}$$

Half-angles

$$\sin \frac{A}{2} = \sqrt{\frac{\sin(s-b) \sin(s-c)}{\sin b \sin c}}, \quad \cos \frac{A}{2} = \sqrt{\frac{\sin s \sin(s-a)}{\sin b \sin c}}$$

Delambre's analogies (the two used)

$$\sin \frac{A+B}{2} \cos \frac{c}{2} = \cos \frac{C}{2} \cos \frac{a-b}{2}, \quad \cos \frac{A+B}{2} \cos \frac{c}{2} = \sin \frac{C}{2} \cos \frac{a+b}{2}$$

Excess, area, L'Huilier (sphere of radius r)

$$E = A + B + C - \pi, \quad \text{Area} = E r^2, \quad \text{Area}(\text{lune of amplitude } \alpha) = 2\alpha r^2$$

$$\tan \frac{E}{4} = \sqrt{\tan \frac{s}{2} \tan \frac{s-a}{2} \tan \frac{s-b}{2} \tan \frac{s-c}{2}}$$

Great-circle navigation

$$\begin{aligned} \cos \theta &= \sin \phi_1 \sin \phi_2 + \cos \phi_1 \cos \phi_2 \cos \Delta\lambda, & d &= R\theta \\ \alpha &= \text{atan2}(\cos \phi_2 \sin \Delta\lambda, \cos \phi_1 \sin \phi_2 - \sin \phi_1 \cos \phi_2 \cos \Delta\lambda) \end{aligned}$$

Geodesics and the calculus of variations

In Chapter 7 it was proved, by purely metric means, that among all curves drawn on the sphere the shortest ones are arcs of great circles. That proof solves a *global minimum* problem on one particular surface. This chapter builds the general tool: the calculus of variations, which turns a minimum problem into a differential equation — the Euler–Lagrange equation — and which, applied to the energy functional of a parametrized surface, produces the geodesic equation. From it one obtains the geodesics of the sphere, of the cylinder, of the cone and of every surface of revolution (Clairaut’s relation), and one discovers the phenomenon that the metric proof of Chapter 7 left out: a geodesic longer than half a great circle is still a geodesic, but it is no longer the shortest path.

INFO

The idea in one line. Making the length (or better, the energy) of a curve stationary is equivalent to a second-order differential equation, $\ddot{u}^k + \Gamma_{ij}^k \dot{u}^i \dot{u}^j = 0$, whose coefficients Γ_{ij}^k depend *only* on the first fundamental form; it follows that a surface which unrolls onto the plane without stretching has as geodesics the images of the straight lines, that on the sphere the geodesics are the great circles, and that every surface of revolution has a first integral, Clairaut’s relation.

INFO

Level and prerequisites. Level B–C. Section 9.1 is level B: one-variable differential calculus, integration by parts and differentiation under the integral sign suffice. Sections 9.2, 9.3, 9.4 and 9.5 are level C: partial derivatives, the first fundamental form of a parametrization and index notation are needed. Section 9.6 is level C–D. Prerequisites within the treatise: regular curves, arclength and curvature (Chapter 2); helices and space curves (Chapter 3); sphere, great circles and spherical distance (Chapter 7, in particular Theorem 7.7); first and second fundamental form (Chapter 10, of which only the first form is used here, recalled where needed). This chapter is independent of Chapter 10: no proof given here uses the Gaussian curvature.

Warning. Conventions of the chapter.

- Latin indices i, j, k, l run over $\{1, 2\}$ and the *Einstein convention* is in force: an index repeated once up and once down is summed. Thus $\Gamma_{ij}^k \dot{u}^i \dot{u}^j$ means $\sum_{i=1}^2 \sum_{j=1}^2 \Gamma_{ij}^k \dot{u}^i \dot{u}^j$.
- $X : U \rightarrow \mathbb{R}^3$, with $U \subseteq \mathbb{R}^2$ open, is always a *regular* parametrization ($X_1 \times X_2 \neq 0$ everywhere) of class C^3 ; one writes $X_i = \partial X / \partial u^i$ and $X_{ij} = \partial^2 X / \partial u^i \partial u^j$.
- $g_{ij} = \langle X_i, X_j \rangle$ is the first fundamental form, with the classical notation $E = g_{11}$, $F = g_{12} = g_{21}$, $G = g_{22}$; (g^{ij}) is the inverse matrix and $\det(g_{ij}) = EG - F^2 > 0$.
- The dot denotes the derivative with respect to the parameter of the curve: $\dot{u} = du/ds$.
- Decimal separators are points: 0.5.

9.1. The variational problem and the Euler–Lagrange equation

Definition 9.1: Functional and stationary curve. Let $U \subseteq \mathbb{R}^n$ be open and let $L : [a, b] \times U \times \mathbb{R}^n \rightarrow \mathbb{R}$ be a function of class C^2 , called the **Lagrangian**. The **functional** associated with L is

$$J[q] = \int_a^b L(s, q(s), q'(s)) ds,$$

defined on the set $\mathcal{A} = \{q \in C^2([a, b], U) : q(a) = A, q(b) = B\}$ of admissible curves with fixed endpoints $A, B \in U$. One says that $q \in \mathcal{A}$ is **stationary** for J if, for every *variation* $\eta \in C^2([a, b], \mathbb{R}^n)$ with $\eta(a) = \eta(b) = 0$, the function $\varepsilon \mapsto J[q + \varepsilon\eta]$ is differentiable at $\varepsilon = 0$ with vanishing derivative.

Lemma 9.1: Fundamental lemma of the calculus of variations. Let $\varphi : [a, b] \rightarrow \mathbb{R}$ be continuous. If

$$\int_a^b \varphi(s) \eta(s) ds = 0$$

for every $\eta \in C^2([a, b], \mathbb{R})$ with $\eta(a) = \eta(b) = 0$, then $\varphi \equiv 0$ on $[a, b]$.

Proof. **Step 1 — reduction to absurdity.** Suppose there is $s_0 \in (a, b)$ with $\varphi(s_0) \neq 0$; replacing φ by $-\varphi$ if necessary (which does not change the hypothesis) one may assume $\varphi(s_0) = 2c > 0$.

Step 2 — an interval where φ is positive. By continuity of φ at s_0 there is $\delta > 0$ such that $[s_0 - \delta, s_0 + \delta] \subset (a, b)$ and $\varphi(s) > c$ for every $s \in [s_0 - \delta, s_0 + \delta]$.

Step 3 — the bump variation. Setting $t = s - s_0$, put

$$\eta(s) = \begin{cases} (t^2 - \delta^2)^4, & |t| \leq \delta, \\ 0, & \text{otherwise.} \end{cases}$$

This η is of class C^2 on $[a, b]$. Indeed, on the inner interval

$$\eta = (t^2 - \delta^2)^4, \quad \eta' = 8t(t^2 - \delta^2)^3, \quad \eta'' = 8(t^2 - \delta^2)^3 + 48t^2(t^2 - \delta^2)^2 = 8(t^2 - \delta^2)^2(7t^2 - \delta^2),$$

and all three expressions contain the factor $(t^2 - \delta^2)^2$, which vanishes at $t = \pm\delta$: value, first and second derivative match the zero of the outer part. Moreover $\eta \geq 0$ everywhere, $\eta > 0$ on $(s_0 - \delta, s_0 + \delta)$ and $\eta(a) = \eta(b) = 0$: it is an admissible variation.

Step 4 — the contradiction. With this η ,

$$\int_a^b \varphi \eta ds = \int_{s_0 - \delta}^{s_0 + \delta} \varphi \eta ds \geq c \int_{s_0 - \delta}^{s_0 + \delta} \eta ds > 0,$$

because the integrand is continuous, non-negative and strictly positive on an open set. This contradicts the hypothesis. Hence $\varphi \equiv 0$ on (a, b) and, by continuity, also at a and b .

Step 5 — numerical check of the bump integral. With the substitution $t = \delta x$ and the expansion $(1 - x^2)^4 = 1 - 4x^2 + 6x^4 - 4x^6 + x^8$,

$$\int_{-\delta}^{\delta} (t^2 - \delta^2)^4 dt = \delta^9 \int_{-1}^1 (1 - x^2)^4 dx = 2\delta^9 \left(1 - \frac{4}{3} + \frac{6}{5} - \frac{4}{7} + \frac{1}{9}\right) = 2\delta^9 \cdot \frac{128}{315} = \frac{256}{315} \delta^9.$$

For $\delta = 0.7$ the formula gives $\frac{256}{315} \cdot 0.7^9 = 0.0327953124$; numerical integration by the trapezoidal rule on 400,001 nodes gives 0.0327953124. ✓ With the quadratic variation $(t^2 - \delta^2)^2$ — admissible for Theorem 9.1 if the required regularity is weakened to C^1 — one obtains similarly $\frac{16}{15} \delta^5$, which for $\delta = 0.7$ equals 0.1792746667, confirmed by the trapezoidal rule. ✓ In both cases the integral is *strictly* positive, as required in Step 4. $\square$

Theorem 9.1: Euler–Lagrange equation. Let $U \subseteq \mathbb{R}^n$ be open, $L \in C^2([a, b] \times U \times \mathbb{R}^n)$ and $q \in C^2([a, b], U)$ with $q(a) = A$, $q(b) = B$. If q is stationary for $J[q] = \int_a^b L(s, q, q') ds$ in the sense of Definition 9.1, then for every $k = 1, \dots, n$ and every $s \in [a, b]$

$$\frac{d}{ds} \frac{\partial L}{\partial v^k}(s, q(s), q'(s)) - \frac{\partial L}{\partial q^k}(s, q(s), q'(s)) = 0,$$

where v denotes the third group of variables of L . In particular every minimum (or maximum) of J on $\mathcal{A}$ of class C^2 satisfies these equations.

Proof. Step 1 — the varied curves remain admissible. The image $q([a, b])$ is a compact set contained in the open set U , hence $\rho = \text{dist}(q([a, b]), \mathbb{R}^n \setminus U) > 0$ (with $\rho = +\infty$ if $U = \mathbb{R}^n$). Fixing a variation η with $\eta(a) = \eta(b) = 0$ and setting $M = \max_{[a, b]} \|\eta\|$, for every $|\varepsilon| < \rho/(M+1)$ the curve $q_\varepsilon = q + \varepsilon\eta$ has image in U , is of class C^2 and has the same endpoints: $q_\varepsilon \in \mathcal{A}$. The functional $\Phi(\varepsilon) = J[q_\varepsilon]$ is therefore defined on a neighbourhood of 0.

Step 2 — differentiation under the integral sign. Put $\Psi(\varepsilon, s) = L(s, q(s) + \varepsilon\eta(s), q'(s) + \varepsilon\eta'(s))$. Since L is C^2 and q, η are C^2 , the function Ψ is C^1 on the compact set $[-\varepsilon_0, \varepsilon_0] \times [a, b]$ for ε_0 small enough; hence $\partial_\varepsilon \Psi$ is continuous, thus uniformly continuous and in particular bounded on that compact set. The theorem on differentiation under the integral sign (applied here in its elementary form: compact domain of integration and continuous partial derivative) gives

$$\Phi'(\varepsilon) = \int_a^b \partial_\varepsilon \Psi(\varepsilon, s) ds,$$

and evaluating at $\varepsilon = 0$, by the chain rule,

$$\Phi'(0) = \int_a^b \left(\frac{\partial L}{\partial q^k} \eta^k + \frac{\partial L}{\partial v^k} (\eta^k)' \right) ds,$$

all partial derivatives being evaluated at $(s, q(s), q'(s))$.

Step 3 — integration by parts. The function $s \mapsto p_k(s) = \frac{\partial L}{\partial v^k}(s, q(s), q'(s))$ is of class C^1 : it is the composition of the C^1 function $\partial L / \partial v^k$ with the C^1 function $s \mapsto (s, q(s), q'(s))$ — here one uses that L is C^2 and that q is C^2 . Hence integration by parts is legitimate and, since $\eta(a) = \eta(b) = 0$,

$$\int_a^b p_k (\eta^k)' ds = [p_k \eta^k]_a^b - \int_a^b p_k' \eta^k ds = - \int_a^b \frac{d}{ds} \left(\frac{\partial L}{\partial v^k} \right) \eta^k ds.$$

Step 4 — the stationarity condition in integral form. Substituting into Step 2 and using $\Phi'(0) = 0$,

$$\int_a^b \left(\frac{\partial L}{\partial q^k} - \frac{d}{ds} \frac{\partial L}{\partial v^k} \right) \eta^k ds = 0 \quad \text{for every admissible variation } \eta.$$

Step 5 — separating the components and conclusion. Fix k_0 and choose η whose only non-vanishing component is the k_0 -th one, $\eta^{k_0} = \psi$ arbitrary of class C^2 with $\psi(a) = \psi(b) = 0$. The identity of Step 4 becomes $\int_a^b \varphi_{k_0} \psi ds = 0$ with $\varphi_{k_0} = \frac{\partial L}{\partial q^{k_0}} - \frac{d}{ds} \frac{\partial L}{\partial v^{k_0}}$, a continuous function on $[a, b]$. By Lemma 9.1, $\varphi_{k_0} \equiv 0$. Repeating for $k_0 = 1, \dots, n$ gives the claim.

Step 6 — the case of a minimum. If $q \in \mathcal{A}$ minimizes J on $\mathcal{A}$, then for every admissible variation the function Φ has a minimum at $\varepsilon = 0$ and is differentiable there (Step 2), hence $\Phi'(0) = 0$: q is stationary and the equations hold. $\square$

Warning. Stationary does not mean minimal. The implication just proved goes only one way: every minimum is stationary, but a stationary curve need not be a minimum. The clearest geometric counterexample is in Section 9.6: on the sphere an arc of a great circle longer than half a circumference satisfies the geodesic equation at every point and yet is not the shortest path between its endpoints.

Corollary 9.1: Beltrami identity. *If the Lagrangian does not depend explicitly on s , that is $L = L(q, v)$, then along every C^2 solution of the Euler–Lagrange equation the quantity*

$$H = \frac{\partial L}{\partial v^k} (q^k)' - L$$

is constant.

Proof. Step 1 — derivative of H . Since q is C^2 and L is C^2 , the function $H(s)$ is differentiable and

$$H' = \frac{d}{ds} \left(\frac{\partial L}{\partial v^k} \right) (q^k)' + \frac{\partial L}{\partial v^k} (q^k)'' - \frac{dL}{ds}.$$

Step 2 — total derivative of L . As L does not depend explicitly on s ,

$$\frac{dL}{ds} = \frac{\partial L}{\partial q^k} (q^k)' + \frac{\partial L}{\partial v^k} (q^k)''.$$

Step 3 — subtraction and use of Euler–Lagrange. Subtracting, the terms in $(q^k)''$ cancel and there remains

$$H' = \left(\frac{d}{ds} \frac{\partial L}{\partial v^k} - \frac{\partial L}{\partial q^k} \right) (q^k)' = 0$$

by Theorem 9.1. Hence H is constant. $\square$

Exercise 9.1. Show that the stationary curves of the length functional $J[y] = \int_{x_0}^{x_1} \sqrt{1 + y'^2} dx$, with fixed endpoints, are exactly the straight line segments.

Solution. Here $n = 1$, $q = y$ and $L(v) = \sqrt{1 + v^2}$, of class C^∞ on all of $\mathbb{R}$: the hypotheses of Theorem 9.1 are satisfied. Since L does not depend on y , one has $\partial L / \partial y = 0$ and the Euler–Lagrange equation reduces to

$$\frac{d}{dx} \frac{y'}{\sqrt{1 + y'^2}} = 0, \quad \text{that is} \quad \frac{y'}{\sqrt{1 + y'^2}} = c \text{ constant.}$$

The function $t \mapsto t / \sqrt{1 + t^2}$ is strictly increasing from -1 to 1 , hence injective: from $y' / \sqrt{1 + y'^2} = c$ it follows that $|c| < 1$ and $y' = c / \sqrt{1 - c^2}$, constant. Therefore y is affine and its graph is a segment. Conversely every segment satisfies the equation. That the segment is in fact the *minimum* (and not merely stationary) follows at once from the triangle inequality, or from $L(\gamma) = \int \sqrt{1 + y'^2} dx \geq \int 1 dx = x_1 - x_0$ with equality if and only if $y' \equiv 0$ (the case of the horizontal segment; the general case reduces to this by a rotation, which is an isometry of the plane, Chapter 5).

9.2. The geodesic equation

Applying Theorem 9.1 to the length functional $L(\gamma) = \int \sqrt{g_{ij} \dot{u}^i \dot{u}^j} ds$ is possible but unpleasant: the square root makes the equation non-linear in an inessential way and, above all, the length

functional is invariant under reparametrization, so that its stationary curves are not determined as *parametrized curves*. The classical remedy is to replace length by energy. The following lemma justifies the replacement.

Lemma 9.2: Energy and length. For a piecewise C^1 curve $\gamma : [a, b] \rightarrow \mathbb{R}^3$ put

$$L(\gamma) = \int_a^b \|\gamma'\| ds, \quad E(\gamma) = \frac{1}{2} \int_a^b \|\gamma'\|^2 ds.$$

Then

$$L(\gamma)^2 \leq 2(b-a)E(\gamma),$$

with equality if and only if $\|\gamma'\|$ is constant. Consequently, if γ_0 minimizes E in the class of piecewise C^1 curves from A to B defined on $[a, b]$ and contained in a set S , then γ_0 has constant speed and minimizes L in the same class.

Proof. Step 1 — the inequality. By the Cauchy–Schwarz inequality in $L^2([a, b])$ applied to the functions $\|\gamma'\|$ and 1,

$$L(\gamma)^2 = \left(\int_a^b \|\gamma'\| \cdot 1 ds \right)^2 \leq \left(\int_a^b \|\gamma'\|^2 ds \right) \left(\int_a^b 1^2 ds \right) = 2E(\gamma)(b-a).$$

The case of equality in Cauchy–Schwarz is the proportionality of the two functions, that is $\|\gamma'\| = \text{const.}$

Step 2 — reparametrization at constant speed. Let $\sigma : [a, b] \rightarrow S$ be a piecewise C^1 curve from A to B with $L(\sigma) = \ell > 0$. The arclength function $t \mapsto \int_a^t \|\sigma'\|$ is continuous and non-decreasing from 0 to ℓ ; composing σ with the affine reparametrization of arclength one obtains a curve $\tilde{\sigma} : [a, b] \rightarrow S$ with the same image, the same endpoints, $L(\tilde{\sigma}) = \ell$ and $\|\tilde{\sigma}'\| \equiv \ell/(b-a)$ (for piecewise C^1 and piecewise regular curves this reparametrization is piecewise C^1). Hence $2(b-a)E(\tilde{\sigma}) = L(\tilde{\sigma})^2 = \ell^2$ by the equality case of Step 1.

Step 3 — the minimum of the energy minimizes the length. Let γ_0 be a minimum of E and σ any competitor. With $\tilde{\sigma}$ as in Step 2,

$$L(\gamma_0)^2 \stackrel{\text{Step 1}}{\leq} 2(b-a)E(\gamma_0) \stackrel{\text{minimum}}{\leq} 2(b-a)E(\tilde{\sigma}) = L(\tilde{\sigma})^2 = L(\sigma)^2,$$

whence $L(\gamma_0) \leq L(\sigma)$: γ_0 minimizes the length.

Step 4 — γ_0 has constant speed. Apply the chain of Step 3 with $\sigma = \gamma_0$: one gets $L(\gamma_0)^2 \leq 2(b-a)E(\gamma_0) \leq 2(b-a)E(\tilde{\gamma}_0) = L(\gamma_0)^2$, hence all inequalities are equalities; in particular equality holds at Step 1 for γ_0 , that is $\|\gamma_0'\|$ is constant.

Step 5 — numerical check. On the interval $[0, 1]$ take the speed profile $\|\gamma'\|(t) = 1 + 0.8\sin(2\pi t)$, which is not constant. Numerical integration on 200,001 nodes gives $L = 1.00000000$ and $2E = 1.32000000$: hence $L^2 = 1.00000000 < 1.32000000$, the inequality is strict, as it must be for a non-constant speed. ✓ In closed form: $L = \int_0^1 (1 + 0.8\sin 2\pi t) dt = 1$ and $2E = \int_0^1 (1 + 0.8\sin 2\pi t)^2 dt = 1 + 0 + 0.64 \cdot \frac{1}{2} = 1.32$. ✓

Definition 9.2: Christoffel symbols. Given a regular parametrization X of class C^3 with first form g_{ij} , the **Christoffel symbols of the second kind** are the functions

$$\Gamma_{ij}^k = \frac{1}{2} g^{kl} (\partial_i g_{jl} + \partial_j g_{il} - \partial_l g_{ij}), \quad i, j, k \in \{1, 2\},$$

where $\partial_i = \partial/\partial u^i$ and (g^{kl}) is the inverse of (g_{ij}) . They are symmetric in the lower indices: $\Gamma_{ij}^k = \Gamma_{ji}^k$.

Lemma 9.3: *The Christoffel symbols are the tangential part of the second derivatives. Let $N = \frac{X_1 \times X_2}{\|X_1 \times X_2\|}$ be the unit normal and put $h_{ij} = \langle X_{ij}, N \rangle$. Then, for all i, j ,*

$$X_{ij} = \Gamma_{ij}^k X_k + h_{ij} N,$$

with the Γ_{ij}^k of Definition 9.2. In particular the Christoffel symbols depend only on the first fundamental form and its first derivatives.

Proof. Step 1 — the decomposition exists and is unique. At every point $\{X_1, X_2, N\}$ is a basis of $\mathbb{R}^3$: indeed X_1, X_2 are independent (regularity) and N is orthogonal to both and non-zero. Hence there exist unique functions A_{ij}^k and B_{ij} with $X_{ij} = A_{ij}^k X_k + B_{ij} N$. Taking the scalar product with N gives immediately $B_{ij} = \langle X_{ij}, N \rangle = h_{ij}$.

Step 2 — the tangential coefficients in terms of the symbols of the first kind. Taking the scalar product with X_l and using $\langle N, X_l \rangle = 0$,

$$[ij, l] := \langle X_{ij}, X_l \rangle = A_{ij}^k g_{kl}.$$

Step 3 — the symbols of the first kind in terms of the metric. Differentiating $g_{jl} = \langle X_j, X_l \rangle$ with respect to u^i (legitimate because X is C^3),

$$\partial_i g_{jl} = [ij, l] + [il, j].$$

The three versions obtained by permuting the indices are

$$\partial_i g_{jl} = [ij, l] + [il, j], \quad \partial_j g_{il} = [ij, l] + [jl, i], \quad \partial_l g_{ij} = [il, j] + [jl, i],$$

where the symmetry $[ij, l] = [ji, l]$ has been used, a consequence of $X_{ij} = X_{ji}$ (Schwarz's theorem, valid because $X \in C^3$). Adding the first two and subtracting the third, the terms $[il, j]$ and $[jl, i]$ cancel and there remains

$$\partial_i g_{jl} + \partial_j g_{il} - \partial_l g_{ij} = 2[ij, l].$$

Step 4 — conclusion. From Step 2, $A_{ij}^k = g^{kl}[ij, l]$, and substituting Step 3 one obtains exactly $A_{ij}^k = \frac{1}{2}g^{kl}(\partial_i g_{jl} + \partial_j g_{il} - \partial_l g_{ij}) = \Gamma_{ij}^k$. The right-hand side contains only g_{ij} , its inverse and its first derivatives: the dependence is therefore only on the first form.

Step 5 — check on the sphere. For $X(\varphi, \vartheta) = r(\sin \vartheta \cos \varphi, \sin \vartheta \sin \varphi, \cos \vartheta)$ one has $E = r^2 \sin^2 \vartheta$, $F = 0$, $G = r^2$ (Chapter 10), and the definition gives

$$\Gamma_{12}^1 = \Gamma_{21}^1 = \cot \vartheta, \quad \Gamma_{11}^2 = -\sin \vartheta \cos \vartheta, \quad \Gamma_{11}^1 = \Gamma_{22}^1 = \Gamma_{12}^2 = \Gamma_{22}^2 = 0.$$

The independent computation by centred finite differences on the parametrization, with $r = 1.7$ and $(\varphi, \vartheta) = (0.83, 1.12)$, gives $\Gamma_{12}^1 = 0.48403726$ against $\cot(1.12) = 0.48403759$ and $\Gamma_{11}^2 = -0.39215770$ against $-\sin(1.12)\cos(1.12) = -0.39215796$; the other four come out of the order of 10^{-10} . ✓ $\square$

Theorem 9.2: Geodesic equation. *Let $X : U \rightarrow \mathbb{R}^3$ be a regular C^3 parametrization of a surface S and let $\gamma(s) = X(u^1(s), u^2(s))$ be a curve of class C^2 on S , defined for $s \in [a, b]$. The following are equivalent:*

- (i) $\gamma''(s)$ is orthogonal to $T_{\gamma(s)}S$ for every s (the acceleration is purely normal);
- (ii) $\ddot{u}^k + \Gamma_{ij}^k \dot{u}^i \dot{u}^j = 0$ for $k = 1, 2$ and every s ;
- (iii) the curve $u = (u^1, u^2)$ is stationary for the energy functional $E[u] = \frac{1}{2} \int_a^b g_{ij}(u) \dot{u}^i \dot{u}^j ds$

among curves with fixed endpoints.

A curve satisfying these conditions is called a **geodesic** and necessarily has constant speed $\|\gamma'\|$.

Proof. Step 1 — decomposition of the acceleration. Differentiating $\gamma = X \circ u$ twice by the chain rule,

$$\gamma' = \dot{u}^i X_i, \quad \gamma'' = \ddot{u}^k X_k + \dot{u}^i \dot{u}^j X_{ij}.$$

Substituting Lemma 9.3,

$$\gamma'' = (\ddot{u}^k + \Gamma_{ij}^k \dot{u}^i \dot{u}^j) X_k + (h_{ij} \dot{u}^i \dot{u}^j) N.$$

The first bracket is the tangential component, the second the normal one.

Step 2 — (i) $\Leftrightarrow$ (ii). The acceleration is purely normal if and only if the tangential component vanishes; since X_1, X_2 are linearly independent, this happens if and only if both coefficients $\ddot{u}^k + \Gamma_{ij}^k \dot{u}^i \dot{u}^j$ vanish.

Step 3 — (iii) $\Rightarrow$ (ii): writing Euler–Lagrange. The Lagrangian $L(u, v) = \frac{1}{2} g_{ij}(u) v^i v^j$ is C^2 because g_{ij} is C^2 (X is C^3). One computes

$$\frac{\partial L}{\partial v^k} = g_{kj} v^j, \quad \frac{\partial L}{\partial u^k} = \frac{1}{2} (\partial_k g_{ij}) v^i v^j,$$

where in the first the symmetry of g has been used. The Euler–Lagrange equation (Theorem 9.1) becomes

$$\frac{d}{ds} (g_{kj} \dot{u}^j) - \frac{1}{2} (\partial_k g_{ij}) \dot{u}^i \dot{u}^j = 0, \quad \text{that is} \quad g_{kj} \ddot{u}^j + (\partial_i g_{kj}) \dot{u}^i \dot{u}^j - \frac{1}{2} (\partial_k g_{ij}) \dot{u}^i \dot{u}^j = 0.$$

Step 4 — symmetrization. The term $(\partial_i g_{kj}) \dot{u}^i \dot{u}^j$ is contracted with the symmetric tensor $\dot{u}^i \dot{u}^j$, so the coefficient may be replaced by its symmetric part in (i, j) :

$$(\partial_i g_{kj}) \dot{u}^i \dot{u}^j = \frac{1}{2} (\partial_i g_{kj} + \partial_j g_{ki}) \dot{u}^i \dot{u}^j.$$

The equation becomes

$$g_{kl} \ddot{u}^l + \frac{1}{2} (\partial_i g_{kj} + \partial_j g_{ki} - \partial_k g_{ij}) \dot{u}^i \dot{u}^j = 0,$$

that is $g_{kl} \ddot{u}^l + [ij, k] \dot{u}^i \dot{u}^j = 0$ with the symbols of the first kind of Lemma 9.3.

Step 5 — contraction with the inverse. Multiplying by g^{mk} and summing over k , since $g^{mk} g_{kl} = \delta_l^m$,

$$\ddot{u}^m + g^{mk} [ij, k] \dot{u}^i \dot{u}^j = \ddot{u}^m + \Gamma_{ij}^m \dot{u}^i \dot{u}^j = 0,$$

which is (ii). All the steps 3–5 are reversible — the only step not trivially invertible is the multiplication by g^{mk} , which is invertible because (g_{ij}) is positive definite — so (ii) $\Rightarrow$ (iii) holds as well.

Step 6 — constant speed. If (i) holds, then

$$\frac{d}{ds} \|\gamma'\|^2 = 2 \langle \gamma'', \gamma' \rangle = 0,$$

because γ'' is normal and $\gamma' = \dot{u}^i X_i$ is tangent. Hence $\|\gamma'\|$ is constant: the hypothesis “parametrized by arclength”, often imposed in the statement of the geodesic equation, is not needed — it is a consequence.

Step 7 — consistency with Lemma 9.2. Step 6 and Lemma 9.2 close the circle: minimizing the energy implies minimizing the length and having constant speed; and the stationary curves for the energy are exactly the geodesics. The converse does *not* hold: a geodesic is not necessarily minimizing (Section 9.6). $\square$

Remark 9.1: What we import: local existence and uniqueness. Equation (ii) of Theorem 9.2 is a system of two second-order differential equations, which becomes a first-order system in $\mathbb{R}^4$ upon setting $w^k = \dot{u}^k$:

$$\dot{u}^k = w^k, \quad \dot{w}^k = -\Gamma_{ij}^k(u) w^i w^j.$$

The right-hand side is of class C^1 in (u, w) , because the Γ_{ij}^k are C^1 when X is C^3 ; in particular it is locally Lipschitz. The **Picard–Lindelöf theorem** (fundamental theorem of ordinary differential equations) then guarantees that for every point $p \in S$ and every vector $w \in T_p S$ there exist $\varepsilon > 0$ and a unique geodesic $\gamma : (-\varepsilon, \varepsilon) \rightarrow S$ with $\gamma(0) = p$ and $\gamma'(0) = w$, and that it depends in a C^1 way on the initial data. **This theorem is imported:** we do not prove it. Its proof (successive approximations and the contraction mapping theorem) lies outside the scope of the treatise and can be found, in exactly the form used here, in Shifrin, *Differential Geometry: A First Course in Curves and Surfaces*, Appendix, §3 Differential Equations, Theorem 3.1 “Fundamental Theorem of ODE’s”, pp. 118–119 (source [1]). Nothing in this chapter depends on existence as such: the geodesics of the sphere, the cylinder and the cone are exhibited explicitly. The imported theorem is needed only for uniqueness, and hence to conclude that the exhibited geodesics are all the geodesics — a step which on the sphere is however also obtained directly in Step 4 of the proof of Theorem 9.3, without recourse to the import.

Lemma 9.4: Local isometries preserve geodesics. Let $S, \bar{S}$ be regular surfaces and $\phi : V \rightarrow \bar{V}$ a **local isometry** between open sets, that is a diffeomorphism such that $\langle d\phi_p(w_1), d\phi_p(w_2) \rangle = \langle w_1, w_2 \rangle$ for every $p \in V$ and $w_1, w_2 \in T_p S$. Then a curve γ in V is a geodesic of S if and only if $\phi \circ \gamma$ is a geodesic of $\bar{S}$.

Proof. Step 1 — two parametrizations with the same first form. Let $X : U \rightarrow V$ be a parametrization of S and put $\bar{X} = \phi \circ X : U \rightarrow \bar{V}$, which is a parametrization of $\bar{S}$ (composition of a regular homeomorphism with a diffeomorphism). By the chain rule $\bar{X}_i = d\phi(X_i)$, hence

$$\bar{g}_{ij} = \langle \bar{X}_i, \bar{X}_j \rangle = \langle d\phi(X_i), d\phi(X_j) \rangle = \langle X_i, X_j \rangle = g_{ij}.$$

Step 2 — the same Christoffel symbols. By Lemma 9.3 the Christoffel symbols are determined by g_{ij} and its derivatives; since $\bar{g}_{ij} = g_{ij}$ as functions on the same domain U , one has $\bar{\Gamma}_{ij}^k = \Gamma_{ij}^k$ at every point of U .

Step 3 — the same equation. A curve $\gamma = X \circ u$ is a geodesic of S if and only if u satisfies $\ddot{u}^k + \Gamma_{ij}^k \dot{u}^i \dot{u}^j = 0$ (Theorem 9.2); the curve $\phi \circ \gamma = \bar{X} \circ u$ has the same coordinates u and is a geodesic of $\bar{S}$ if and only if u satisfies $\ddot{u}^k + \bar{\Gamma}_{ij}^k \dot{u}^i \dot{u}^j = 0$. By Step 2 the two conditions coincide. $\square$

9.3. The geodesics of the sphere are the great circles

Theorem 9.3: The geodesics of S^2 are the great circles. Let $S^2(O, r) \subset \mathbb{R}^3$ be the sphere with centre the origin and radius r . A curve $\gamma : [a, b] \rightarrow S^2(O, r)$ of class C^2 is a geodesic if and only if there is $c \geq 0$ such that

$$\gamma(s) = \cos\left(\frac{cs}{r} + \alpha\right)P + \sin\left(\frac{cs}{r} + \alpha\right)Q,$$

with $P, Q \in \mathbb{R}^3$ orthogonal of norm r and $\alpha \in \mathbb{R}$: that is, if and only if it traverses at constant speed c an arc of the great circle $S^2(O, r) \cap \text{span}\{P, Q\}$ (or is constant, for $c = 0$).

Proof. Step 1 — the normal of the sphere. Since $\|\gamma(s)\| = r$ for every s , the tangent plane at $\gamma(s)$ is $\gamma(s)^\perp$ and the unit normal is $N = \gamma/r$. By Theorem 9.2(i) — obtained by applying Euler–Lagrange to the energy functional — the curve is a geodesic if and only if $\gamma''(s)$ is parallel to $\gamma(s)$, that is

$$\gamma''(s) = \lambda(s) \gamma(s)$$

for some function λ , which is continuous because $\lambda = \langle \gamma'', \gamma \rangle / r^2$.

Step 2 — λ is constant. Differentiating the identity $\langle \gamma, \gamma \rangle = r^2$ twice:

$$\langle \gamma, \gamma' \rangle = 0, \quad \langle \gamma', \gamma' \rangle + \langle \gamma, \gamma'' \rangle = 0.$$

By Step 6 of the proof of Theorem 9.2 the speed $\|\gamma'\| = c$ is constant, hence $\langle \gamma, \gamma'' \rangle = -c^2$; on the other hand, from Step 1, $\langle \gamma, \gamma'' \rangle = \lambda \|\gamma\|^2 = \lambda r^2$. Therefore

$$\lambda \equiv -\frac{c^2}{r^2}.$$

Step 3 — integrating the linear equation. The condition becomes

$$\gamma'' + \omega^2 \gamma = 0, \quad \omega = \frac{c}{r} \quad (\geq 0),$$

a linear system with constant coefficients in the three components of γ , which are decoupled. If $c = 0$ then $\gamma'' = 0$ and $\gamma' = \text{const}$ with $\|\gamma'\| = 0$: the curve is constant. If $c > 0$, every component is a combination of $\cos \omega s$ and $\sin \omega s$, hence

$$\gamma(s) = \cos(\omega s) V + \sin(\omega s) W, \quad V = \gamma(0), \quad W = \frac{\gamma'(0)}{\omega}.$$

Step 4 — the constraints on V and W . From $\|\gamma(0)\| = r$ it follows that $\|V\| = r$; from $\langle \gamma, \gamma' \rangle = 0$ at $s = 0$ that $\langle V, W \rangle = 0$; from $\|\gamma'(0)\| = c$ that $\|W\| = c/\omega = r$. Hence V, W are orthogonal of norm r and the curve describes, at constant speed c , the intersection of $S^2(O, r)$ with the plane $\text{span}\{V, W\}$ through the origin, that is a great circle (Definition 7.4). The form of the statement is obtained by putting $\alpha = 0$, $P = V$, $Q = W$; the parameter α accounts for a shift of the parameter.

Step 5 — the converse. If $\gamma(s) = \cos(\omega s + \alpha)P + \sin(\omega s + \alpha)Q$ with $P \perp Q$, $\|P\| = \|Q\| = r$ and $\omega = c/r$, then $\|\gamma\|^2 = r^2 \cos^2 + r^2 \sin^2 = r^2$ (the curve lies on the sphere), $\gamma'' = -\omega^2 \gamma$ is parallel to γ , that is normal to the sphere, and by Theorem 9.2(i) γ is a geodesic. Moreover $\gamma' = \omega(-\sin(\cdot)P + \cos(\cdot)Q)$ has norm $\omega r = c$.

Step 6 — no charts, no use of the import. The proof uses no coordinates on the sphere — hence has no exceptions at the poles — and does not use the existence and uniqueness theorem of Remark 9.1: uniqueness is obtained by explicitly integrating the linear equation of Step 3.

Step 7 — consistency with Chapter 7. Theorem 7.7 proves, by metric means and without the calculus of variations, that the *minor* arc of a great circle realizes the distance between two points. Here a different and complementary statement has been proved: the curves satisfying the *local* stationarity condition are exactly the constant-speed parametrizations of the great circles. The two statements fit together without overlapping: the first gives the global minimum, the second the differential characterization; and the second is wider, because it includes *non-minimizing* arcs (Section 9.6). Neither result is re-proved here from the other.

Step 8 — numerical check. On the unit sphere take $P = (1, 0, 0)$, $Q = (0, 1, 0)$, $c = 1$: one obtains $\gamma(s) = (\cos s, \sin s, 0)$, the equator, with $\gamma'' = -\gamma$ exactly normal. ✓ Take instead the parallel of colatitude ϑ_0 , traversed at unit speed: $\gamma(s) = (\sin \vartheta_0 \cos \omega s, \sin \vartheta_0 \sin \omega s, \cos \vartheta_0)$ with $\omega = 1/\sin \vartheta_0$. The tangential component of the acceleration, $\gamma'' - \langle \gamma'', \gamma \rangle \gamma$, has numerical norm 0.577350 for $\vartheta_0 = \pi/3$ and 1.000000 for $\vartheta_0 = \pi/4$; the theoretical values are $|\cot(\pi/3)| = 0.577350$ and $|\cot(\pi/4)| = 1.000000$, that is the geodesic curvature of the parallel. ✓ For $\vartheta_0 = \pi/2$ (equator) the tangential component vanishes. ✓ □

In coordinates: the Christoffel symbols of the sphere. It is worth seeing the same conclusion with the coordinate machinery, which is what one uses on an arbitrary surface. With $u^1 = \varphi$, $u^2 = \vartheta$ and $E = r^2 \sin^2 \vartheta$, $F = 0$, $G = r^2$, Definition 9.2 gives, as checked in Step 5 of the proof of Lemma 9.3,

$$\Gamma_{12}^1 = \cot \vartheta, \quad \Gamma_{11}^2 = -\sin \vartheta \cos \vartheta,$$

and all the others vanish. The geodesic equation therefore becomes the system

$$\ddot{\varphi} + 2 \cot \vartheta \dot{\varphi} \dot{\vartheta} = 0, \quad \ddot{\vartheta} - \sin \vartheta \cos \vartheta \dot{\varphi}^2 = 0.$$

The first equation, multiplied by $\sin^2 \vartheta$, is exactly $\frac{d}{ds}(\sin^2 \vartheta \dot{\varphi}) = 0$: it is Clairaut's first integral of Section 9.5. The *meridians* $\varphi \equiv \varphi_0$, $\vartheta(s) = \vartheta_0 + s/r$ satisfy both equations (the first because $\dot{\varphi} = 0$, the second because $\ddot{\vartheta} = 0$ and $\dot{\varphi} = 0$): they are geodesics. Every great circle is obtained from a meridian by a rotation of $\mathbb{R}^3$, which is an isometry of the sphere, and isometries preserve geodesics (Lemma 9.4): hence all great circles are geodesics. That there are no others follows from the uniqueness of Remark 9.1, since through every point and every tangent direction there passes a great circle. This route is more instructive but less economical than the main proof, which avoids the import. $\square$

Exercise 9.2. Why is a parallel other than the equator not a geodesic of the sphere? Give two independent reasons.

Solution. *First reason (vectorial).* Let $\vartheta_0 \neq \pi/2$ and traverse the parallel at unit speed as in Step 8 of the proof of Theorem 9.3, on the unit S^2 . The acceleration γ'' is horizontal and points towards the z -axis, while the normal to the sphere is γ , which has vertical component $\cos \vartheta_0 \neq 0$: the two vectors are not parallel. In formulas, the tangential component is

$$\gamma'' - \langle \gamma'', \gamma \rangle \gamma, \quad \|\gamma'' - \langle \gamma'', \gamma \rangle \gamma\| = |\cot \vartheta_0|,$$

non-zero for $\vartheta_0 \neq \pi/2$. By Theorem 9.2(i) the parallel is not a geodesic.

Second reason (in coordinates). On the parallel $\vartheta \equiv \vartheta_0$ one has $\dot{\vartheta} = \ddot{\vartheta} = 0$ and $\dot{\varphi} = \pm 1/\sin \vartheta_0 \neq 0$; the second equation of the *dimvariante* becomes $0 - \sin \vartheta_0 \cos \vartheta_0 \dot{\varphi}^2 = 0$, that is $\cos \vartheta_0 = 0$: satisfied only by $\vartheta_0 = \pi/2$, the equator. The general criterion for surfaces of revolution is Proposition 9.4.

Interpretation. The number $|\cot \vartheta_0|$ is the **geodesic curvature** of the parallel: it measures how much the curve “steers” while remaining on the surface. It is 0 at the equator and diverges near the poles, where the parallel is a very tight little circle. The value $\kappa_g = \cot \vartheta_0$ for the parallel of colatitude ϑ_0 is confirmed in Shifrin, solution of exercise 2.4.4 (source [1]).

✓

9.4. Cylinder and cone: geodesics by development

Lemma 9.4 makes the geodesics of all surfaces that “unroll” onto the plane without stretching almost free of charge. The strategy is always the same: exhibit a parametrization of the plane with the *same* first fundamental form as the surface, and read the straight lines of the plane on the surface.

Lemma 9.5: *The geodesics of the plane are the straight lines. In the plane, parametrized by $Y(u, v) = (u, v, 0)$, one has $E = G = 1$, $F = 0$ and all the Christoffel*

symbols vanish. The geodesics are therefore the curves $u(s) = a_1s + b_1$, $v(s) = a_2s + b_2$: the straight lines traversed at constant speed (and the points, for $a_1 = a_2 = 0$).

Proof. From $Y_1 = (1, 0, 0)$ and $Y_2 = (0, 1, 0)$ it follows that $g_{11} = g_{22} = 1$, $g_{12} = 0$: the first form is constant, hence all the $\partial_i g_{jl}$ vanish and, by Definition 9.2, $\Gamma_{ij}^k \equiv 0$. The geodesic equation of Theorem 9.2(ii) reduces to $\ddot{u}^k = 0$, whose general solution is affine in s . The speed $\sqrt{a_1^2 + a_2^2}$ is constant, as it must be by Step 6 of the same proof. $\square$

Proposition 9.1: Geodesics of the cylinder. Let $C_R = \{(x, y, z) : x^2 + y^2 = R^2\}$ be the right circular cylinder of radius $R > 0$, parametrized by $X(u, v) = (R \cos u, R \sin u, v)$. Then:

- (i) the first form is $I = R^2 du^2 + dv^2$, with constant coefficients, and the map ϕ sending $X(u, v)$ to $(Ru, v, 0)$ is a local isometry onto the plane;
- (ii) the geodesics of C_R are the curves $u(s) = as + u_0$, $v(s) = bs + v_0$, that is the **circular helices** for $a, b \neq 0$, the horizontal circles for $b = 0$ and the vertical generators for $a = 0$;
- (iii) between two distinct points $P_0 = X(u_0, v_0)$ and $P_1 = X(u_1, v_1)$ there pass infinitely many geodesics, of lengths $\sqrt{R^2(\Delta u + 2\pi n)^2 + (\Delta v)^2}$ for $n \in \mathbb{Z}$, with $\Delta u = u_1 - u_0 \in (-\pi, \pi]$ and $\Delta v = v_1 - v_0$; the shortest is the one with $n = 0$.

Proof. Step 1 — first form of the cylinder. $X_1 = (-R \sin u, R \cos u, 0)$ and $X_2 = (0, 0, 1)$ give $E = R^2$, $F = 0$, $G = 1$: constants. The cross product $X_1 \times X_2 = (R \cos u, R \sin u, 0)$ is non-zero, hence X is regular.

Step 2 — the same first form on the plane. The parametrization of the plane $\tilde{Y}(u, v) = (Ru, v, 0)$ has $\tilde{Y}_1 = (R, 0, 0)$, $\tilde{Y}_2 = (0, 1, 0)$, hence $\tilde{E} = R^2$, $\tilde{F} = 0$, $\tilde{G} = 1$: identical to those of the cylinder. The map $\phi = \tilde{Y} \circ X^{-1}$, defined on every open set where X is invertible (for instance $u \in (u_*, u_* + 2\pi)$), is therefore a local isometry, because $d\phi(X_i) = \tilde{Y}_i$ and the matrix of scalar products coincides. This proves (i).

Step 3 — the geodesics. By Step 2 and Lemma 9.4, $\gamma = X \circ u$ is a geodesic of the cylinder if and only if $\tilde{Y} \circ u$ is a geodesic of the plane, that is (Lemma 9.5) if and only if $s \mapsto (Ru^1(s), u^2(s))$ is affine, that is if and only if u^1 and u^2 are affine. Carrying this back to the cylinder: for $a, b \neq 0$ one obtains $\gamma(s) = (R \cos(as + u_0), R \sin(as + u_0), bs + v_0)$, which is the circular helix of Chapter 3; for $b = 0$ the circle $z = v_0$; for $a = 0$ the vertical generator. This proves (ii). Note that the same result follows directly: since the first form is constant, all the Christoffel symbols vanish and the geodesic equation is $\ddot{u} = \ddot{v} = 0$.

Step 4 — the multiplicity of paths. The points $X(u, v)$ and $X(u + 2\pi n, v)$ coincide. Fixing P_0 and P_1 , for every $n \in \mathbb{Z}$ the geodesic with u running from u_0 to $u_0 + \Delta u + 2\pi n$ and v from v_0 to v_1 joins the two points; developed on the plane it is the segment with legs $R|\Delta u + 2\pi n|$ and $|\Delta v|$, of length $\sqrt{R^2(\Delta u + 2\pi n)^2 + (\Delta v)^2}$, since the development preserves lengths. The function $n \mapsto |\Delta u + 2\pi n|$ with $\Delta u \in (-\pi, \pi]$ is minimal at $n = 0$, hence the shortest geodesic is the one that makes no whole turns. This proves (iii).

Step 5 — numerical check. With $R = 1$, $\Delta u = \pi/2$ and $\Delta v = 1$ the lengths $\sqrt{(\pi/2 + 2\pi n)^2 + 1}$ are, for $n = -2, -1, 0, 1, 2$: 11.040953, 4.817324, 1.862096, 7.917388, 14.172491. The minimum is 1.862096 for $n = 0$, as predicted; the closed-form check gives $\sqrt{(\pi/2)^2 + 1} = \sqrt{2.467401 + 1} = \sqrt{3.467401} = 1.862096$. $\checkmark$ The numerical computation of the Christoffel symbols of the cylinder by finite differences gives eight values all equal to 0 within machine precision. $\checkmark$ $\square$

Figure 9.1: The development of the cylinder onto the plane is a local isometry (Proposition 9.1(i)): the straight lines of the rectangle become the helices of the cylinder. The nodes of the polyline are the points $(8 + 1.2 \cos t, 0.3 + 2.4 t/(2\pi))$ for $t = 0, \pi/4, \dots, 2\pi$, computed by hand: 9.200; 8.849; 8.000; 7.151; 6.800; 7.151; 8.000; 8.849; 9.200.

Proposition 9.2: Geodesics of the cone. Let K_α be the right circular cone of half-angle $\alpha \in (0, \pi/2)$ with the vertex removed, parametrized by

$$X(u, v) = (v \sin \alpha \cos u, v \sin \alpha \sin u, v \cos \alpha), \quad u \in \mathbb{R}, v > 0.$$

Then:

- (i) the first form is $I = v^2 \sin^2 \alpha du^2 + dv^2$, which coincides with the first form of the plane in polar coordinates (θ, ρ) via $\theta = u \sin \alpha$, $\rho = v$; the cone, cut along a generator, develops isometrically onto a circular sector of opening $\beta = 2\pi \sin \alpha$;
- (ii) the geodesics of K_α are the generators $u = \text{const}$ and the curves

$$v(u) = \frac{d}{\cos(\sin \alpha (u - u_0))}, \quad d > 0, \quad |\sin \alpha (u - u_0)| < \frac{\pi}{2},$$

traversed at constant speed.

Proof. Step 1 — first form of the cone. One has $X_1 = v \sin \alpha (-\sin u, \cos u, 0)$ and $X_2 = (\sin \alpha \cos u, \sin \alpha \sin u, \cos \alpha)$, hence

$$E = v^2 \sin^2 \alpha, \quad F = v \sin^2 \alpha (-\sin u \cos u + \cos u \sin u) = 0, \quad G = \sin^2 \alpha + \cos^2 \alpha = 1.$$

Since $v > 0$ and $\sin \alpha > 0$ one has $EG - F^2 = v^2 \sin^2 \alpha > 0$: the parametrization is regular.

Step 2 — the same first form on the plane. The parametrization of the plane $\tilde{Y}(u, v) = (v \cos(u \sin \alpha), v \sin(u \sin \alpha), 0)$ has $\tilde{Y}_1 = v \sin \alpha (-\sin(u \sin \alpha), \cos(u \sin \alpha), 0)$ and $\tilde{Y}_2 = (\cos(u \sin \alpha), \sin(u \sin \alpha), 0)$, hence $\tilde{E} = v^2 \sin^2 \alpha$, $\tilde{F} = 0$, $\tilde{G} = 1$: identical to those of the cone. As u runs over an interval of width 2π (the cone minus one generator), the polar angle $\theta = u \sin \alpha$ varies by $\beta = 2\pi \sin \alpha$: the sector. This proves (i).

Step 3 — the straight lines of the sector. By Lemma 9.4 and Lemma 9.5, the geodesics of the cone are the preimages of the straight lines of the sector. In polar coordinates a line is of two kinds: the lines through the origin, $\theta = \text{const}$, which lift to the generators $u = \text{const}$; and the lines not through the origin, of normal equation

$$\rho \cos(\theta - \theta_0) = d, \quad d > 0,$$

with d the distance from the origin and θ_0 the direction of the foot of the perpendicular. Substituting $\theta = u \sin \alpha$, $\rho = v$ and setting $u_0 = \theta_0 / \sin \alpha$ one gets $v \cos(\sin \alpha (u - u_0)) = d$, that is the formula of the statement. This proves (ii).

Step 4 — numerical check. With $\alpha = 35^\circ$ and $(u, v) = (0.7, 2.3)$, the finite-difference computation gives, both for the cone and for the plane sector, the same matrix

$$(g_{ij}) = \begin{pmatrix} 1.74035672 & 0 \\ 0 & 1 \end{pmatrix};$$

the expected value is $v^2 \sin^2 \alpha = 2.3^2 \cdot \sin^2 35^\circ = 5.29 \times 0.329009 = 1.74035672$. ✓ □

Proposition 9.3: When a geodesic of the cone self-intersects. With the notation of Proposition 9.2, a geodesic of the cone which is not a generator self-intersects if and only if

$$\sin \alpha < \frac{1}{2}, \quad \text{that is} \quad \alpha < 30^\circ,$$

equivalently if and only if the opening of the development $\beta = 2\pi \sin \alpha$ is less than π .

Proof. **Step 1 — the interval of definition.** The geodesic $v(u) = d / \cos(\sin \alpha (u - u_0))$ is defined exactly where the cosine is positive, that is for $|\sin \alpha (u - u_0)| < \pi/2$: the set of values of u is the open interval with centre u_0 and width

$$\Delta u = \frac{\pi}{\sin \alpha}.$$

Step 2 — what self-intersection means. Two parameters $u_1 \neq u_2$ give the same point of the cone if and only if $u_2 - u_1 \in 2\pi\mathbb{Z} \setminus \{0\}$ and $v(u_1) = v(u_2)$. Since v is even about u_0 and strictly increasing for $u > u_0$, the equality $v(u_1) = v(u_2)$ with $u_1 \neq u_2$ forces u_1 and u_2 to be symmetric about u_0 , that is $u_1 = u_0 - t$, $u_2 = u_0 + t$ with $t > 0$; the condition $u_2 - u_1 = 2t \in 2\pi\mathbb{Z}$ gives $t = \pi m$ with $m \geq 1$ an integer.

Step 3 — existence of such a t . It is necessary and sufficient that $t = \pi$ (the case $m = 1$; if $m = 1$ works, self-intersections exist a fortiori) lie in the interval of definition, that is $\pi < \Delta u/2 = \pi/(2 \sin \alpha)$, which is equivalent to $2 \sin \alpha < 1$, that is $\sin \alpha < 1/2$ and hence $\alpha < 30^\circ$. If instead $\sin \alpha \geq 1/2$ then $\Delta u/2 \leq \pi$ and no $t = \pi m$ is admissible: the geodesic does not self-intersect.

Step 4 — geometric reading. The condition $\sin \alpha < 1/2$ is equivalent to $\beta = 2\pi \sin \alpha < \pi$: the development is a sector narrower than a half-plane, and a line entering it must leave it “on the same side”, so that closing the sector up the two branches meet. For $\beta \geq \pi$ the two branches diverge and never touch.

Step 5 — numerical check. $\alpha = 20^\circ$: $\Delta u = \pi / \sin 20^\circ = 3.141593 / 0.342020 = 9.185402 > 2\pi = 6.283185$, self-intersection. $\alpha = 30^\circ$: $\Delta u = \pi / 0.5 = 6.283185 = 2\pi$, the limiting case. $\alpha = 40^\circ$: $\Delta u = \pi / 0.642788 = 4.887451 < 6.283185$, no self-intersection. ✓ □

9.5. Clairaut’s relation

Definition 9.3: Surface of revolution. Let $f, h : I \rightarrow \mathbb{R}$ be of class C^3 on an interval I , with $f > 0$ and $f'^2 + h'^2 > 0$ everywhere. The **surface of revolution** generated by the profile $v \mapsto (f(v), 0, h(v))$ is the surface parametrized by

$$X(u, v) = (f(v) \cos u, f(v) \sin u, h(v)), \quad u \in \mathbb{R}, v \in I.$$

The curves $v = \text{const}$ are called **parallels** (circles of radius $f(v)$), those with $u = \text{const}$ **meridians**.

Figure 9.2: Development of the cone of half-angle $\alpha = 30^\circ$: a sector of opening $\beta = 2\pi \sin 30^\circ = \pi$. The geodesics are the segments; the one drawn has endpoints $(3 \cos 20^\circ, 3 \sin 20^\circ) = (2.819, 1.026)$ and $(3 \cos 160^\circ, 3 \sin 160^\circ) = (-2.819, 1.026)$, coordinates computed by hand, and lies at distance $d = 1.026$ from the vertex. For $\alpha < 30^\circ$ the sector is narrower than π and the geodesic, on closing the cone up, self-intersects (Proposition 9.3).

Lemma 9.6: First form of a surface of revolution. With the notation of Definition 9.3,

$$E = f(v)^2, \quad F = 0, \quad G = f'(v)^2 + h'(v)^2.$$

In particular parallels and meridians are orthogonal, and the Christoffel symbols are

$$\Gamma_{11}^1 = 0, \quad \Gamma_{12}^1 = \frac{f'}{f}, \quad \Gamma_{22}^1 = 0, \quad \Gamma_{11}^2 = -\frac{ff'}{G}, \quad \Gamma_{12}^2 = 0, \quad \Gamma_{22}^2 = \frac{G'}{2G}.$$

Proof. Step 1 — the metric coefficients. $X_1 = f(-\sin u, \cos u, 0)$ and $X_2 = (f' \cos u, f' \sin u, h')$ give $E = f^2(\sin^2 u + \cos^2 u) = f^2$, $F = ff'(-\sin u \cos u + \cos u \sin u) = 0$, $G = f'^2(\cos^2 u + \sin^2 u) + h'^2 = f'^2 + h'^2$. The hypothesis $f > 0$ and $f'^2 + h'^2 > 0$ gives $EG - F^2 = f^2G > 0$: regularity.

Step 2 — the Christoffel symbols in the orthogonal case. With $F = 0$ the inverse matrix is $g^{11} = 1/E$, $g^{22} = 1/G$, $g^{12} = 0$, and Definition 9.2 gives the general formulas

$$\Gamma_{11}^1 = \frac{E_u}{2E}, \quad \Gamma_{12}^1 = \frac{E_v}{2E}, \quad \Gamma_{22}^1 = -\frac{G_u}{2E}, \quad \Gamma_{11}^2 = -\frac{E_v}{2G}, \quad \Gamma_{12}^2 = \frac{G_u}{2G}, \quad \Gamma_{22}^2 = \frac{G_v}{2G},$$

where the subscript denotes the partial derivative. Here $E = f^2$ does not depend on u and neither does G , hence $E_u = G_u = 0$, $E_v = 2ff'$ and $G_v = G'$; substituting one obtains the stated values.

Step 3 — numerical check on the torus. For the torus $f(v) = a + b \cos v$, $h(v) = b \sin v$ with $a = 2$, $b = 1$ one has $G = b^2 \sin^2 v + b^2 \cos^2 v = b^2 = 1$ and $\Gamma_{11}^2 = -ff'/G = (a + b \cos v)b \sin v$. The finite-difference computation gives, at $u = 0.3$: for $v = 0$ the value 0.00000000 (formula: 0), for $v = \pi/2$ the value 1.99999967 (formula: $2 \cdot 1 = 2$), for $v = \pi$ the value 0.00000000 (formula: 0). ✓ $\square$

Theorem 9.4: Clairaut's relation. Let S be a surface of revolution as in Definition 9.3 and let $\gamma(s) = X(u(s), v(s))$ be a curve of class C^2 parametrized by arclength. Let $r(s) = f(v(s))$ denote the radius of the parallel through $\gamma(s)$ and $\psi(s) \in [0, \pi]$ the angle between $\gamma'(s)$ and the direction of the meridian. Then:

- (i) if γ is a geodesic, the quantity $r \sin \psi = f^2 \dot{u}$ is constant along γ (Clairaut's relation);
- (ii) conversely, if $r \sin \psi$ is constant along γ and no subarc of γ is contained in a parallel, then γ is a geodesic.

Proof. Step 1 — identification of $r \sin \psi$. The direction of the parallel is $X_1/\|X_1\| = X_1/f$; that of the meridian is $X_2/\sqrt{G}$. Since the two are orthogonal (Lemma 9.6) and $\|\gamma'\| = 1$, the angle ψ with the meridian satisfies

$$\sin \psi = \left\langle \gamma', \frac{X_1}{f} \right\rangle = \frac{\dot{u} \langle X_1, X_1 \rangle + \dot{v} \langle X_2, X_1 \rangle}{f} = \frac{f^2 \dot{u}}{f} = f \dot{u},$$

up to sign, which depends on the direction of travel. Hence $r \sin \psi = f \cdot f \dot{u} = f^2 \dot{u} = E \dot{u}$.

Step 2 — (i): u is a cyclic coordinate. The energy Lagrangian is $L = \frac{1}{2}(f(v)^2 \dot{u}^2 + G(v) \dot{v}^2)$ and does not depend on u . The Euler–Lagrange equation for $k = 1$ (Theorem 9.1) is therefore

$$\frac{d}{ds} \frac{\partial L}{\partial \dot{u}} = \frac{\partial L}{\partial u} = 0, \quad \text{that is} \quad \frac{d}{ds} (f^2 \dot{u}) = 0.$$

By Theorem 9.2(iii) the geodesics are the stationary curves of the energy: the quantity $f^2 \dot{u} = r \sin \psi$ is constant. This proves (i).

Step 3 — the two geodesic equations in explicit form. With the symbols of Lemma 9.6, the geodesic equation reads

$$(A) \quad \frac{d}{ds} (f^2 \dot{u}) = 0, \quad (B) \quad 2G\ddot{v} + G'\dot{v}^2 - 2ff'\dot{u}^2 = 0,$$

where (A) is the first equation multiplied by f^2 and (B) is the second multiplied by $2G$ — the computation is the one in Step 4 of the proof of Theorem 9.2 with the values of Lemma 9.6. To these one adds the unit-speed constraint

$$(C) \quad f^2 \dot{u}^2 + G \dot{v}^2 = 1.$$

Step 4 — (ii): (A) and (C) imply (B). Differentiate (C) with respect to s , recalling that f and G depend on s only through v :

$$2ff'\dot{v}\dot{u}^2 + 2f^2\dot{u}\ddot{u} + G'\dot{v}^3 + 2G\dot{v}\ddot{v} = 0.$$

On the other hand (A) expanded is $2ff'\dot{v}\dot{u} + f^2\ddot{u} = 0$, hence $f^2\dot{u}\ddot{u} = -2ff'\dot{v}\dot{u}^2$. Substituting:

$$2ff'\dot{v}\dot{u}^2 - 4ff'\dot{v}\dot{u}^2 + G'\dot{v}^3 + 2G\dot{v}\ddot{v} = 0,$$

that is

$$\dot{v} \cdot (2G\ddot{v} + G'\dot{v}^2 - 2ff'\dot{u}^2) = 0.$$

The bracket is exactly the left-hand side of (B). Hence (B) holds at every point where $\dot{v} \neq 0$.

Step 5 — conclusion of (ii). By hypothesis no subarc of γ lies in a parallel, that is the set $Z = \{s : \dot{v}(s) = 0\}$ has empty interior; its complement $\{\dot{v} \neq 0\}$ is therefore open and dense. On it (B) holds by Step 4; since the left-hand side of (B) is a continuous function of s (the second derivatives exist and are continuous, γ being of class C^2 and f, G of class C^2), it vanishes on the closure as well, that is on all of $[a, b]$. Together with (A), which is the hypothesis, both geodesic equations hold: γ is a geodesic.

Step 6 — the hypothesis is not superfluous. If the clause about parallels is dropped, statement (ii) is false: any parallel, traversed at unit speed, has $\psi \equiv \pi/2$ and $r \equiv f(v_0)$, hence $r \sin \psi$ constant, but it is a geodesic only in special cases (Proposition 9.4). This is exactly the point where Step 4 fails to conclude, because $\dot{v} \equiv 0$.

Step 7 — comparison with the literature. The statement with the clause “no part of the curve is contained in a parallel” is that of Shifrin, Proposition 4.4 “Clairaut’s relation”, pp. 73–75 (source [1]), who formulates the relation with the angle to the parallel, that is $r \cos \omega = \text{const}$ with $\omega = \pi/2 - \psi$: the two writings are the same thing. $\checkmark$ $\square$

Proposition 9.4: Which parallels are geodesics. With the notation of Definition 9.3, the parallel $v \equiv v_0$ (traversed at constant speed) is a geodesic if and only if $f'(v_0) = 0$, that is if and only if v_0 is a critical point of the radius.

Proof. Step 1 — the equations on the parallel. On the parallel $\dot{v} \equiv 0$, $\ddot{v} \equiv 0$ and $\dot{u} \equiv c \neq 0$ constant. Equation (A) of Step 3 of the proof of Theorem 9.4 is automatically satisfied, because $f^2 \dot{u} = f(v_0)^2 c$ is constant. Equation (B) reduces to $-2f(v_0)f'(v_0)c^2 = 0$.

Step 2 — conclusion. Since $f(v_0) > 0$ and $c \neq 0$, equation (B) is equivalent to $f'(v_0) = 0$.

Step 3 — the two examples. *Sphere* ($f(\vartheta) = r \sin \vartheta$): $f' = r \cos \vartheta = 0$ if and only if $\vartheta = \pi/2$, the equator. This recovers, by a completely different route, Exercise 9.2. *Torus* ($f(v) = a + b \cos v$ with $a > b > 0$): $f' = -b \sin v = 0$ if and only if $v = 0$ or $v = \pi$, that is the outer equator (radius $a + b$, maximal) and the inner equator (radius $a - b$, minimal). No other parallel of the torus is a geodesic. $\square$

9.6. Beyond half a sphere: geodesics that stop minimizing

Theorem 7.7 of Chapter 7 says that the *minor* arc of a great circle realizes the distance. Theorem 9.3 of this chapter says that *all* arcs of great circles are geodesics. The two statements are not in conflict: together they say that the stationarity condition is necessary but not sufficient. This section measures exactly where sufficiency is lost.

Proposition 9.5: The conjugate point at the antipode. On $S^2(O, r)$ fix A with $\|A\| = r$ and take two orthonormal vectors w_1, w_2 orthogonal to A . The family of unit-speed geodesics issuing from A

$$\gamma_\vartheta(s) = \cos \frac{s}{r} A + \sin \frac{s}{r} r (\cos \vartheta w_1 + \sin \vartheta w_2), \quad \vartheta \in \mathbb{R},$$

satisfies: $\gamma_\vartheta(0) = A$ for every ϑ , and $\gamma_\vartheta(\pi r) = -A$ for every ϑ . Moreover the variation field $J(s) = \frac{\partial \gamma_\vartheta}{\partial \vartheta} \Big|_{\vartheta=0}$ equals $J(s) = r \sin \frac{s}{r} w_2$: it vanishes at $s = 0$ and at $s = \pi r$, and is non-zero in between. Hence all the geodesics issuing from A meet again at $-A$ after length πr : $-A$ is **conjugate** to A .

Proof. Step 1 — they are geodesics. Putting $Q_\vartheta = r(\cos \vartheta w_1 + \sin \vartheta w_2)$, one has $\|Q_\vartheta\| = r$ and $\langle A, Q_\vartheta \rangle = 0$: by Theorem 9.3 (Step 5) the curve $\gamma_\vartheta(s) = \cos(s/r)A + \sin(s/r)Q_\vartheta$ is a geodesic of speed $\|Q_\vartheta\|/r = 1$.

Step 2 — the endpoint values. $\gamma_\vartheta(0) = A$ because $\cos 0 = 1$ and $\sin 0 = 0$; $\gamma_\vartheta(\pi r) = \cos \pi A + \sin \pi Q_\vartheta = -A$, for every ϑ .

Step 3 — the variation field. Differentiating with respect to ϑ at $\vartheta = 0$: $\partial_\vartheta Q_\vartheta|_0 = r(-\sin 0 w_1 + \cos 0 w_2) = r w_2$, hence

$$J(s) = \sin \frac{s}{r} r w_2.$$

It vanishes for $s = 0$ and $s = \pi r$, and has norm $r|\sin(s/r)| > 0$ for $0 < s < \pi r$.

Step 4 — the Jacobi equation, verified by hand. Putting $j(s) = \|J(s)\| = r \sin(s/r)$ for $s \in (0, \pi r)$, one has

$$j''(s) = -\frac{1}{r^2} r \sin \frac{s}{r} = -K j(s), \quad K = \frac{1}{r^2},$$

that is $j'' + K j = 0$ with the Gaussian curvature $K = 1/r^2$ of the sphere (Chapter 10). This is the Jacobi equation in constant curvature, verified here by direct computation and without any need of the general theory.

Step 5 — numerical check. With $r = 1$, $A = (0, 0, 1)$, $w_1 = (1, 0, 0)$, $w_2 = (0, 1, 0)$: $\gamma_0(s) = (\sin s, 0, \cos s)$ and $\gamma_{\pi/2}(s) = (0, \sin s, \cos s)$, two distinct meridians; at $s = \pi$ both equal $(0, 0, -1) = -A$. ✓ And $J(s) = \sin s (0, 1, 0)$, with $J(0) = J(\pi) = 0$ and $\|J(\pi/2)\| = 1$. ✓ □

Theorem 9.5: Loss of minimality beyond half a sphere. On $S^2(O, r)$ consider the unit-speed geodesic arc $\gamma : [0, \ell] \rightarrow S^2(O, r)$, $\gamma(s) = \cos(s/r)A + \sin(s/r)Q$ with $\|A\| = \|Q\| = r$, $\langle A, Q \rangle = 0$. Then:

- (i) if $\ell \leq \pi r$, the arc is minimizing, that is $\ell = \text{dist}(\gamma(0), \gamma(\ell))$ (uniquely so for $\ell < \pi r$);
- (ii) if $\ell > \pi r$, the arc is not minimizing: there is a curve on the sphere with the same endpoints and strictly smaller length, and precisely

$$\text{dist}(\gamma(0), \gamma(\ell)) = r \arccos\left(\cos \frac{\ell}{r}\right) < \ell.$$

In particular the length πr — half a great circle, that is the distance to the antipode — is the exact threshold.

Proof. Step 1 — the distance between the endpoints. Since $\langle A, Q \rangle = 0$ and $\|A\| = \|Q\| = r$,

$$\langle \gamma(0), \gamma(\ell) \rangle = \left\langle A, \cos \frac{\ell}{r} A + \sin \frac{\ell}{r} Q \right\rangle = r^2 \cos \frac{\ell}{r}.$$

By Theorem 7.8 of Chapter 7 the spherical distance between two points P_1, P_2 is $r \arccos(\langle P_1, P_2 \rangle / r^2)$, hence

$$\text{dist}(\gamma(0), \gamma(\ell)) = r \arccos\left(\cos \frac{\ell}{r}\right).$$

Step 2 — (i). If $0 \leq \ell \leq \pi r$ then $\ell/r \in [0, \pi]$, an interval on which $\arccos \circ \cos$ is the identity: the distance equals ℓ , and the arc realizes it. Uniqueness for $\ell < \pi r$ and non-uniqueness for $\ell = \pi r$ are the content of Theorem 7.7, which we do not re-prove.

Step 3 — (ii): the inequality. Let $\ell > \pi r$ and put $t = \ell/r > \pi$. The function $t \mapsto \arccos(\cos t)$ equals $2\pi - t$ for $t \in [\pi, 2\pi]$, and is in any case always $\leq \pi < t$. Hence

$$\text{dist}(\gamma(0), \gamma(\ell)) = r \arccos(\cos t) \leq \pi r < r t = \ell.$$

The distance is strictly less than the length of the arc: the arc is not minimizing.

Step 4 — the explicit competitor. There is no need to invoke the existence of the minimum: if $\pi r < \ell < 2\pi r$ the shortest competitor is the *complementary* arc of the same great circle, traversed in the opposite direction, of length $2\pi r - \ell < \ell$; if $\ell \geq 2\pi r$ the curve has already made at least one full turn and one reduces to the previous case by subtracting $2\pi r$ until the remaining length lies in $[0, 2\pi r)$. In both cases the competitor is an arc of a great circle with the same endpoints.

Step 5 — why exactly πr : the link with conjugate points. The threshold is no accident. By Proposition 9.5 all the geodesics issuing from A meet again at $-A$ after length exactly πr . Past that point the geodesic “has already spent” its single encounter with the neighbouring ones: between $\gamma(0)$ and $\gamma(\ell)$ with $\ell > \pi r$ there is a second, shorter geodesic, and the long arc ceases to be minimal. The general theory (Morse index theorem, Jacobi’s theorem) proves that this is the mechanism on *every* surface: a geodesic stops minimizing as soon as it passes the first conjugate point — see Remark 9.2. On the sphere, however, the conclusion is obtained by the elementary computation of Steps 1–4, with no theory.

Step 6 — numerical check. On the unit S^2 ($r = 1$), for $\ell = 2.000000$ one has $\arccos(\cos 2) = 2.000000$: no gain, the arc is minimizing (indeed $2 < \pi$). For $\ell = \pi = 3.141593$: $\arccos(\cos \pi) = 3.141593$, still minimizing, but this is the limiting case. For $\ell = 4.000000$: $\arccos(\cos 4) =$

$2.283185 = 2\pi - 4$, with gain 1.716815. For $\ell = 5.000000$: $\arccos(\cos 5) = 1.283185 = 2\pi - 5$, with gain 3.716815. ✓ The values $2\pi - 4 = 2.283185$ and $2\pi - 5 = 1.283185$ agree with the numerical arccosine. ✓ □

Remark 9.2: What we import: Jacobi fields and conjugate points. Proposition 9.5 exhibits a Jacobi field on the sphere and verifies its equation by hand; Theorem 9.5 concludes on the sphere with an elementary argument. Two general statements remain **imported**, and are used in no proof of this chapter: (a) on an arbitrary surface the variation fields of families of geodesics satisfy the Jacobi equation $\nabla_s^2 J + K J = 0$; (b) a geodesic ceases to be minimizing as soon as it passes the first conjugate point (Jacobi's theorem). The proofs require the covariant derivative and the second variation formula for length, which are not developed in the treatise; the reference is do Carmo, *Differential Geometry of Curves and Surfaces*, Chapter 5, and Kühnel, *Differential Geometry: Curves — Surfaces — Manifolds* (sources [2] and [4]). Nothing proved above depends on (a) or (b): they serve only to frame the spherical phenomenon as a case of a general rule.

Figure 9.3: The conjugate point. All the geodesics issuing from A — the meridians — meet again at the antipode $-A$ after length πr , whatever the initial direction (Proposition 9.5). Before $-A$ each arc is the shortest path; beyond $-A$ none of them is (Theorem 9.5).

Exercise 9.3. Set up and reduce to quadrature, using the Beltrami identity, the Euler–Lagrange equation of the *brachistochrone*: the curve of fastest descent under gravity between two points, described by the functional $J[y] = \int_0^{x_1} \sqrt{\frac{1+y'^2}{2gy}} dx$ (with $y > 0$ measured downwards).

Solution. The Lagrangian $L(y, v) = \sqrt{(1+v^2)/(2gy)}$ does not depend explicitly on x and is C^2 on the open set $\{y > 0\} \times \mathbb{R}$: Corollary 9.1 applies. One computes

$$\frac{\partial L}{\partial v} = \frac{1}{\sqrt{2gy}} \cdot \frac{v}{\sqrt{1+v^2}},$$

hence

$$H = \frac{\partial L}{\partial v} y' - L = \frac{1}{\sqrt{2gy}} \left(\frac{y'^2}{\sqrt{1+y'^2}} - \sqrt{1+y'^2} \right) = \frac{1}{\sqrt{2gy}} \cdot \frac{y'^2 - (1+y'^2)}{\sqrt{1+y'^2}} = -\frac{1}{\sqrt{2gy}\sqrt{1+y'^2}}.$$

The Beltrami identity gives $H = \text{const}$, that is

$$y(1+y'^2) = k \quad \text{a positive constant.}$$

This is the equation of the cycloid: setting $y = \frac{k}{2}(1 - \cos \tau)$ one gets $y'^2 = k/y - 1 = \frac{2 - (1 - \cos \tau)}{1 - \cos \tau} = \frac{1 + \cos \tau}{1 - \cos \tau} = \cot^2 \frac{\tau}{2}$, whence $dx = dy/y' = \frac{k}{2} \sin \tau \cdot \tan \frac{\tau}{2} d\tau = \frac{k}{2}(1 - \cos \tau) d\tau$ and therefore $x = \frac{k}{2}(\tau - \sin \tau) + x_0$: the parametrization of the cycloid of Chapter 2. *Check:* $\sin \tau \tan(\tau/2) = 2 \sin \frac{\tau}{2} \cos \frac{\tau}{2} \cdot \frac{\sin(\tau/2)}{\cos(\tau/2)} = 2 \sin^2 \frac{\tau}{2} = 1 - \cos \tau$. ✓ The brachistochrone is thus an arc of a cycloid — the same curve whose evolute is a cycloid, and the same one that solves the isochronous pendulum problem.

9.7. Industrial applications

Optimal trajectory planning. The calculus of variations is the foundation of optimal planning: one minimizes a functional (length, energy, time, jerk) and the Euler–Lagrange equation (Theorem 9.1) gives the necessary optimality conditions. In controllers and off-line programming toolboxes (**ABB** RobotStudio, **KUKA**.Sim, **FANUC** ROBOGUIDE, **Yaskawa** MotoSim) jerk-limited motion profiles and minimum-energy trajectories derive from this principle; on motion PLCs (**Siemens**, **Rockwell**, **Schneider**) trapezoidal and S-curve velocity profiles are the discrete implementation of constraints on the derivative of the acceleration. Geodesics are the “pure” case — minimal length on the configuration space — extended in practice with control-effort terms and constraints, solved numerically by direct collocation methods or by variational integrators.

Machining on developable surfaces. Proposition 9.2 and Proposition 9.1 are the reason why cutting, welding or deposition along a cylinder or a cone are programmed *in the developed plane*: the three-dimensional problem reduces to a two-dimensional one, and the straight trajectories of the plane lift to exact helices and conical spirals. The quantitative criterion telling when this is legitimate is the vanishing of the Gaussian curvature (Chapter 10).

Great-circle navigation and Clairaut. Clairaut’s relation (Theorem 9.4) is the mathematical form of a fact well known to navigators: along a great-circle route the product of the cosine of the latitude and the sine of the azimuth stays constant. It is the invariant that allows one to compute in advance the maximum latitude reached by a route, without integrating the geodesic equation (Exercise 9.6).

Filament winding. In the production of composite tanks and pipes the fibre must follow a geodesic of the mandrel in order not to slip: on a cylindrical mandrel these are the helices (Proposition 9.1), on a spherical cap the arcs of great circles (Theorem 9.3), and on general surfaces of revolution the trajectory is computed from Clairaut’s invariant.

9.8. Assigned exercises

Exercise 9.4. Goal: apply Proposition 9.4 and Clairaut’s relation to a surface whose parallel radii are not monotone. **Estimated time:** 25 minutes.

Consider the torus of revolution with $f(v) = a + b \cos v$, $h(v) = b \sin v$, $a > b > 0$. (i) Compute E , F , G and check that $G = b^2$. (ii) Determine all the parallels which are geodesics and describe them geometrically. (iii) A geodesic starts from a point of the outer equator making an angle ψ_0 with the meridian. Using Theorem 9.4, determine the minimum radius of the parallel it can reach and discuss for which ψ_0 it gets as far as the inner equator. Carry out the computation for $a = 2$, $b = 1$ and $\psi_0 = 30^\circ$.

Exercise 9.5. Goal: use the development of the cone to compute a geodesic and recognize its self-intersection. **Estimated time:** 30 minutes.

Let K_α be the cone of half-angle $\alpha = 20^\circ$ with the vertex removed. (i) Compute the opening β of the development sector and check that $\beta < \pi$. (ii) On the cone take the two points $P_0 = X(0, 3)$ and $P_1 = X(2\pi/3, 3)$. Determine, in the developed sector, the segment joining them, its distance d from the vertex and its length; compare the latter with the length of the path $P_0 \rightarrow \text{vertex} \rightarrow P_1$ along two generators (which equals 6). (iii) Decide whether the geodesic of part (ii), when extended, self-intersects, and compute at which value of u this happens.

Exercise 9.6. Goal: use Clairaut's invariant in navigation and check it against numerical integration of the geodesic. **Estimated time:** 20 minutes.

On the spherical Earth a great-circle route starts from latitude $\phi_0 = 45^\circ$ N with azimuth $Az = 60^\circ$ (measured clockwise from North). (i) Write Clairaut's relation in the form $\cos \phi \sin Az = \text{const}$, justifying its equivalence with Theorem 9.4. (ii) Compute the maximum latitude reached by the route, knowing that at its northernmost point the route is tangent to the parallel. (iii) Check that the same route, continuing, reaches the minimum latitude $-\phi_{\max}$ and explain why.

9.9. Worked exercises

Exercise 9.7. On the cylinder of radius $R = 1$ consider the points $P_0 = X(0, 0)$ and $P_1 = X(\pi/2, 1)$. Determine all the geodesics joining them, their lengths and the shortest one; compare with the chord in space and with the path “first turn, then climb”.

Solution. Strategy. Develop the cylinder onto the plane (Proposition 9.1(i)), count the segments joining the images of the two points taking periodicity into account, and compare the lengths with two explicit competing paths.

Step 1 — the development. The map $X(u, v) \mapsto (Ru, v) = (u, v)$ (since $R = 1$) is a local isometry onto the plane; P_0 goes to $(0, 0)$ and P_1 goes to all the points $(\pi/2 + 2\pi n, 1)$ with $n \in \mathbb{Z}$, because u and $u + 2\pi$ determine the same point of the cylinder.

Step 2 — the geodesics and their lengths. By Lemma 9.4 the geodesics correspond to the segments $(0, 0) \rightarrow (\pi/2 + 2\pi n, 1)$, of length

$$\ell_n = \sqrt{\left(\frac{\pi}{2} + 2\pi n\right)^2 + 1}.$$

There are infinitely many: one for each (signed) whole number of turns around the axis.

Step 3 — the numerical values.

$$\ell_{-2} = 11.040953, \quad \ell_{-1} = 4.817324, \quad \ell_0 = 1.862096, \quad \ell_1 = 7.917388, \quad \ell_2 = 14.172491.$$

The minimum is $\ell_0 = 1.862096$.

Step 4 — independent check. In closed form $\ell_0 = \sqrt{(\pi/2)^2 + 1} = \sqrt{2.467401 + 1} = \sqrt{3.467401} = 1.862096$; the numerical computation gives the same value to six decimals. ✓ Moreover $\ell_{-1} = \sqrt{(\pi/2 - 2\pi)^2 + 1} = \sqrt{(-4.712389)^2 + 1} = \sqrt{23.206609} = 4.817324$ ✓, and the asymmetry $\ell_{-1} < \ell_1$ is correct because $|\pi/2 - 2\pi| = 4.712389 < |\pi/2 + 2\pi| = 7.853982$.

Step 5 — the competitors. The *chord* in space between $P_0 = (1, 0, 0)$ and $P_1 = (0, 1, 1)$ measures $\sqrt{1 + 1 + 1} = \sqrt{3} = 1.732051$: smaller than ℓ_0 , but it is not a path on the cylinder. The path “first turn along the circle $z = 0$, then climb along the generator” measures

$R \cdot \pi/2 + 1 = 1.570796 + 1 = 2.570796 > 1.862096$: it is an admissible path but not a geodesic, and it is longer. ✓

Interpretation. On the cylinder the shortest path exists and is unique, but there are infinitely many geodesics between two points: stationarity does not suffice to select the minimum. It is the same phenomenon as on the sphere (Theorem 9.5), with one difference: here the failure of minimality comes from topology (the cylinder is not simply connected) and not from conjugate points — indeed the cylinder has vanishing Gaussian curvature and no conjugate points.

Typical errors. (a) Forgetting periodicity and concluding that the geodesic is unique. (b) Confusing the chord with the distance on the surface. (c) Using the formula for ℓ_n with Δu taken outside $(-\pi, \pi]$, and getting the minimizing index wrong.

Extension. For $\Delta u = \pi$ (diametrically opposite points at the same height) one has $\ell_0 = \ell_{-1} = \sqrt{\pi^2 + \Delta v^2}$: the minimum exists but is *not* unique, in perfect analogy with the antipodal points of the sphere (Exercise 7.3).

Exercise 9.8. On the unit sphere compute the length of the path along the parallel of latitude 60° N between two points 90° apart in longitude, and compare it with the length of the geodesic joining them. Check that the ratio is consistent with the fact that the parallel is not a geodesic.

Solution. Strategy. Compute separately the length along the parallel (elementary) and the geodesic distance (with the scalar product), then check the latter with the spherical law of cosines.

Step 1 — the two points. With latitude $\phi = 60^\circ$, that is colatitude $\vartheta_0 = 30^\circ$, and longitudes 0° and 90° :

$$A = (\sin 30^\circ, 0, \cos 30^\circ) = (0.5, 0, 0.866025), \quad B = (0, 0.5, 0.866025).$$

Check: $\|A\|^2 = 0.25 + 0.75 = 1$ ✓.

Step 2 — the path along the parallel. The parallel has radius $\sin \vartheta_0 = 0.5$ and the arc subtended by $90^\circ = \pi/2$ measures

$$\ell_{\text{par}} = 0.5 \cdot \frac{\pi}{2} = 0.785398.$$

Step 3 — the geodesic. $\langle A, B \rangle = 0.5 \cdot 0 + 0 \cdot 0.5 + 0.866025^2 = 0.750000$, hence

$$\ell_{\text{geo}} = \arccos(0.750000) = 0.722734.$$

Step 4 — independent check with the spherical law of cosines. In the triangle pole– A – B the two polar sides measure $\vartheta_0 = 30^\circ = 0.523599$ and the angle at the pole is 90° . Proposition 7.2 of Chapter 7 gives

$$\cos c = \cos^2 30^\circ + \sin^2 30^\circ \cos 90^\circ = 0.750000 + 0 = 0.750000,$$

that is $c = 0.722734$. ✓ The two computations agree to six decimals.

Step 5 — the comparison. $\ell_{\text{geo}} = 0.722734 < 0.785398 = \ell_{\text{par}}$: the geodesic is shorter by 8.0% (the parallel exceeds it by $0.785398/0.722734 = 1.086700$, that is by 8.67%). Hence the parallel is not minimizing, and a fortiori not a geodesic (Proposition 9.4), consistently with its geodesic curvature $\kappa_g = |\cot 30^\circ| = 1.732051 \neq 0$ (Exercise 9.2).

Interpretation. This is why transoceanic routes “climb” towards the pole instead of following the parallel: the geodesic cuts across higher latitudes. The gain grows with latitude:

at latitude 80° , with the same difference of longitude, the parallel measures $\sin 10^\circ \cdot \pi/2 = 0.272700$ and the geodesic $\arccos(\cos^2 10^\circ + \sin^2 10^\circ \cos 90^\circ) = \arccos(0.969846) = 0.245885$, an excess of 10.9%.

Typical errors. (a) Using the radius of the sphere instead of the radius of the parallel to compute ℓ_{par} . (b) Confusing latitude and colatitude in the scalar product. (c) Applying the *plane* law of cosines to a spherical triangle.

Extension. Repeat at the equator ($\vartheta_0 = 90^\circ$): $\ell_{\text{par}} = \pi/2 = \ell_{\text{geo}}$, because the equator *is* a geodesic. The gain is zero, as it must be.

Exercise 9.9. Check that, on the unit sphere, Clairaut's relation $\sin \vartheta \sin \psi = \text{const}$ is equivalent to the fact that every great circle lies on a plane through the centre, and use it to determine the minimum colatitude reached by a great circle crossing the equator at angle ι .

Solution. Strategy. Compute Clairaut's constant at two particular points of the same geodesic — the crossing of the equator and the point of maximum latitude — and compare the result with the vectorial description of the great circle.

Step 1 — the constant at the equator. On the unit sphere the radius of the parallel of colatitude ϑ is $r(\vartheta) = \sin \vartheta$. At the equator $\vartheta = \pi/2$, hence $r = 1$; if the geodesic crosses the equator making the angle ι with the equator itself, the angle with the meridian is $\psi = \pi/2 - \iota$ and

$$c = r \sin \psi = 1 \cdot \sin \left(\frac{\pi}{2} - \iota \right) = \cos \iota.$$

Step 2 — the point of maximum latitude. At the northernmost point the geodesic is tangent to the parallel, that is $\psi = \pi/2$ and $\sin \psi = 1$. Hence

$$c = r(\vartheta_{\min}) \cdot 1 = \sin \vartheta_{\min}, \quad \text{so that} \quad \sin \vartheta_{\min} = \cos \iota, \quad \vartheta_{\min} = \frac{\pi}{2} - \iota.$$

The minimum colatitude is $\pi/2 - \iota$: the maximum latitude is exactly ι .

Step 3 — independent vectorial check. The great circle crossing the equator at angle ι lies in the plane orthogonal to the unit vector $n = (0, -\sin \iota, \cos \iota)$ (for a suitable choice of the starting longitude). A point $P = (\sin \vartheta \cos \varphi, \sin \vartheta \sin \varphi, \cos \vartheta)$ belongs to the circle if and only if $\langle P, n \rangle = 0$, that is

$$-\sin \vartheta \sin \varphi \sin \iota + \cos \vartheta \cos \iota = 0, \quad \text{i.e.} \quad \tan \vartheta \sin \varphi = \cot \iota.$$

The colatitude is minimal when $\tan \vartheta$ is minimal positive, that is for $\sin \varphi = 1$: $\tan \vartheta_{\min} = \cot \iota$, hence $\vartheta_{\min} = \pi/2 - \iota$. ✓ The result agrees with Step 2.

Step 4 — numerical values. For $\iota = 30^\circ$: $c = \cos 30^\circ = 0.866025$ and $\vartheta_{\min} = 60^\circ$, that is maximum latitude 30° . For $\iota = 60^\circ$: $c = 0.500000$, maximum latitude 60° . For $\iota = 90^\circ$ (a meridian): $c = 0$ and the geodesic passes through the pole, maximum latitude 90° . ✓ The case $\iota = 0$ gives $c = 1$ and $\vartheta_{\min} = \pi/2$: the equator itself, which never moves away. ✓

Interpretation. Clairaut's constant c is the cosine of the inclination of the plane of the great circle with respect to the equatorial plane: a single number summarizing the whole geodesic. It is the same invariant which, in mechanics, is called the angular momentum about the axis.

Typical errors. (a) Confusing the angle with the meridian and the angle with the parallel (the relation has $\sin$ with the first and $\cos$ with the second). (b) Using the latitude instead of the radius of the parallel, which on the unit sphere is $\cos(\text{lat})$ and not lat . (c) Forgetting that ψ is not constant along the geodesic: what is constant is the product $r \sin \psi$.

Extension. The same constant answers at once another question: a geodesic with a given c never touches the parallels of radius $r < c$, because $\sin \psi \leq 1$ forces $r \geq c$. On the sphere

this excludes a polar cap of colatitude $\arcsin c$; on the torus it excludes a band around the inner equator (Exercise 9.4).

9.10. Self-assessment quiz

1. A curve γ on a surface S is a *geodesic*, by definition (Theorem 9.2), when
 - A) $\gamma'' = 0$
 - B) γ'' is orthogonal to the tangent plane at every point
 - C) γ is the shortest path between its endpoints
 - D) γ has zero curvature in $\mathbb{R}^3$
2. In the proof of the Euler–Lagrange equation, the hypothesis that makes the boundary term in the integration by parts vanish is
 - A) L of class C^2
 - B) $\eta(a) = \eta(b) = 0$
 - C) q of class C^2
 - D) U open
3. For the sphere of radius r in coordinates (φ, ϑ) the Christoffel symbol Γ_{11}^2 equals
 - A) $\cot \vartheta$
 - B) $-\sin \vartheta \cos \vartheta$
 - C) $-r^2 \sin \vartheta \cos \vartheta$
 - D) 0
4. A great-circle route starts at latitude 45° N with azimuth 60° . The maximum latitude it reaches equals, in degrees,
 - A) 45.000000
 - B) 52.238756
 - C) 60.000000
 - D) 30.000000
5. In the proof that the geodesics of S^2 are the great circles, the step that turns the condition $\gamma'' = \lambda\gamma$ into an integrable linear equation is
 - A) differentiating $\|\gamma\|^2 = r^2$, which shows that $\lambda = -c^2/r^2$ is constant
 - B) the fundamental lemma of the calculus of variations
 - C) Clairaut’s relation
 - D) the Picard–Lindelöf theorem
6. A student claims: “the arc of a great circle of length 4 on the unit sphere is the shortest path between its endpoints, because it is a geodesic”. The error is
 - A) it is not a geodesic
 - B) being a geodesic is necessary but not sufficient: the distance is $2\pi - 4 = 2.283185 < 4$
 - C) the length is miscomputed
 - D) none, the claim is correct
7. On a cone of half-angle $\alpha = 20^\circ$, a geodesic which is not a generator
 - A) never self-intersects
 - B) self-intersects, because $\beta = 2\pi \sin 20^\circ = 2.148573 < \pi$
 - C) is always closed
 - D) coincides with a parallel
8. Clairaut’s relation *together with its converse* (a constant-speed curve satisfying it and containing no arc of a parallel is a geodesic) is stated as
 - A) the Gauss–Bonnet theorem
 - B) Proposition 4.4 of Shifrin, *Differential Geometry: A First Course in Curves and Surfaces*, pp. 73–75
 - C) Meusnier’s theorem
 - D) Dandelin’s theorem

9.11. Teacher’s key

BEST PRACTICE

Q1 — answer B. *Rationale:* Theorem 9.2 states the equivalence between purely normal acceleration, the equation with the Christoffel symbols and stationarity of the energy; the working definition is (i). *Distractors:* A holds only in the plane (a curved geodesic in space has $\gamma'' \neq 0$); C is implied by minimality but not equivalent, as Theorem 9.5 shows; D confuses curvature in $\mathbb{R}^3$ with geodesic curvature. *Diagnosed error:* identifying geodesic with shortest path. *Source:* Shifrin, §2.4, p. 66 ff. *Prerequisite:* decomposition of a vector into tangential and normal parts. *Remediation:* redo Step 1 of the proof of Theorem 9.2 on the great circle and on the parallel.

Q2 — answer B. *Rationale:* Step 3 uses $[p_k \eta^k]_a^b = 0$, which holds precisely because the variation vanishes at the endpoints; the other hypotheses are used elsewhere (A and C for the differentiability of p_k , D for the good definition of the varied curves in Step 1). *Distractors:* all three are true hypotheses of the theorem, but not the one that kills the boundary term: the question checks that one knows what each hypothesis is for. *Diagnosed error:* listing hypotheses without knowing where they act. *Source:* Gelfand–Fomin, *Calculus of Variations*, Ch. 1. *Prerequisite:* integration by parts. *Remediation:* redo Step 3 with $\eta(b) \neq 0$ and see what natural boundary condition appears.

Q3 — answer B. *Rationale:* with $E = r^2 \sin^2 \vartheta$, $F = 0$, $G = r^2$ one has $\Gamma_{11}^2 = -E_\vartheta/(2G) = -2r^2 \sin \vartheta \cos \vartheta/(2r^2) = -\sin \vartheta \cos \vartheta$: the radius cancels. *Distractors:* A is Γ_{12}^1 ; C is the error of forgetting to divide by $G = r^2$; D is the value of the other four symbols. *Diagnosed error:* failing to cancel the scale factors and believing that the Christoffel symbols depend on the radius. *Source:* computation in Step 5 of the proof of Lemma 9.3, with numerical check by finite differences. *Prerequisite:* inverting a diagonal matrix. *Remediation:* recompute all six symbols for $r = 1$ and for $r = 2$ and observe that they agree.

Q4 — answer B. *Rationale:* Clairaut's constant equals $\cos 45^\circ \sin 60^\circ = 0.707107 \times 0.866025 = 0.612372$; at the northernmost point $\sin \text{Az} = 1$, hence $\cos \phi_{\max} = 0.612372$ and $\phi_{\max} = \arccos(0.612372) = 52.238756^\circ$. *Distractors:* A is the starting latitude (the route climbs, it does not stay); C confuses azimuth with latitude; D is $90^\circ - 60^\circ$. *Diagnosed error:* not recognizing that the invariant links two different points of the same geodesic. *Source:* Theorem 9.4 and a check by numerical integration of the geodesic equations of the sphere, which gives 52.2386° against the closed-form value 52.238756° . *Prerequisite:* arc-cosine. *Remediation:* repeat the computation for $\text{Az} = 90^\circ$ (does the route stay on the parallel? no: check) and for $\text{Az} = 0^\circ$.

Q5 — answer A. *Rationale:* Step 2 differentiates $\|\gamma\|^2 = r^2$ twice, uses the constancy of the speed (Step 6 of Theorem 9.2) and obtains $\lambda r^2 = -c^2$; only then is $\gamma'' + \omega^2 \gamma = 0$ linear with constant coefficients and integrable. *Distractors:* B is used in Theorem 9.1, not here; C gives a first integral but not the general solution; D is deliberately avoided (Step 6 of the same proof). *Diagnosed error:* not distinguishing between an equation with variable coefficients and one with constant coefficients. *Source:* do Carmo, Chapter 4 (source [2]); the proof given here is vectorial and self-contained. *Prerequisite:* second-order linear equations with constant coefficients. *Remediation:* rewrite Step 2 forgetting the constancy of the speed and see that the equation cannot be integrated in closed form.

Q6 — answer B. *Rationale:* by Theorem 9.5(ii) with $r = 1$ and $\ell = 4 > \pi$ the distance equals $\arccos(\cos 4) = 2\pi - 4 = 2.283185$, realized by the complementary arc. *Distractors:* A is false (the arc is a geodesic, Theorem 9.3); C is irrelevant; D accepts the error. *Diagnosed error:* confusing a necessary with a sufficient condition. *Source:* Theorem 9.5, Step 6, numerical check. *Prerequisite:* periodicity of the cosine. *Remediation:* tabulate ℓ and $\arccos(\cos \ell)$ for $\ell = 1, 2, 3, \pi, 4, 5, 6$ and locate where the two columns diverge.

Q7 — answer B. *Rationale:* by Proposition 9.3 self-intersection occurs if and only if $\alpha < 30^\circ$; here $\alpha = 20^\circ$ and $\beta = 2\pi \sin 20^\circ = 6.283185 \times 0.342020 = 2.148573 < \pi = 3.141593$. *Distractors:* A is the correct answer for $\alpha > 30^\circ$; C is false (the geodesics of the cone are not closed, apart from degenerate cases); D confuses geodesic and parallel. *Diagnosed error:* failing to translate a condition on the surface into one on the development. *Source:* Proposition 9.3, Step 5. *Prerequisite:* development of the cone. *Remediation:* draw the sector for $\alpha = 20^\circ, 30^\circ$ and 40° and trace a segment in each.

Q8 — answer B. *Rationale:* the statement with the clause “no part of the curve lies in a parallel” — indispensable, as Step 6 of the proof of Theorem 9.4 shows — is Proposition 4.4 of Shifrin, pp. 73–75, section 2.4 “Covariant Differentiation, Parallel Translation, and Geodesics”. *Distractors:* A, C and D are real theorems but on different subjects; they check that the student does not “recognize” a name at random. *Diagnosed error:* citing from memory without checking. *Source:* the same set of notes, verified on 5 September 2026 (source [1]). *Prerequisite:* none. *Remediation:* open the source and compare the statement with Theorem 9.4, noting that Shifrin uses the angle with the parallel (cosine) and we the angle with the meridian (sine).

Answers to the assigned exercises.

Exercise 9.4. (i) By Lemma 9.6, $E = (a + b \cos v)^2$, $F = 0$ and $G = f'^2 + h'^2 = b^2 \sin^2 v + b^2 \cos^2 v = b^2$: constant. (ii) By Proposition 9.4 the geodesic parallels are those with $f'(v) = -b \sin v = 0$, that is $v = 0$ (outer equator, radius $a + b$) and $v = \pi$ (inner equator, radius $a - b$); no others. With $a = 2$, $b = 1$: radii 3 and 1. (iii) Clairaut’s constant is $c = r_0 \sin \psi_0 = (a + b) \sin \psi_0$; the minimum reachable radius is $r_{\min} = c$, because $\sin \psi \leq 1$ forces $r \geq c$. With $a = 2$, $b = 1$, $\psi_0 = 30^\circ$: $c = 3 \times 0.5 = 1.5$, hence the geodesic does not go below the parallel of radius 1.5; since $a - b = 1 < 1.5$, it does *not* reach the inner equator. The condition for reaching it is $c \leq a - b$, that is $\sin \psi_0 \leq (a - b)/(a + b) = 1/3 = 0.333333$, that is $\psi_0 \leq 19.471221^\circ$.

Exercise 9.5. (i) $\beta = 2\pi \sin 20^\circ = 6.283185 \times 0.342020 = 2.148573 < \pi = 3.141593$ ✓. (ii) In the development the two points have polar coordinates $(\theta, \rho) = (0, 3)$ and $(\frac{2\pi}{3} \sin 20^\circ, 3) = (0.716191, 3)$; the angle between them is $\Delta\theta = 0.716191$ rad. The segment joining them has length $2 \cdot 3 \sin(\Delta\theta/2) = 6 \times \sin(0.358096) = 6 \times 0.350488 = 2.102928$ and lies at distance $d = 3 \cos(\Delta\theta/2) = 3 \times 0.936570 = 2.809710$ from the vertex. The path through the vertex measures $3 + 3 = 6 > 2.102928$: the geodesic is far shorter. ✓(iii) Yes: by Proposition 9.3, since $\alpha = 20^\circ < 30^\circ$, the extended geodesic self-intersects; this happens for $u = u_0 \pm \pi$, that is when the two branches are 2π apart in u . Here $u_0 = \pi/3$ (by symmetry between 0 and $2\pi/3$), hence the self-intersection is at the parameters $u = \pi/3 - \pi = -2.094395$ and $u = \pi/3 + \pi = 4.188790$, which are the same point on the cone; the radius is $v = d / \cos(\pi \sin 20^\circ) = 2.809710 / \cos(1.074287) = 2.809710 / 0.477159 = 5.888$.

Exercise 9.6. (i) On the unit sphere the radius of the parallel of latitude ϕ is $r = \cos \phi$ and the angle with the meridian is the azimuth Az (measured from North): the relation $r \sin \psi = \text{const}$ of Theorem 9.4 becomes $\cos \phi \sin \text{Az} = \text{const}$. (ii) $c = \cos 45^\circ \sin 60^\circ = 0.707107 \times 0.866025 = 0.612372$; at the point of maximum latitude $\sin \text{Az} = 1$, hence $\phi_{\max} = \arccos(0.612372) = 52.238756^\circ$. Direct numerical integration of the geodesic equations of the sphere gives 52.2386° : agreement within the discretization error. ✓(iii) The great circle is symmetric about the centre of the sphere: if it contains the point of latitude $\phi_{\max}$, it also contains its antipode, of latitude $-\phi_{\max}$, and by Theorem 9.3 the geodesic traverses the whole of it. The route therefore oscillates between -52.238756° and $+52.238756^\circ$, and never enters the two polar caps of half-width 37.761244° .

9.12. Chapter formulary

Calculus of variations

$$J[q] = \int_a^b L(s, q, q') ds; \quad \frac{d}{ds} \frac{\partial L}{\partial q'^k} - \frac{\partial L}{\partial q^k} = 0$$

$$\text{Beltrami (if } \partial_s L = 0) : \quad H = \frac{\partial L}{\partial q'^k} q'^k - L = \text{const}$$

$$L(\gamma)^2 \leq 2(b-a)E(\gamma), \quad E(\gamma) = \frac{1}{2} \int_a^b \|\gamma'\|^2 ds, \quad \text{equality} \iff \|\gamma'\| = \text{const}$$

Geodesics of a surface

$$\Gamma_{ij}^k = \frac{1}{2} g^{kl} (\partial_i g_{jl} + \partial_j g_{il} - \partial_l g_{ij}); \quad X_{ij} = \Gamma_{ij}^k X_k + h_{ij} N$$

$$\ddot{u}^k + \Gamma_{ij}^k \dot{u}^i \dot{u}^j = 0 \iff \gamma'' \perp T_p S \iff \delta E = 0; \quad \|\gamma'\| = \text{const}$$

$$F = 0 : \quad \Gamma_{11}^1 = \frac{E_u}{2E}, \quad \Gamma_{12}^1 = \frac{E_v}{2E}, \quad \Gamma_{22}^1 = -\frac{G_u}{2E}, \quad \Gamma_{11}^2 = -\frac{E_v}{2G}, \quad \Gamma_{12}^2 = \frac{G_u}{2G}, \quad \Gamma_{22}^2 = \frac{G_v}{2G}$$

Sphere of radius r , coordinates (φ, ϑ)

$$E = r^2 \sin^2 \vartheta, \quad F = 0, \quad G = r^2; \quad \Gamma_{12}^1 = \cot \vartheta, \quad \Gamma_{11}^2 = -\sin \vartheta \cos \vartheta$$

$$\ddot{\varphi} + 2 \cot \vartheta \dot{\varphi} \dot{\vartheta} = 0, \quad \ddot{\vartheta} - \sin \vartheta \cos \vartheta \dot{\varphi}^2 = 0$$

$$\gamma(s) = \cos \frac{cs}{r} P + \sin \frac{cs}{r} Q, \quad P \perp Q, \quad \|P\| = \|Q\| = r \quad (\text{great circles})$$

$$\kappa_g(\text{parallel of colatitude } \vartheta_0) = \frac{|\cot \vartheta_0|}{r}; \quad \ell > \pi r \Rightarrow \text{dist} = r \arccos \left(\cos \frac{\ell}{r} \right) < \ell$$

Cylinder, cone, surfaces of revolution

$$\text{cylinder } R : I = R^2 du^2 + dv^2, \quad \Gamma_{ij}^k = 0, \quad \text{geodesics} = \text{helices } u = as + u_0, \quad v = bs + v_0$$

$$\text{cone } \alpha : I = v^2 \sin^2 \alpha du^2 + dv^2, \quad \beta = 2\pi \sin \alpha, \quad v = \frac{d}{\cos(\sin \alpha (u - u_0))}$$

$$\text{self-intersection} \iff \sin \alpha < \frac{1}{2} \iff \alpha < 30^\circ$$

$$\text{revolution} : E = f^2, \quad F = 0, \quad G = f'^2 + h'^2; \quad \text{Clairaut} : r \sin \psi = f^2 \dot{u} = \text{const}$$

$$\text{parallel } v_0 \text{ geodesic} \iff f'(v_0) = 0$$

Local theory of surfaces

A surface carries two distinct measures. The *first fundamental form* measures lengths, angles and areas *on* the surface: it is everything a two-dimensional inhabitant could detect without ever leaving its own world. The *second fundamental form* measures how the surface bends *in* space: it is what one sees from outside. From them come the principal curvatures, the mean curvature and the Gaussian curvature; and from them comes the result that Gauss himself judged remarkable enough to call it *egregium*: the Gaussian curvature, defined by means of the second form, is in fact expressible through the first form alone. The two-dimensional inhabitant, who cannot see its surface from outside, can nevertheless measure its curvature — and discover, for instance, that its world is not a plane.

INFO

The idea in one line. The product of the two principal curvatures, $K = \kappa_1 \kappa_2$, seems to depend on the way the surface is embedded in space, because it is defined with the second form; the Gauss equation shows instead that K is written with E, F, G and their derivatives alone, so that two isometric surfaces have the same K point by point — and no piece of a sphere ($K = 1/r^2$) can be flattened onto a plane ($K = 0$) without stretching it.

INFO

Level and prerequisites. Level C. Sections 10.1 and 10.2 are level B–C: the scalar and cross product in $\mathbb{R}^3$, partial derivatives and the linear algebra of quadratic forms in two variables suffice. Sections 10.3, 10.5 and 10.6 are level C. Section 10.4, which contains the proof of the *Theorema Egregium*, is level C–D. Prerequisites within the treatise: curvature of a plane curve and of a space curve (Chapters 2 and 3); sphere, spherical coordinates and area element (Chapter 7); Christoffel symbols, geodesic equation and local isometries (Chapter 9, from which this chapter takes over without re-proving them Lemma 9.3 and Lemma 9.4); Gauss–Bonnet for the geodesic triangle (Chapter 7) and global Gauss–Bonnet (Chapter 4).

Warning. Conventions of the chapter.

- The index conventions of Chapter 9 are in force: Latin indices in $\{1, 2\}$, Einstein summation convention, $X_i = \partial X / \partial u^i$, $X_{ij} = \partial^2 X / \partial u^i \partial u^j$; X is always regular and of class C^3 .
- $g_{ij} = \langle X_i, X_j \rangle$ with $E = g_{11}$, $F = g_{12}$, $G = g_{22}$ and $D = EG - F^2 > 0$; $h_{ij} = \langle X_{ij}, N \rangle$ with $e = h_{11}$, $f = h_{12}$, $g = h_{22}$.
- The unit normal is always the one *induced by the parametrization*, $N = (X_1 \times X_2) / \|X_1 \times X_2\|$. Changing orientation, N , II , the principal curvatures and H change sign; K does *not*, being a product of two principal curvatures. Whenever the sign of H is stated, the chosen normal is indicated.
- **Beware of the clash of symbols:** g denotes both the matrix g_{ij} of the first form and the coefficient h_{22} of the second. The context always distinguishes them (the first carries indices, the second appears next to e and f); where the risk of confusion is real

the index notation h_{ij} is used.

- Decimal separators are points: 0.5.

10.1. The first fundamental form

Definition 10.1: Regular surface and first fundamental form. A set $S \subset \mathbb{R}^3$ is a **regular surface** if every point of it has a neighbourhood V in S for which there exist an open set $U \subseteq \mathbb{R}^2$ and a map $X : U \rightarrow V$ of class C^3 , bijective with continuous inverse, such that $X_1(q) \times X_2(q) \neq 0$ for every $q \in U$; X is called a **parametrization**. The **first fundamental form** at $p = X(q)$ is the quadratic form on the tangent plane $T_p S = \text{span}\{X_1, X_2\}$

$$I_p(w) = \langle w, w \rangle, \quad w = a^i X_i,$$

which in coordinates reads $I = E du^2 + 2F du dv + G dv^2$ with

$$E = \langle X_1, X_1 \rangle, \quad F = \langle X_1, X_2 \rangle, \quad G = \langle X_2, X_2 \rangle.$$

Lemma 10.1: Lagrange's identity and the determinant of the first form. For every pair of vectors $a, b \in \mathbb{R}^3$ one has $\|a \times b\|^2 = \|a\|^2 \|b\|^2 - \langle a, b \rangle^2$. In particular

$$\|X_1 \times X_2\|^2 = EG - F^2 = D > 0,$$

and the matrix (g_{ij}) is positive definite.

Proof. Step 1 — the identity. If a or b is zero both sides vanish. Otherwise, letting $\theta \in [0, \pi]$ be the angle between a and b , one has $\|a \times b\| = \|a\| \|b\| \sin \theta$ and $\langle a, b \rangle = \|a\| \|b\| \cos \theta$; squaring and adding,

$$\|a \times b\|^2 + \langle a, b \rangle^2 = \|a\|^2 \|b\|^2 (\sin^2 \theta + \cos^2 \theta) = \|a\|^2 \|b\|^2.$$

Step 2 — consequence for the first form. Applying this to $a = X_1$, $b = X_2$ one obtains $\|X_1 \times X_2\|^2 = EG - F^2$. Regularity gives $X_1 \times X_2 \neq 0$, hence $D > 0$.

Step 3 — positive definiteness. The matrix (g_{ij}) is symmetric, has $E = \|X_1\|^2 > 0$ and determinant $D > 0$: by Sylvester's criterion of leading principal minors it is positive definite. This is also seen directly: $I(a^i X_i) = \|a^i X_i\|^2 \geq 0$, with equality only if $a^i X_i = 0$, that is $a = 0$ by the independence of X_1, X_2 . $\square$

Proposition 10.1: What the first form measures. Let $X : U \rightarrow S$ be a parametrization. Then:

(i) the length of a curve $\gamma = X \circ u$ with $u : [a, b] \rightarrow U$ of class C^1 equals $L(\gamma) = \int_a^b \sqrt{g_{ij} \dot{u}^i \dot{u}^j} ds$;

(ii) the angle θ between two non-zero tangent vectors $w = a^i X_i$ and $z = b^j X_j$ satisfies

$$\cos \theta = \frac{g_{ij} a^i b^j}{\sqrt{g_{kl} a^k a^l} \sqrt{g_{mn} b^m b^n}};$$

(iii) the area of a region $R \subseteq S$ contained in $V = X(U)$ equals $\text{Area}(R) = \iint_{X^{-1}(R)} \sqrt{EG - F^2} du^1 du^2$, and the value does not depend on the chosen parametrization.

Proof. Step 1 — (i). By the chain rule $\gamma' = \dot{u}^i X_i$, hence $\|\gamma'\|^2 = \langle \dot{u}^i X_i, \dot{u}^j X_j \rangle = g_{ij} \dot{u}^i \dot{u}^j$; integrating the norm gives the length.

Step 2 — (ii). It is the definition of the angle between two vectors, $\cos \theta = \langle w, z \rangle / (\|w\| \|z\|)$, rewritten with $\langle w, z \rangle = g_{ij} a^i b^j$ and $\|w\|^2 = g_{kl} a^k a^l$.

Step 3 — (iii), definition of the area. The area of R is by definition the integral over $X^{-1}(R)$ of the area of the infinitesimal parallelogram spanned by $X_1 du^1$ and $X_2 du^2$, which equals $\|X_1 \times X_2\| du^1 du^2$; by Lemma 10.1 that quantity is $\sqrt{EG - F^2} du^1 du^2$.

Step 4 — (iii), independence of the parametrization. Let $\bar{X} = X \circ \phi$ with $\phi : \bar{U} \rightarrow U$ a diffeomorphism, and let J be the Jacobian matrix of ϕ . By the chain rule $\bar{X}_i = (\partial_i \phi^k) X_k$, hence

$$\bar{X}_1 \times \bar{X}_2 = (\partial_1 \phi^1 \partial_2 \phi^2 - \partial_1 \phi^2 \partial_2 \phi^1) X_1 \times X_2 = \det J \cdot X_1 \times X_2,$$

because the terms with the same factor twice vanish ($X_k \times X_k = 0$). Hence $\|\bar{X}_1 \times \bar{X}_2\| = |\det J| \|X_1 \times X_2\|$, and the change of variables formula for double integrals gives the same value for the area.

Step 5 — check on the sphere. With $X(\varphi, \vartheta)$ the spherical coordinates, Exercise 10.1 gives $\sqrt{EG - F^2} = r^2 \sin \vartheta$, that is exactly the area element of Lemma 7.1 of Chapter 7, which in turn, integrated over the whole sphere, gives $4\pi r^2$. ✓ □

Exercise 10.1. Compute the first fundamental form and the area element of the sphere of radius r parametrized by $X(\varphi, \vartheta) = r(\sin \vartheta \cos \varphi, \sin \vartheta \sin \varphi, \cos \vartheta)$, with $\vartheta \in (0, \pi)$.

Solution. $X_\varphi = r(-\sin \vartheta \sin \varphi, \sin \vartheta \cos \varphi, 0)$ and $X_\vartheta = r(\cos \vartheta \cos \varphi, \cos \vartheta \sin \varphi, -\sin \vartheta)$. Hence

$$E = r^2 \sin^2 \vartheta (\sin^2 \varphi + \cos^2 \varphi) = r^2 \sin^2 \vartheta, \quad G = r^2 (\cos^2 \vartheta + \sin^2 \vartheta) = r^2,$$

$$F = r^2 \sin \vartheta \cos \vartheta (-\sin \varphi \cos \varphi + \cos \varphi \sin \varphi) = 0.$$

Therefore $I = r^2 \sin^2 \vartheta d\varphi^2 + r^2 d\vartheta^2$ and $\sqrt{EG - F^2} = r^2 \sin \vartheta$: parallels and meridians are orthogonal and the sphere is a surface of revolution with profile $f(\vartheta) = r \sin \vartheta$, $h(\vartheta) = r \cos \vartheta$ (Definition 9.3), consistently with Lemma 9.6, which gives $E = f'^2 = r^2 \sin^2 \vartheta$ and $G = f'^2 + h'^2 = r^2 \cos^2 \vartheta + r^2 \sin^2 \vartheta = r^2$. ✓ Regularity requires $\sin \vartheta \neq 0$: the two poles must be excluded from this chart, not from the sphere. *Numerical check:* for $r = 1.7$ and $\vartheta = 1.12$ the formula gives $E = 1.7^2 \sin^2(1.12) = 2.89 \times 0.810181 = 2.34142253$ and $G = 2.89$; the numerical computation by finite differences on the parametrization gives 2.34142252 and 2.88999999. ✓

Example 10.1: First forms recurring in the chapter.

- *Plane*, $Y(u, v) = (u, v, 0)$: $E = G = 1$, $F = 0$.
- *Cylinder* of radius R , $X(u, v) = (R \cos u, R \sin u, v)$: $E = R^2$, $F = 0$, $G = 1$ (Proposition 9.1).
- *Cone* of half-angle α , $X(u, v) = (v \sin \alpha \cos u, v \sin \alpha \sin u, v \cos \alpha)$ with $v > 0$: $E = v^2 \sin^2 \alpha$, $F = 0$, $G = 1$ (Proposition 9.2).
- *Surface of revolution* with profile (f, h) : $E = f'^2$, $F = 0$, $G = f'^2 + h'^2$ (Lemma 9.6).
- *Torus* $X(u, v) = ((a + b \cos v) \cos u, (a + b \cos v) \sin u, b \sin v)$ with $a > b > 0$: $E = (a + b \cos v)^2$, $F = 0$, $G = b^2$.
- *Catenoid* $X(u, v) = (\cosh v \cos u, \cosh v \sin u, v)$: $E = G = \cosh^2 v$, $F = 0$ — a conformal first form.

10.2. Gauss map and second fundamental form

Definition 10.2: Gauss map and second fundamental form. Given a parametrization $X : U \rightarrow S$, the **Gauss map** is

$$N = \frac{X_1 \times X_2}{\|X_1 \times X_2\|} : U \rightarrow S^2,$$

the unit normal vector. The **second fundamental form** at $p = X(q)$ is the quadratic form on the tangent plane

$$\Pi_p(w) = h_{ij}a^i a^j, \quad w = a^i X_i, \quad h_{ij} = \langle X_{ij}, N \rangle,$$

which in classical notation reads $\Pi = e du^2 + 2f du dv + g dv^2$ with $e = h_{11}$, $f = h_{12} = h_{21}$, $g = h_{22}$.

Definition 10.3: Shape operator. The **shape operator** (or Weingarten operator) at p is $\mathcal{S}_p = -dN_p : T_p S \rightarrow T_p S$, where dN_p is the differential of the Gauss map, read as a linear map of the tangent plane into itself (which is legitimate because $T_{N(p)} S^2$ and $T_p S$ are both $N(p)^\perp$).

Proposition 10.2: Weingarten formulas and self-adjointness. With the preceding notation:

- (i) N_i is tangent and $\langle N_i, X_j \rangle = -h_{ij}$; consequently $N_i = -h_{ij}g^{jk}X_k$ and $\mathcal{S}(X_i) = h_{ij}g^{jk}X_k$;
- (ii) $\langle \mathcal{S}(w), z \rangle = \Pi(w, z) = \langle w, \mathcal{S}(z) \rangle$ for all $w, z \in T_p S$: $\mathcal{S}$ is self-adjoint with respect to the first form;
- (iii) the matrix of $\mathcal{S}$ in the basis $\{X_1, X_2\}$, written by columns, is $I^{-1}\Pi$, and hence

$$\det \mathcal{S} = \frac{eg - f^2}{EG - F^2}, \quad \text{tr } \mathcal{S} = \frac{eG - 2fF + gE}{EG - F^2};$$

- (iv) $\mathcal{S}$ has two real eigenvalues and, if they are distinct, orthogonal eigenvectors.

Proof. Step 1 — N_i is tangent. From $\langle N, N \rangle \equiv 1$, differentiating with respect to u^i , one obtains $2\langle N_i, N \rangle = 0$: hence $N_i \perp N$, that is $N_i \in T_p S$ and one writes $N_i = a_i^k X_k$.

Step 2 — the scalar product with X_j . From $\langle N, X_j \rangle \equiv 0$, differentiating with respect to u^i ,

$$\langle N_i, X_j \rangle + \langle N, X_{ji} \rangle = 0, \quad \text{that is} \quad \langle N_i, X_j \rangle = -h_{ij}.$$

On the other hand $\langle N_i, X_j \rangle = a_i^k g_{kj}$, hence $a_i^k g_{kj} = -h_{ij}$ and, multiplying by g^{jm} and summing, $a_i^m = -h_{ij}g^{jm}$. Since $\mathcal{S}(X_i) = -dN(X_i) = -N_i$, it follows that $\mathcal{S}(X_i) = h_{ij}g^{jk}X_k$. This proves (i).

Step 3 — (ii). It suffices to check it on the basis:

$$\langle \mathcal{S}(X_i), X_j \rangle = \langle -N_i, X_j \rangle = h_{ij},$$

an expression symmetric in i and j (because $X_{ij} = X_{ji}$ by Schwarz's theorem, valid since X is of class C^3). By bilinearity the equality extends to all tangent vectors, and $\Pi(w, z)$ is the symmetric bilinear form associated with the quadratic form Π .

Step 4 — (iii). From Step 2, the k -th component of $\mathcal{S}(X_i)$ is $h_{ij}g^{jk}$; the matrix by columns therefore has at entry (k, i) the number $g^{kj}h_{ji}$, that is it is the matrix product $I^{-1}\Pi$ (using the symmetry of I^{-1} and of Π). The determinant of a product is the product of the determinants:

$\det \mathcal{S} = \det(\text{II})/\det(\text{I}) = (eg - f^2)/(EG - F^2)$. For the trace one carries out the product:

$$\text{I}^{-1}\text{II} = \frac{1}{D} \begin{pmatrix} G & -F \\ -F & E \end{pmatrix} \begin{pmatrix} e & f \\ f & g \end{pmatrix} = \frac{1}{D} \begin{pmatrix} Ge - Ff & Gf - Fg \\ -Fe + Ef & -Ff + Eg \end{pmatrix},$$

whose trace is $(Ge - Ff - Ff + Eg)/D = (eG - 2fF + gE)/D$.

Step 5 — (iv). Choose an orthonormal basis $\{v_1, v_2\}$ of $T_p S$; in it the matrix of $\mathcal{S}$ is $\begin{pmatrix} p & q \\ q & r \end{pmatrix}$, symmetric by (ii) (the entry (i, j) is $\langle \mathcal{S}(v_j), v_i \rangle$). The characteristic polynomial $\lambda^2 - (p+r)\lambda + (pr - q^2)$ has discriminant

$$(p+r)^2 - 4(pr - q^2) = (p-r)^2 + 4q^2 \geq 0,$$

hence two real eigenvalues. If they are distinct and $\mathcal{S}v = \kappa_1 v$, $\mathcal{S}w = \kappa_2 w$, then $\kappa_1 \langle v, w \rangle = \langle \mathcal{S}v, w \rangle = \langle v, \mathcal{S}w \rangle = \kappa_2 \langle v, w \rangle$, whence $(\kappa_1 - \kappa_2) \langle v, w \rangle = 0$ and therefore $\langle v, w \rangle = 0$. If they coincide, $\mathcal{S}$ is a multiple of the identity (a symmetric 2×2 matrix with vanishing discriminant has $p = r$ and $q = 0$) and every orthonormal basis consists of eigenvectors. $\square$

Proposition 10.3: Normal curvature and Meusnier's theorem. Let γ be a C^2 curve on S parametrized by arclength with $\gamma(0) = p$ and $\gamma'(0) = w$, $\|w\| = 1$. Then the **normal curvature** $\kappa_n = \langle \gamma''(0), N(p) \rangle$ depends only on w and not on the curve:

$$\kappa_n(w) = \text{II}_p(w) = \langle \mathcal{S}(w), w \rangle.$$

Moreover, letting $\kappa_1 \leq \kappa_2$ be the roots of the characteristic polynomial of $\mathcal{S}$ and $\{v_1, v_2\}$ an orthonormal basis of eigenvectors,

$$\kappa_n(\cos \theta v_1 + \sin \theta v_2) = \kappa_1 \cos^2 \theta + \kappa_2 \sin^2 \theta \quad (\text{Euler's formula}),$$

and $\kappa_1 = \min_{\|w\|=1} \kappa_n(w)$, $\kappa_2 = \max_{\|w\|=1} \kappa_n(w)$.

Proof. Step 1 — computation of κ_n . Writing $\gamma = X \circ u$, Step 1 of the proof of Theorem 9.2 gives $\gamma'' = (\ddot{u}^k + \Gamma_{ij}^k \dot{u}^i \dot{u}^j) X_k + h_{ij} \dot{u}^i \dot{u}^j N$. Since $\langle X_k, N \rangle = 0$,

$$\kappa_n = \langle \gamma'', N \rangle = h_{ij} \dot{u}^i \dot{u}^j = \text{II}(w),$$

where $w = \dot{u}^i X_i = \gamma'(0)$: it depends only on w . This is Meusnier's theorem in the form needed here: all curves on S through p with the same tangent have the same normal curvature.

Step 2 — the expression with the shape operator. By Proposition 10.2(ii), $\text{II}(w) = \text{II}(w, w) = \langle \mathcal{S}(w), w \rangle$.

Step 3 — Euler's formula. In the orthonormal basis of eigenvectors, $\mathcal{S}(v_1) = \kappa_1 v_1$ and $\mathcal{S}(v_2) = \kappa_2 v_2$; putting $w = \cos \theta v_1 + \sin \theta v_2$ (which is a unit vector),

$$\langle \mathcal{S}(w), w \rangle = \langle \kappa_1 \cos \theta v_1 + \kappa_2 \sin \theta v_2, \cos \theta v_1 + \sin \theta v_2 \rangle = \kappa_1 \cos^2 \theta + \kappa_2 \sin^2 \theta.$$

Step 4 — extrema. Since $\cos^2 \theta + \sin^2 \theta = 1$, the expression of Step 3 is a convex combination of κ_1 and κ_2 : it ranges between the minimum κ_1 (attained at $\theta = 0$) and the maximum κ_2 (at $\theta = \pi/2$). $\square$

Exercise 10.2. Compute the Gauss map and the second fundamental form of the sphere of radius r in the parametrization of Exercise 10.1, and deduce the shape operator.

Solution. Step 1 — the Gauss map. From the computation of X_φ and X_ϑ in Exercise 10.1,

$$X_\varphi \times X_\vartheta = -r \sin \vartheta \cdot X, \quad \|X_\varphi \times X_\vartheta\| = r^2 \sin \vartheta,$$

(check it component by component: the first is $r^2 \sin \vartheta (\sin \vartheta \cos \varphi) \cdot (-1)$, and similarly the other two), hence

$$N = -\frac{X}{r}.$$

The normal induced by this parametrization is the *inner* one: it points towards the centre.

Step 2 — the second form. With $X_{\varphi\varphi} = -r \sin \vartheta (\cos \varphi, \sin \varphi, 0)$, $X_{\vartheta\vartheta} = -X$ and $X_{\varphi\vartheta} = r \cos \vartheta (-\sin \varphi, \cos \varphi, 0)$:

$$e = \left\langle X_{\varphi\varphi}, -\frac{X}{r} \right\rangle = \frac{r \sin \vartheta}{r} \langle (\cos \varphi, \sin \varphi, 0), X \rangle = \sin \vartheta \cdot r \sin \vartheta = r \sin^2 \vartheta,$$

$$g = \left\langle -X, -\frac{X}{r} \right\rangle = \frac{r^2}{r} = r, \quad f = -\frac{r \cos \vartheta}{r} \cdot r \sin \vartheta (-\sin \varphi \cos \varphi + \cos \varphi \sin \varphi) = 0.$$

Hence $\text{II} = r \sin^2 \vartheta d\varphi^2 + r d\vartheta^2 = \frac{1}{r} \text{I}$: the second form is proportional to the first, a sign that the sphere bends equally in every direction.

Step 3 — shape operator. By Proposition 10.2(iii), $\mathcal{S} = \text{I}^{-1}\text{II} = \text{I}^{-1} \cdot \frac{1}{r}\text{I} = \frac{1}{r} \text{id}$: every direction is principal and $\kappa_1 = \kappa_2 = 1/r$ (with the inner normal). *Numerical check:* for $r = 1.7$ and $(\varphi, \vartheta) = (0.83, 1.12)$ the finite-difference computation gives $N = (-0.607456, -0.664212, -0.435682)$, which agrees to six decimals with $-X/r$ ✓; $e = 1.37730691$ against $r \sin^2 \vartheta = 1.7 \times 0.810181 = 1.37730737$ ✓; $g = 1.70000000$ and $f = 0$ ✓; and the eigenvalues of $\mathcal{S}$ both come out 0.58823510 against $1/1.7 = 0.58823529$. ✓

10.3. Principal, mean and Gaussian curvatures

Definition 10.4: Principal, Gaussian and mean curvatures. The eigenvalues κ_1, κ_2 of the shape operator $\mathcal{S}_p$ are the **principal curvatures** at p , and the corresponding eigenvectors the **principal directions**. One sets

$$K = \kappa_1 \kappa_2 = \det \mathcal{S} = \frac{eg - f^2}{EG - F^2} \quad (\text{Gaussian curvature}),$$

$$H = \frac{\kappa_1 + \kappa_2}{2} = \frac{1}{2} \text{tr} \mathcal{S} = \frac{eG - 2fF + gE}{2(EG - F^2)} \quad (\text{mean curvature}).$$

A point at which $\kappa_1 = \kappa_2$ is called **umbilic**; a surface with $H \equiv 0$ is called **minimal**.

Corollary 10.1: Inequality between the two curvatures. At every point $H^2 \geq K$, with equality if and only if the point is umbilic. In particular, if $K > 0$ then $H \neq 0$: a minimal surface has no points of positive Gaussian curvature.

Proof. Since κ_1, κ_2 are real (Proposition 10.2(iv)),

$$H^2 - K = \left(\frac{\kappa_1 + \kappa_2}{2} \right)^2 - \kappa_1 \kappa_2 = \frac{(\kappa_1 - \kappa_2)^2}{4} \geq 0,$$

with equality if and only if $\kappa_1 = \kappa_2$, that is at an umbilic point. If $K > 0$ and $H = 0$, one would have $0 = H^2 \geq K > 0$: absurd. $\square$

Proposition 10.4: Curvatures of the sphere. For $S^2(O, r)$, with the inner normal, one has $\kappa_1 = \kappa_2 = 1/r$ at every point, hence $K = 1/r^2$ and $H = 1/r$, constants; every point is umbilic. With the outer normal $\kappa_1 = \kappa_2 = -1/r$, $H = -1/r$ and $K = 1/r^2$ as before.

Proof. Step 1 — via the shape operator. With the inner normal $N(P) = -P/r$ (where O is the origin), the Gauss map is linear in P , hence $dN_P(w) = -w/r$ for every $w \in T_P S^2$ and

$$\mathcal{S}_P = -dN_P = \frac{1}{r} \text{id}.$$

Every vector is an eigenvector with eigenvalue $1/r$: the principal curvatures coincide and $K = 1/r^2$, $H = 1/r$.

Step 2 — via the forms in coordinates. Step 3 of the solution of Exercise 10.2 gives the same result in spherical coordinates, and confirms it by the explicit computation

$$K = \frac{eg - f^2}{EG - F^2} = \frac{r \sin^2 \vartheta \cdot r - 0}{r^2 \sin^2 \vartheta \cdot r^2} = \frac{r^2 \sin^2 \vartheta}{r^4 \sin^2 \vartheta} = \frac{1}{r^2},$$

$$H = \frac{eG - 2fF + gE}{2(EG - F^2)} = \frac{r \sin^2 \vartheta \cdot r^2 + r \cdot r^2 \sin^2 \vartheta}{2r^4 \sin^2 \vartheta} = \frac{2r^3 \sin^2 \vartheta}{2r^4 \sin^2 \vartheta} = \frac{1}{r}.$$

Step 3 — change of orientation. Replacing N by $-N$ changes the sign of all the h_{ij} , hence of $\mathcal{S}$, of κ_1, κ_2 and of H ; the product $K = \kappa_1 \kappa_2$ does not change. This is why K is an invariant of the surface while H depends on the chosen orientation.

Step 4 — consistency with Chapter 7. Step 2 of the proof of Theorem 7.11 uses exactly this computation, with the inner normal, to identify the factor $1/r^2$ in the spherical excess with the Gaussian curvature. ✓ □

Exercise 10.3. Show that the cylinder of radius R has $K \equiv 0$ and $H = -1/(2R)$ with the normal induced by the parametrization $X(u, v) = (R \cos u, R \sin u, v)$, and identify the principal directions.

Solution. From Example 10.1, $E = R^2$, $F = 0$, $G = 1$. The cross product $X_u \times X_v = (-R \sin u, R \cos u, 0) \times (0, 0, 1) = (R \cos u, R \sin u, 0)$ has norm R , hence $N = (\cos u, \sin u, 0)$: the outer normal. With $X_{uu} = (-R \cos u, -R \sin u, 0)$, $X_{uv} = 0$ and $X_{vv} = 0$:

$$e = \langle X_{uu}, N \rangle = -R \cos^2 u - R \sin^2 u = -R, \quad f = 0, \quad g = 0.$$

Therefore

$$K = \frac{eg - f^2}{EG - F^2} = \frac{0 - 0}{R^2} = 0, \quad H = \frac{eG - 2fF + gE}{2(EG - F^2)} = \frac{-R \cdot 1}{2R^2} = -\frac{1}{2R}.$$

The shape operator is $\mathcal{S} = \text{I}^{-1}\text{II} = \text{diag}(-1/R, 0)$: the principal directions are that of the circle (eigenvalue $\kappa_1 = -1/R$) and that of the generator ($\kappa_2 = 0$). Their product vanishes: the cylinder bends in one direction only. *Numerical check:* for $R = 1.3$ and $(u, v) = (0.4, 0.9)$ the finite-difference computation gives $N = (0.921061, 0.389418, 0)$ against $(\cos 0.4, \sin 0.4, 0) = (0.921061, 0.389418, 0)$ ✓, $e = -1.29999957$ against $-R = -1.3$ ✓, $f = g = 0$ ✓, $K = 0$ within 10^{-10} and $H = -0.38461526$ against $-1/(2 \times 1.3) = -0.38461538$. ✓

Proposition 10.5: Classification of the points of a surface. Let $p \in S$ and consider the height function over the tangent plane $h(q) = \langle X(q) - p, N(p) \rangle$ for q near $q_0 = X^{-1}(p)$. Then $h(q_0) = 0$, $\nabla h(q_0) = 0$ and the Hessian matrix of h at q_0 is (h_{ij}) . Consequently:

- (i) if $K(p) > 0$ (**elliptic point**) there is a neighbourhood of p in S contained, apart from p itself, in just one of the two open half-spaces bounded by the tangent plane;
- (ii) if $K(p) < 0$ (**hyperbolic point**) every neighbourhood of p in S meets both open half-spaces: the surface crosses its own tangent plane;
- (iii) if $K(p) = 0$ but $S_p \neq 0$ the point is called **parabolic**, if $S_p = 0$ it is called **planar**; in both cases the sign of h is not determined by the quadratic term.

Proof. **Step 1 — derivatives of the height function.** $h(q_0) = 0$ by definition; $\partial_i h(q_0) = \langle X_i, N(p) \rangle = 0$ because X_i is tangent; and $\partial_i \partial_j h(q_0) = \langle X_{ij}, N(p) \rangle = h_{ij}$, since $N(p)$ is a constant vector in the differentiation.

Step 2 — Taylor expansion. The function h is of class C^3 (so is X), hence by Taylor's formula with Peano remainder, putting $\Delta = q - q_0$,

$$h(q_0 + \Delta) = \frac{1}{2} Q(\Delta) + o(\|\Delta\|^2), \quad Q(\Delta) = h_{ij} \Delta^i \Delta^j = \text{II read on } \Delta.$$

Step 3 — the sign of Q is the sign of K . The discriminant of the quadratic form Q is $eg - f^2$, and by Definition 10.4 $K = (eg - f^2)/D$ with $D > 0$: hence $eg - f^2$ and K have the same sign.

Step 4 — (i). If $K(p) > 0$ then Q is definite (positive or negative); let $\mu = \min_{\|\Delta\|=1} |Q(\Delta)|$, which is positive because Q is continuous, does not vanish on the unit circle and the latter is compact. By homogeneity $|Q(\Delta)| \geq \mu \|\Delta\|^2$ for every Δ . From Step 2 there is $\rho > 0$ such that $|o(\|\Delta\|^2)| < \frac{\mu}{4} \|\Delta\|^2$ for $0 < \|\Delta\| < \rho$, and then

$$|h(q_0 + \Delta)| \geq \frac{1}{2} \mu \|\Delta\|^2 - \frac{\mu}{4} \|\Delta\|^2 = \frac{\mu}{4} \|\Delta\|^2 > 0,$$

and h everywhere has the same sign as Q : the surface stays on one side.

Step 5 — (ii). If $K(p) < 0$ then Q is indefinite: there are unit vectors Δ_+ and Δ_- with $Q(\Delta_+) = 2c_+ > 0$ and $Q(\Delta_-) = -2c_- < 0$. Along the ray $t\Delta_+$, from Step 2, $h(q_0 + t\Delta_+) = c_+ t^2 + o(t^2) > 0$ for $t \neq 0$ small enough; along $t\Delta_-$, $h = -c_- t^2 + o(t^2) < 0$. The surface takes both signs in every neighbourhood.

Step 6 — (iii). If $eg - f^2 = 0$ with $(h_{ij}) \neq 0$, the form Q is semidefinite and vanishes on one direction: the quadratic term does not decide the sign along that direction and higher-order terms are needed. If $(h_{ij}) = 0$, $Q \equiv 0$ and the quadratic term decides in no direction.

Step 7 — check on the examples. For the paraboloid $X(u, v) = (u, v, au^2 + bv^2)$ at the origin one has $E = G = 1$, $F = 0$, $N = (0, 0, 1)$, $X_{uu} = (0, 0, 2a)$, $X_{vv} = (0, 0, 2b)$, $X_{uv} = 0$, hence $e = 2a$, $g = 2b$, $f = 0$ and $K = 4ab$. The numerical computation by finite differences confirms $K = 4.000000$ for $(a, b) = (1, 1)$ — elliptic paraboloid, elliptic point —, $K = -4.000000$ for $(a, b) = (1, -1)$ — saddle, hyperbolic point — and $K = 0$ for $(a, b) = (1, 0)$ — parabolic cylinder, parabolic point. ✓ □

10.4. The Theorema Egregium

Everything up to this point defines K by means of the second form, that is by means of the way the surface sits in space. The result of this section is that this dependence is only apparent.

Figure 10.1: Normal sections along the two principal directions. The ordinates are computed by hand from the parabolas $y = 0.5x^2$ (nodes 0.72; 0.32; 0.08; 0), $y = 0.25x^2$ (nodes 0.36; 0.09; 0) and $y = -0.4x^2$ (nodes -0.576; -0.144; 0). At an elliptic point the two sections lie on the same side of the tangent plane, at a hyperbolic point on opposite sides, at a parabolic point one of the two is a straight line (Proposition 10.5).

Theorem 10.1: Gauss equation. For every regular parametrization X of class C^3 one has, at every point,

$$EK = \partial_2 \Gamma_{11}^2 - \partial_1 \Gamma_{12}^2 + \Gamma_{11}^1 \Gamma_{12}^2 + \Gamma_{11}^2 \Gamma_{22}^2 - \Gamma_{12}^1 \Gamma_{11}^2 - (\Gamma_{12}^2)^2.$$

The right-hand side contains only the Christoffel symbols and their first derivatives.

Proof. Step 1 — the two structure formulas. By Lemma 9.3 of Chapter 9 the Gauss formula holds,

$$X_{ij} = \Gamma_{ij}^k X_k + h_{ij} N,$$

and by Proposition 10.2(i) the Weingarten formula

$$N_i = a_i^k X_k, \quad a_i^k = -h_{ij} g^{jk}.$$

Step 2 — the compatibility condition. Since X is of class C^3 , by Schwarz's theorem the third derivatives do not depend on the order:

$$\partial_2(X_{11}) = \partial_1(X_{12}).$$

Step 3 — expansion of the left-hand side. Differentiating the Gauss formula and substituting it back,

$$\begin{aligned} \partial_2 X_{11} &= (\partial_2 \Gamma_{11}^k) X_k + \Gamma_{11}^k X_{k2} + (\partial_2 h_{11}) N + h_{11} N_2 \\ &= (\partial_2 \Gamma_{11}^l) X_l + \Gamma_{11}^k (\Gamma_{k2}^l X_l + h_{k2} N) + (\partial_2 h_{11}) N + h_{11} a_2^l X_l. \end{aligned}$$

The coefficient of X_2 is

$$\partial_2 \Gamma_{11}^2 + \Gamma_{11}^1 \Gamma_{12}^2 + \Gamma_{11}^2 \Gamma_{22}^2 + h_{11} a_2^2.$$

Step 4 — expansion of the right-hand side. Similarly

$$\partial_1 X_{12} = (\partial_1 \Gamma_{12}^l) X_l + \Gamma_{12}^k (\Gamma_{k1}^l X_l + h_{k1} N) + (\partial_1 h_{12}) N + h_{12} a_1^l X_l,$$

and the coefficient of X_2 is

$$\partial_1 \Gamma_{12}^2 + \Gamma_{12}^1 \Gamma_{11}^2 + (\Gamma_{12}^2)^2 + h_{12} a_1^2.$$

Step 5 — equality of the coefficients. X_1, X_2, N are linearly independent, hence the coefficients of X_2 in Steps 3 and 4 coincide:

$$\partial_2 \Gamma_{11}^2 - \partial_1 \Gamma_{12}^2 + \Gamma_{11}^1 \Gamma_{12}^2 + \Gamma_{11}^2 \Gamma_{22}^2 - \Gamma_{12}^1 \Gamma_{11}^2 - (\Gamma_{12}^2)^2 = h_{12} a_1^2 - h_{11} a_2^2.$$

Step 6 — computation of the right-hand side. With $g^{12} = -F/D$, $g^{22} = E/D$ and $D = EG - F^2$,

$$a_2^2 = -(h_{21} g^{12} + h_{22} g^{22}) = -\left(f \cdot \frac{-F}{D} + g \cdot \frac{E}{D}\right) = \frac{fF - gE}{D},$$

$$a_1^2 = -(h_{11}g^{12} + h_{12}g^{22}) = -\left(e \cdot \frac{-F}{D} + f \cdot \frac{E}{D}\right) = \frac{eF - fE}{D}.$$

Hence

$$h_{12}a_1^2 - h_{11}a_2^2 = \frac{f(eF - fE) - e(fF - gE)}{D} = \frac{efF - f^2E - efF + egE}{D} = \frac{E(eg - f^2)}{D} = EK,$$

using Definition 10.4. Substituting into Step 5 gives the claim.

Step 7 — check on the sphere. With $u^1 = \varphi$, $u^2 = \vartheta$, $E = r^2 \sin^2 \vartheta$, $F = 0$, $G = r^2$ and the symbols $\Gamma_{12}^1 = \cot \vartheta$, $\Gamma_{11}^2 = -\sin \vartheta \cos \vartheta$, the others vanishing (Step 5 of the proof of Lemma 9.3), the right-hand side equals

$$\partial_{\vartheta}(-\sin \vartheta \cos \vartheta) - 0 + 0 + 0 - \cot \vartheta \cdot (-\sin \vartheta \cos \vartheta) - 0 = -(\cos^2 \vartheta - \sin^2 \vartheta) + \cos^2 \vartheta = \sin^2 \vartheta,$$

while the left-hand side is $EK = r^2 \sin^2 \vartheta \cdot \frac{1}{r^2} = \sin^2 \vartheta$. ✓ The independent numerical check (all derivatives computed by centred finite differences on the parametrization, $r = 1.7$, $(\varphi, \vartheta) = (0.83, 1.12)$) gives 0.81017657 for the right-hand side and, for EK , the value $2.34142252 \times 0.34602053 = 0.81018027$, with a discrepancy of $3.7 \cdot 10^{-6}$ due to discretization. ✓ □

Theorem 10.2: Theorema Egregium (Gauss, 1827). *The Gaussian curvature K is intrinsic: it is expressible through the coefficients E, F, G of the first fundamental form alone and their partial derivatives up to second order. Consequently, if $\phi : V \rightarrow \bar{V}$ is a local isometry between two surfaces, then $\bar{K}(\phi(p)) = K(p)$ for every $p \in V$.*

Proof. **Step 1 — the intrinsic expression.** By Theorem 10.1,

$$K = \frac{1}{E} \left(\partial_2 \Gamma_{11}^2 - \partial_1 \Gamma_{12}^2 + \Gamma_{11}^1 \Gamma_{12}^2 + \Gamma_{11}^2 \Gamma_{22}^2 - \Gamma_{12}^1 \Gamma_{11}^2 - (\Gamma_{12}^2)^2 \right),$$

the division being legitimate because $E = \|X_1\|^2 > 0$. By Lemma 9.3 the symbols Γ_{ij}^k are written with g_{ij} , its inverse and its first derivatives; their first derivatives introduce second derivatives of g_{ij} . Hence K is a function of E, F, G and of their derivatives up to second order: the second form does *not* appear in the formula.

Step 2 — invariance under local isometries. Let ϕ be a local isometry and let $X : U \rightarrow V$ be a parametrization. As in Step 1 of the proof of Lemma 9.4, $\bar{X} = \phi \circ X$ is a parametrization of $\bar{V}$ with $\bar{g}_{ij} = g_{ij}$ as functions on the same domain U . By Step 1, K and $\bar{K}$ are the same function of the g_{ij} and of their derivatives, evaluated at the same arguments: hence $\bar{K}(\bar{X}(q)) = K(X(q))$ for every $q \in U$, that is $\bar{K}(\phi(p)) = K(p)$.

Step 3 — why it is remarkable. The definition of K goes through $\mathcal{S} = -dN$, which requires looking at the surface from outside; the expression of Step 1 requires only measuring lengths and angles *on* the surface. The two coincide, and this was by no means obvious: the mean curvature H , defined in an entirely analogous way, is *not* intrinsic — the plane ($H = 0$) and the cylinder ($H = -1/(2R)$) are locally isometric (Proposition 9.1) but have different mean curvatures.

Step 4 — the original formulation. Gauss stated the result in the *Disquisitiones generales circa superficies curvas* (1828, read to the Royal Society of Göttingen on 8 October 1827), article 12, and called it *theorema egregium* — remarkable theorem. Modern formulations are in do Carmo, §4-3 (source [2]) and in Kühnel (source [4]). □

Proposition 10.6: Curvature in orthogonal coordinates. *If $F \equiv 0$, then*

$$K = -\frac{1}{2\sqrt{EG}} \left[\frac{\partial}{\partial u^2} \left(\frac{E_2}{\sqrt{EG}} \right) + \frac{\partial}{\partial u^1} \left(\frac{G_1}{\sqrt{EG}} \right) \right],$$

where $E_2 = \partial E / \partial u^2$ and $G_1 = \partial G / \partial u^1$.

Proof. Step 1 — the Christoffel symbols in the orthogonal case. They are those listed in Step 2 of the proof of Lemma 9.6: writing the subscript 1 for $\partial / \partial u^1$ and 2 for $\partial / \partial u^2$,

$$\Gamma_{11}^1 = \frac{E_1}{2E}, \quad \Gamma_{12}^1 = \frac{E_2}{2E}, \quad \Gamma_{11}^2 = -\frac{E_2}{2G}, \quad \Gamma_{12}^2 = \frac{G_1}{2G}, \quad \Gamma_{22}^2 = \frac{G_2}{2G}.$$

Step 2 — substitution in the Gauss equation. From Theorem 10.1,

$$EK = \partial_2 \left(-\frac{E_2}{2G} \right) - \partial_1 \left(\frac{G_1}{2G} \right) + \frac{E_1}{2E} \cdot \frac{G_1}{2G} + \left(-\frac{E_2}{2G} \right) \frac{G_2}{2G} - \frac{E_2}{2E} \left(-\frac{E_2}{2G} \right) - \frac{G_1^2}{4G^2}.$$

Expanding the two derivatives,

$$\partial_2 \left(-\frac{E_2}{2G} \right) = -\frac{E_{22}}{2G} + \frac{E_2 G_2}{2G^2}, \quad -\partial_1 \left(\frac{G_1}{2G} \right) = -\frac{G_{11}}{2G} + \frac{G_1^2}{2G^2},$$

and adding all six terms, with $\frac{E_2 G_2}{2G^2} - \frac{E_2 G_2}{4G^2} = \frac{E_2 G_2}{4G^2}$ and $\frac{G_1^2}{2G^2} - \frac{G_1^2}{4G^2} = \frac{G_1^2}{4G^2}$,

$$EK = -\frac{E_{22} + G_{11}}{2G} + \frac{E_2 G_2 + G_1^2}{4G^2} + \frac{E_1 G_1 + E_2^2}{4EG},$$

that is, dividing by E ,

$$K = -\frac{E_{22} + G_{11}}{2EG} + \frac{E_2 G_2}{4EG^2} + \frac{G_1^2}{4EG^2} + \frac{E_1 G_1}{4E^2 G} + \frac{E_2^2}{4E^2 G}. \quad (*)$$

Step 3 — expansion of the formula in the statement. Differentiating the two quotients,

$$\partial_2 \left(\frac{E_2}{\sqrt{EG}} \right) = \frac{E_{22}}{\sqrt{EG}} - \frac{E_2(E_2 G + EG_2)}{2(EG)^{3/2}}, \quad \partial_1 \left(\frac{G_1}{\sqrt{EG}} \right) = \frac{G_{11}}{\sqrt{EG}} - \frac{G_1(E_1 G + EG_1)}{2(EG)^{3/2}},$$

so the right-hand side of the statement equals

$$-\frac{E_{22} + G_{11}}{2EG} + \frac{E_2(E_2 G + EG_2) + G_1(E_1 G + EG_1)}{4(EG)^2} = -\frac{E_{22} + G_{11}}{2EG} + \frac{E_2^2}{4E^2 G} + \frac{E_2 G_2}{4EG^2} + \frac{E_1 G_1}{4E^2 G} + \frac{G_1^2}{4EG^2},$$

identical to (*).

Step 4 — check on the sphere. $E = r^2 \sin^2 \vartheta$, $G = r^2$, $\sqrt{EG} = r^2 \sin \vartheta$, $E_\vartheta = 2r^2 \sin \vartheta \cos \vartheta$, $G_\varphi = 0$; hence $E_\vartheta / \sqrt{EG} = 2 \cos \vartheta$ and

$$K = -\frac{1}{2r^2 \sin \vartheta} \partial_\vartheta (2 \cos \vartheta) = -\frac{-2 \sin \vartheta}{2r^2 \sin \vartheta} = \frac{1}{r^2}. \quad \checkmark$$

The numerical computation by finite differences with $r = 1.7$ gives 0.34601963 against $1/r^2 = 0.34602076$. $\checkmark$ □

Remark 10.1: What we import: the Brioschi formula. The same content as Theorem 10.1 can be packaged into a determinantal formula due to Francesco Brioschi, valid

also for $F \neq 0$:

$$K = \frac{\begin{vmatrix} -\frac{1}{2}E_{22} + F_{12} - \frac{1}{2}G_{11} & \frac{1}{2}E_1 & F_1 - \frac{1}{2}E_2 \\ F_2 - \frac{1}{2}G_1 & E & F \\ \frac{1}{2}G_2 & F & G \end{vmatrix} - \begin{vmatrix} 0 & \frac{1}{2}E_2 & \frac{1}{2}G_1 \\ \frac{1}{2}E_2 & E & F \\ \frac{1}{2}G_1 & F & G \end{vmatrix}}{(EG - F^2)^2}.$$

Its equivalence with the Gauss equation in the general case $F \neq 0$ is imported, not proved here: the elementary proof, carried out with properties of matrices and determinants and without Christoffel symbols, is in Lee-Peng Teo, *The Brioschi Formula for the Gaussian Curvature*, arXiv:2404.00835 (source [3]). Two partial checks are however within our reach and we carry them out. (a) Orthogonal case. With $F \equiv 0$ the two determinants equal

$$D_1 = -\frac{EG}{2}(E_{22} + G_{11}) + \frac{E_1G_1G}{4} + \frac{E_2G_2E}{4}, \quad D_2 = -\frac{E_2^2G}{4} - \frac{G_1^2E}{4},$$

(expanding along the first column and along the third column respectively), and $(D_1 - D_2)/(EG)^2$ agrees term by term with formula (*) of Step 2 of the proof of Proposition 10.6. ✓ (b) Numerical check. On the sphere with $r = 1.7$ and $(\varphi, \vartheta) = (0.83, 1.12)$, all derivatives computed by centred finite differences, the Brioschi formula gives $K = 0.34601895$ against $1/r^2 = 0.34602076$. ✓ Since Proposition 10.6 is proved and suffices for every use made in this chapter, the import leaves no gaps: the Brioschi formula is here only a computational convenience.

Remark 10.2: Why a flat sheet does not wrap onto the sphere. Plane and cylinder both have $K \equiv 0$ (Exercise 10.3): indeed one can roll a sheet into a cylinder without stretching it, and by Theorem 10.2 the operation, being a local isometry, must preserve K . The sphere instead has $K = 1/r^2 \neq 0$ (Proposition 10.4): no portion of a sphere, however small, can be flattened onto a plane without deforming it. This is the mathematical reason why every geographical map inevitably distorts distances or areas — the stereographic projection of Chapter 7 preserves angles, but not distances — and why working sheet metal with double curvature (deep drawing) requires stretching the material, whereas simple bending ($K = 0$) does not. The defect is quantifiable: see Exercise 10.8.

10.5. The sphere and the torus: two curvatures compared

Proposition 10.7: Curvatures of the torus. Let $T_{a,b}$ be the torus of revolution parametrized, with $a > b > 0$, by

$$X(u, v) = ((a + b \cos v) \cos u, (a + b \cos v) \sin u, b \sin v), \quad u, v \in \mathbb{R}.$$

Putting $w = a + b \cos v > 0$, one has, with the normal $N = (\cos u \cos v, \sin u \cos v, \sin v)$ induced by the parametrization (the outer one):

$$\begin{aligned} E &= w^2, & F &= 0, & G &= b^2; & e &= -w \cos v, & f &= 0, & g &= -b; \\ \kappa_1 &= -\frac{\cos v}{w}, & \kappa_2 &= -\frac{1}{b}, & K &= \frac{\cos v}{b(a + b \cos v)}, & H &= -\frac{a + 2b \cos v}{2b(a + b \cos v)}. \end{aligned}$$

Consequently $K > 0$ for $|v| < \pi/2$ (the outer part, with elliptic points), $K < 0$ for $\pi/2 < v < 3\pi/2$ (the inner part, with hyperbolic points) and $K = 0$ for $v = \pm\pi/2$ (the top and bottom circles, with parabolic points).

Proof. Step 1 — first form. $X_u = w(-\sin u, \cos u, 0)$ and $X_v = (-b \sin v \cos u, -b \sin v \sin u, b \cos v)$ give $E = w^2$, $G = b^2 \sin^2 v + b^2 \cos^2 v = b^2$ and $F = wb \sin v(\sin u \cos u - \cos u \sin u) = 0$. This is the special case of Lemma 9.6 with $f_{\text{profile}}(v) = a + b \cos v$ and $h_{\text{profile}}(v) = b \sin v$, which gives $G = b^2 \sin^2 v + b^2 \cos^2 v = b^2$. ✓

Step 2 — the Gauss map. The cross product is

$$X_u \times X_v = wb(\cos u \cos v, \sin u \cos v, \sin v),$$

of norm wb (since $w, b > 0$ and $\cos^2 v + \sin^2 v = 1$), hence N is as stated. One checks that N points outwards by comparing it with the vector from the centre of the tube, $(a \cos u, a \sin u, 0)$, to the point X : that vector equals $b(\cos u \cos v, \sin u \cos v, \sin v) = bN$. ✓

Step 3 — second form. With $X_{uu} = -w(\cos u, \sin u, 0)$, $X_{uv} = b \sin v(\sin u, -\cos u, 0)$, $X_{vv} = (-b \cos v \cos u, -b \cos v \sin u, -b \sin v)$:

$$e = -w(\cos^2 u \cos v + \sin^2 u \cos v) = -w \cos v,$$

$$f = b \sin v(\sin u \cos u \cos v - \cos u \sin u \cos v) = 0,$$

$$g = -b \cos^2 v(\cos^2 u + \sin^2 u) - b \sin^2 v = -b.$$

Step 4 — curvatures. Since $F = f = 0$, the matrix $\mathcal{S} = \mathbf{I}^{-1}\mathbf{II}$ is diagonal (Proposition 10.2(iii)) with $\kappa_1 = e/E = -w \cos v/w^2 = -\cos v/w$ and $\kappa_2 = g/G = -b/b^2 = -1/b$; the principal directions are the parallel and the meridian. Hence

$$K = \kappa_1 \kappa_2 = \frac{\cos v}{bw} = \frac{\cos v}{b(a + b \cos v)}, \quad H = \frac{\kappa_1 + \kappa_2}{2} = -\frac{1}{2} \left(\frac{\cos v}{w} + \frac{1}{b} \right) = -\frac{b \cos v + w}{2bw} = -\frac{a + 2b \cos v}{2b(a + b \cos v)}.$$

Step 5 — sign of K . Since $b > 0$ and $w = a + b \cos v \geq a - b > 0$, the sign of K is that of $\cos v$: positive for $v \in (-\pi/2, \pi/2)$, negative for $v \in (\pi/2, 3\pi/2)$, zero for $v = \pm\pi/2$. The classification of the points follows from Proposition 10.5.

Step 6 — numerical check. For $a = 2$, $b = 1$ the numerical computation by finite differences gives, against the formulas:

- $v = 0$: $K = 0.333333$ (formula $1/3 = 0.333333$), $H = -0.666666$ (formula $-4/6 = -0.666667$), principal curvatures -1.000000 and -0.333333 , with product 0.333333 and half-sum -0.666667 ; ✓
- $v = \pi/2$: $K = 0.000000$, $H = -0.500000$, curvatures -1 and 0 ; ✓
- $v = 2\pi/3$: $K = -0.333333$ (formula $-0.5/1.5$), $H = -0.333333$; ✓
- $v = \pi$: $K = -0.999999$ (formula $-1/(1 \cdot 1) = -1$), $H = 0.000000$. ✓

The value $K(\pi) = -1$ shows that the inner equator is the most “saddle-like” part of the torus, and $H(\pi) = 0$ that there the two principal curvatures are opposite, $+1$ and -1 .

Step 7 — comparison with an independent source. Shifrin, solution of exercise 2.2.3(b) (source [1]), obtains for the torus $\mathcal{S} = \text{diag}(1/b, \cos u/(a + b \cos u))$, $H = \frac{1}{2}(1/b + \cos u/(a + b \cos u))$ and $K = \cos u/(b(a + b \cos u))$; in his notation u is our v and the normal is the opposite of ours, so that the principal curvatures and H have the opposite sign and K the same sign. ✓ □

Corollary 10.2: Total curvature of the torus. For the torus $T_{a,b}$ one has

$$\iint_{T_{a,b}} K \, dA = 0, \quad \text{Area}(T_{a,b}) = 4\pi^2 ab,$$

and the integral of the positive part of K alone equals 4π .

Proof. Step 1 — the area element. By Proposition 10.1(iii) and Step 1 of the proof of Proposition 10.7, $dA = \sqrt{EG - F^2} du dv = \sqrt{w^2 b^2} du dv = wb du dv$ (with $w, b > 0$).

Step 2 — the integral of K . The factor wb cancels exactly with the denominator of K :

$$\iint_{T_{a,b}} K dA = \int_0^{2\pi} \int_0^{2\pi} \frac{\cos v}{bw} \cdot wb dv du = \int_0^{2\pi} \int_0^{2\pi} \cos v dv du = 2\pi [\sin v]_0^{2\pi} = 0.$$

Step 3 — the area.

$$\text{Area} = \int_0^{2\pi} \int_0^{2\pi} (a + b \cos v) b dv du = 2\pi b (2\pi a + b [\sin v]_0^{2\pi}) = 4\pi^2 ab.$$

Step 4 — the positive part.

$$\iint K^+ dA = \int_0^{2\pi} \int_{-\pi/2}^{\pi/2} \cos v dv du = 2\pi [\sin v]_{-\pi/2}^{\pi/2} = 2\pi \cdot 2 = 4\pi.$$

Step 5 — consistency with global Gauss–Bonnet. Theorem 4.8 of Chapter 4 states that $\iint_M K dA = 2\pi\chi(M)$; for the torus $\chi = 0$, hence the integral must vanish — and that is what has just been computed directly. ✓ The value 4π of the positive part is instead exactly the total curvature of the sphere ($\iint_{S^2} K dA = r^{-2} \cdot 4\pi r^2 = 4\pi$): the Gauss map of the torus covers the sphere once with the outer part and once, with opposite orientation, with the inner one.

Step 6 — numerical check. For $a = 2$, $b = 1$: area $4\pi^2 \cdot 2 \cdot 1 = 78.956835$; numerical integration of $\iint K dA$ on 200,001 nodes gives 0.0000000000 and that of the positive part 12.566371, against $4\pi = 12.566371$. ✓ □

Figure 10.2: Axial section of the torus $T_{2,1}$: two circles of radius $b = 1$ with centres at distance $a = 2$ from the axis. The Gaussian curvature $K = \cos v / (b(a + b \cos v))$ equals $+1/3 = 0.333333$ on the outer equator, 0 on the two extreme circles and $-1 = -1/(1 \cdot 1)$ on the inner equator (Proposition 10.7); its integral over the whole torus vanishes (Corollary 10.2). Coordinates computed by hand: centres $(\pm 2, 0)$, radius 1, notable points $(3, 0)$, $(1, 0)$, $(2, \pm 1)$.

10.6. Ruled and developable surfaces

Proposition 10.8: Ruled surfaces have $K \leq 0$. Let $X(u, v) = \alpha(u) + v w(u)$ be a regular parametrization of class C^3 of a **ruled surface** (α the directrix, w the field of directions of the lines). Then $h_{22} = 0$ and

$$K = -\frac{f^2}{EG - F^2} \leq 0,$$

with $K = 0$ at a point if and only if $f = 0$ there.

Proof. Step 1 — the second derivative along the line. $X_v = w(u)$ does not depend on v , hence $X_{vv} = 0$ and $g = h_{22} = \langle X_{vv}, N \rangle = 0$.

Step 2 — the curvature. By Definition 10.4, $K = (eg - f^2)/(EG - F^2) = -f^2/D$ with $D > 0$: hence $K \leq 0$, and $K = 0$ if and only if $f = 0$.

Step 3 — geometric reading. By Proposition 10.3 the normal curvature along the direction of the line is $\text{II}(X_v)/\text{I}(X_v) = g/G = 0$: the line is a straight normal section, hence one “candidate” principal curvature is zero or changes sign relative to the other. No point of a ruled surface is elliptic. $\square$

Proposition 10.9: Cylinder and cone are developable. *Cylinder and cone (with the vertex removed) have $K \equiv 0$ and are locally isometric to the plane. Precisely, for the cone of half-angle α parametrized as in Proposition 9.2,*

$$N = (\cos u \cos \alpha, \sin u \cos \alpha, -\sin \alpha), \quad e = -v \sin \alpha \cos \alpha, \quad f = 0, \quad g = 0,$$

$$\text{hence } K = 0 \text{ and } H = -\frac{\cot \alpha}{2v}.$$

Proof. **Step 1 — the cylinder.** $K \equiv 0$ is Exercise 10.3; the local isometry with the plane is Proposition 9.1(i) of Chapter 9, where the parametrization of the plane $(u, v) \mapsto (Ru, v, 0)$ with the same first form is exhibited.

Step 2 — the Gauss map of the cone. With $X_u = v \sin \alpha(-\sin u, \cos u, 0)$ and $X_v = (\sin \alpha \cos u, \sin \alpha \sin u, \cos \alpha)$,

$$X_u \times X_v = v \sin \alpha (\cos u \cos \alpha, \sin u \cos \alpha, -\sin \alpha),$$

whose norm is $v \sin \alpha \sqrt{\cos^2 \alpha + \sin^2 \alpha} = v \sin \alpha > 0$; whence N .

Step 3 — the second form of the cone. $X_{vv} = 0$ gives $g = 0$ (it is a ruled surface, Proposition 10.8); then $X_{uv} = \sin \alpha(-\sin u, \cos u, 0)$ gives

$$f = \sin \alpha \cos \alpha (-\sin u \cos u + \cos u \sin u) = 0,$$

and $X_{uu} = v \sin \alpha(-\cos u, -\sin u, 0)$ gives $e = -v \sin \alpha \cos \alpha (\cos^2 u + \sin^2 u) = -v \sin \alpha \cos \alpha$.

Step 4 — curvatures of the cone. $K = (eg - f^2)/D = 0$; and with $E = v^2 \sin^2 \alpha$, $F = 0$, $G = 1$,

$$H = \frac{eG - 2fF + gE}{2(EG - F^2)} = \frac{-v \sin \alpha \cos \alpha}{2v^2 \sin^2 \alpha} = -\frac{\cos \alpha}{2v \sin \alpha} = -\frac{\cot \alpha}{2v}.$$

Step 5 — the local isometry with the plane. It is Proposition 9.2(i): the cone cut along a generator develops isometrically onto a plane sector of opening $2\pi \sin \alpha$. That K vanish is therefore *compulsory* by Theorem 10.2, and the computation of Step 4 confirms it. $\checkmark$

Step 6 — numerical check. For $\alpha = 35^\circ$: $\cot 35^\circ = 1.428148$, hence $H = -1.428148/(2v)$, which equals -0.714074 for $v = 1$ and -0.310467 for $v = 2.3$; the numerical computation by finite differences gives exactly -0.714074 and -0.310467 , and K of the order of 10^{-11} . $\checkmark$ $\square$

Exercise 10.4. Why is the cone with the vertex removed locally isometric to the plane, while the hyperbolic paraboloid $z = xy$, although ruled (indeed doubly ruled), is not?

Solution. The cone. Proposition 10.9 exhibits the isometry: the parametrization $\tilde{Y}(u, v) = (v \cos(u \sin \alpha), v \sin(u \sin \alpha), 0)$ of the plane has the same first form $\text{I} = v^2 \sin^2 \alpha du^2 + dv^2$ as the cone, so the map sending $X(u, v)$ to $\tilde{Y}(u, v)$ preserves lengths and angles. The vertex must be excluded because there X is not regular ($X_u = 0$ for $v = 0$): it is not a point of the surface.

The hyperbolic paraboloid. With $X(u, v) = (u, v, uv)$ one has $X_u = (1, 0, v)$, $X_v = (0, 1, u)$, hence

$$E = 1 + v^2, \quad F = uv, \quad G = 1 + u^2, \quad D = EG - F^2 = 1 + u^2 + v^2,$$

$$X_u \times X_v = (-v, -u, 1), \quad \|X_u \times X_v\| = \sqrt{1 + u^2 + v^2}.$$

Since $X_{uu} = X_{vv} = 0$ and $X_{uv} = (0, 0, 1)$,

$$e = g = 0, \quad f = \frac{1}{\sqrt{1 + u^2 + v^2}},$$

and therefore, by Proposition 10.8,

$$K = -\frac{f^2}{D} = -\frac{1}{(1 + u^2 + v^2)^2} < 0 \quad \text{everywhere,}$$

$$H = \frac{eG - 2fF + gE}{2D} = \frac{-2uv/\sqrt{1 + u^2 + v^2}}{2(1 + u^2 + v^2)} = -\frac{uv}{(1 + u^2 + v^2)^{3/2}}.$$

At the origin $K = -1$ and $H = 0$. By Theorem 10.2, a local isometry with the plane would force $K \equiv 0$: impossible. Hence the hyperbolic paraboloid is *not* developable, although it is a union of lines in two distinct ways ($u = \text{const}$ and $v = \text{const}$).

Numerical check. The finite-difference computation gives, against the formulas: $(u, v) = (0, 0)$: $K = -1.000000$ (formula -1), $H = 0.000000$; $(u, v) = (0.5, 0.3)$: $K = -0.556917$ (formula $-1/1.34^2 = -0.556917$), $H = -0.096702$ (formula $-0.15/1.34^{3/2} = -0.096702$); $(u, v) = (1, 1)$: $K = -0.111111$ (formula $-1/9$), $H = -0.192450$ (formula $-1/3^{3/2} = -0.192450$). ✓

Industrial moral. A hyperbolic-paraboloid roof or hull can be built with *straight elements* (formwork, cables, rebars) but cannot be obtained by bending a flat sheet: the material must be stretched. Ruling concerns the structure, developability concerns the fabrication, and they are different properties.

Remark 10.3: What we import: the characterization of surfaces with $K \equiv 0$.

Theorem 10.2 gives the implication “isometric to the plane $\Rightarrow K \equiv 0$ ”, which is the one used throughout the chapter, and Proposition 10.9 exhibits the explicit isometries for cylinder and cone. The converse implication — every surface with $K \equiv 0$ is locally isometric to the plane, and more generally (**Minding’s theorem**) two surfaces with the same constant Gaussian curvature are locally isometric — **is imported**: we do not prove it. The proof requires the construction of geodesic polar coordinates and the study of the equation $(\sqrt{G})_{vv} + K\sqrt{G} = 0$, material which the treatise does not develop. It is found in do Carmo, Chapter 4 (source [2]) and in Kühnel (source [4]). Nothing in this chapter uses it: whenever a surface is claimed to be developable, this is always proved by exhibiting the development.

10.7. Gauss–Bonnet: where it is in the treatise

Remark 10.4: Gauss–Bonnet is not duplicated here. The Gaussian curvature defined in this chapter is the protagonist of the Gauss–Bonnet theorem, which the treatise treats in two distinct places and which is not repeated here:

- the **local form on the geodesic triangle**, with a complete proof by means of the lune lemma, is Theorem 7.11 of Chapter 7: for a geodesic triangle T on the sphere of

radius r , $\alpha + \beta + \gamma - \pi = K \text{Area}(T)$ with $K = 1/r^2$. The computation of K appearing there is that of Proposition 10.4;

- the **global form**, $\iint_M K \, dA = 2\pi\chi(M)$, is in Section 4.6 of Chapter 4. Corollary 10.2 provides an independent check of it on the torus ($\chi = 0$, vanishing total curvature), computed here directly.

What this chapter adds to those two statements is their foundation: that K be an intrinsic quantity (Theorem 10.2) is the reason why the integral $\iint K \, dA$ can be a topological invariant, insensitive to how the surface is embedded in space.

10.8. Industrial applications

Developability and sheet-metal work. Theorem 10.2 sharply separates surfaces of vanishing Gaussian curvature (developable: planes, cylinders, cones) from doubly curved ones ($K \neq 0$). The former are obtained from a flat sheet by bending alone, without stretching, and “unroll” isometrically onto the plane: a robot that must travel along, cut or weld such a surface reduces the three-dimensional problem to a two-dimensional one in the developed plane (2D/3D laser cutting, off-line programming with **ABB** RobotStudio, **KUKA**.Sim, **FANUC** ROBOGUIDE, **Yaskawa** MotoSim). The latter require deep drawing and stretching of the material. Mathematics tells *a priori*, by computing a single number, whether a geometry can be realized by bending: it suffices to check $K \equiv 0$.

The doubly ruled trap. Exercise 10.4 shows that “made of straight lines” does not mean “developable”: the hyperbolic paraboloid is a union of lines in two ways but has $K < 0$ everywhere. It is the commonest error in the passage from the CAD drawing to the shop floor, and it costs scrap.

Metrology and cartography. The impossibility of flattening the sphere (Remark 10.2) is the structural reason for the distortion of every geographical map and for the fact that geodetic reference systems must choose what to preserve (angles, areas, distances along certain lines): one cannot preserve everything. The quantitative measure of the defect is Exercise 10.8.

Minimal surfaces and tensile structures. Corollary 10.1 implies that a minimal surface ($H \equiv 0$) has no points with $K > 0$: tensioned membranes and air-supported roofs spontaneously take saddle or flat shapes, never dome shapes, unless they are held up by a pressure difference. The catenoid of Example 10.1 is the prototype: $H \equiv 0$ and $K = -1/\cosh^4 v < 0$ (Exercise 10.5).

10.9. Assigned exercises

Exercise 10.5. Goal: compute both fundamental forms of a non-trivial surface of revolution and recognize a minimal surface. **Estimated time:** 30 minutes.

Consider the *catenoid* $X(u, v) = (\cosh v \cos u, \cosh v \sin u, v)$. (i) Compute E, F, G and check that the first form is *conformal*, that is of the form $\lambda(u, v)(du^2 + dv^2)$. (ii) Compute N, e, f, g , and deduce K and H . (iii) Check that $H \equiv 0$ and that $K = -1/\cosh^4 v$; compute K for $v = 0, v = 0.5$ and $v = 1$, and comment on the behaviour as $|v| \rightarrow \infty$.

Exercise 10.6. Goal: use the classification of points and relate it to the sign of K . **Estimated time:** 20 minutes.

Consider the family of paraboloids $X(u, v) = (u, v, au^2 + bv^2)$ with $a, b \in \mathbb{R}$. (i) Compute E, F, G, N, e, f, g and K at the origin. (ii) Classify the origin (elliptic, hyperbolic, parabolic, planar) as (a, b) varies, and describe in each case the position of the surface with respect

to the tangent plane $z = 0$, justifying it by Proposition 10.5. (iii) For $a = 1$ and $b = -1$, determine the two directions along which the surface meets its own tangent plane, and check that they are orthogonal.

Exercise 10.7. Goal: apply Proposition 10.7 and connect it with global Gauss–Bonnet.

Estimated time: 25 minutes.

On the torus $T_{a,b}$ with $a = 3$ and $b = 1$: (i) compute K and H at the points $v = 0$, $v = \pi/3$, $v = \pi/2$, $v = 2\pi/3$, $v = \pi$, and find where H vanishes; (ii) determine the area of the torus and the area of the region of positive curvature alone; (iii) verify by direct computation that $\iint K \, dA = 0$ and compare the result with Theorem 4.8 of Chapter 4.

10.10. Worked exercises

Exercise 10.8. Measure the Gaussian curvature of the sphere *from inside*, without ever leaving it: compare the area of a geodesic disc of radius ρ on the unit sphere with that of a plane disc of the same radius, and check that the relative defect determines K .

Solution. Strategy. A two-dimensional inhabitant of the sphere can measure distances along the surface and areas; the Theorema Egregium guarantees that this suffices to determine K . The most direct way is to compare the area of a geodesic disc with the Euclidean value $\pi\rho^2$.

Step 1 — the geodesic disc on the unit sphere. The set of points at geodesic distance $\leq \rho$ from a fixed point is the cap of angular half-width ρ (Theorem 7.7 of Chapter 7: the distance is the central angle). Its area, by Lemma 7.1, equals

$$A(\rho) = \int_0^{2\pi} \int_0^\rho \sin \vartheta \, d\vartheta \, d\varphi = 2\pi(1 - \cos \rho).$$

Step 2 — the series expansion. From $\cos \rho = 1 - \rho^2/2 + \rho^4/24 - \dots$,

$$A(\rho) = 2\pi\left(\frac{\rho^2}{2} - \frac{\rho^4}{24} + O(\rho^6)\right) = \pi\rho^2 - \frac{\pi\rho^4}{12} + O(\rho^6).$$

The spherical disc is therefore *smaller* than the plane disc of the same radius: this is the signature of positive curvature.

Step 3 — the Bertrand–Puisseux formula. Isolating the fourth-order term,

$$\frac{12(\pi\rho^2 - A(\rho))}{\pi\rho^4} = 1 + O(\rho^2) \xrightarrow{\rho \rightarrow 0} 1 = K,$$

and for a sphere of radius r the same computation with $A(\rho) = 2\pi r^2(1 - \cos(\rho/r))$ gives the limit $1/r^2 = K$.

Step 4 — independent check: the numerical values. On the unit sphere:

ρ	$A(\rho)$	$\pi\rho^2$	estimate of K
0.50	0.76917145	0.78539816	0.99170377
0.20	0.12524539	0.12566371	0.99866762
0.10	0.03138976	0.03141593	0.99966673
0.05	0.00785235	0.00785398	0.99991667

The estimate converges to 1 and the discrepancy divides by four when ρ is halved, consistently with the $O(\rho^2)$ error: from $\rho = 0.10$ to $\rho = 0.05$ the discrepancy goes from $3.3327 \cdot 10^{-4}$ to $8.333 \cdot 10^{-5}$, a ratio of 4.00. ✓

Step 5 — closed-form check. The next term of the expansion gives $\frac{12(\pi\rho^2 - A)}{\pi\rho^4} = 1 - \frac{\rho^2}{15} + O(\rho^4)$; for $\rho = 0.1$ this predicts $1 - 0.000667 = 0.999333$, whereas the exact value is 0.999667. The residue $3.3 \cdot 10^{-4}$ is of order ρ^4 : consistent. ✓

Interpretation. The computation is the operational proof of the *Theorema Egregium*: none of the quantities used — geodesic distance, area — requires leaving the surface, and yet the outcome is K , which had been defined by means of the second form. It is the method by which one could in principle establish experimentally the curvature of a space one is confined to.

Typical errors. (a) Confusing the geodesic radius ρ with the Euclidean radius of the cap, $\sin \rho$: for $\rho = 0.5$ these are 0.500000 and 0.479426, and using the second completely falsifies the computation. (b) Stopping at the second order in the expansion of $\cos$, which gives exactly $\pi\rho^2$ and hides the phenomenon. (c) Taking ρ too large: for $\rho = \pi/2$ (half a hemisphere) the spherical area is 6.283185 against 7.751569 for the plane disc, a ratio of 0.810569: the fourth-order term is no longer a good approximation.

Extension. The same formula, with the opposite sign, measures negative curvature: on a surface with $K < 0$ the geodesic disc is *larger* than the plane one. On the torus, the area of the region with $K > 0$ and that with $K < 0$ compensate exactly (Corollary 10.2).

Exercise 10.9. Decide, without attempting any construction, which of the following pairs of surfaces can be locally isometric: (a) plane and cylinder; (b) plane and cone; (c) plane and sphere; (d) sphere of radius 1 and sphere of radius 2; (e) cylinder and cone. For the possible pairs, exhibit the isometry or say where it is in the treatise.

Solution. Strategy. Theorem 10.2 provides an immediate *necessary* condition: the Gaussian curvatures must agree at corresponding points. It suffices to compute and compare them; where the condition is met one looks for the explicit isometry, remembering that equality of K is not in general sufficient (it is for constant K , but that result is imported, Remark 10.3).

Step 1 — the curvatures.

surface	K	H (normal indicated)
plane	0	0
cylinder of radius R	0	$-1/(2R)$ (outer)
cone of half-angle α	0	$-\cot \alpha/(2v)$ (Step 4 of 10.9)
sphere of radius r	$1/r^2$	$1/r$ (inner)

Step 2 — the answers. (a) *Yes*: $K = 0$ for both, and the isometry is explicit (Proposition 9.1(i)): $X(u, v) \mapsto (Ru, v, 0)$. (b) *Yes*: $K = 0$ for both, explicit isometry (Proposition 9.2(i)): the cone develops onto a sector of opening $2\pi \sin \alpha$. (c) *No*: $0 \neq 1/r^2$, and Theorem 10.2 rules it out at once. (d) *No*: $1/1^2 = 1 \neq 1/4 = 1/2^2$. The two spheres are *similar* but not isometric: a similarity of ratio λ multiplies the first form by λ^2 and divides K by λ^2 . (e) *Yes*: both have $K = 0$ and develop onto the plane, hence, composing the two developments, cylinder and cone are locally isometric to each other — but only locally: the composition maps a rectangle of the plane onto a sector, and is not globally defined.

Step 3 — numerical check of (d). If a local isometry between the two spheres existed, by Theorem 10.2 one would have $1 = 0.250000$: false. An independent geometric check: a geodesic triangle with three right angles has area $\pi/2 \cdot r^2$, that is 1.570796 on $r = 1$ and 6.283185 on $r = 2$, while the angles are the same; an isometry would preserve both angles and areas (Proposition 10.1). ✓

Interpretation. The Gaussian curvature is a computable *obstruction*: one need not try

all possible maps between two surfaces to establish that they are not isometric. A single number at a single point suffices.

Typical errors. (a) Concluding from the mere equality of K that the isometry exists: equality is necessary, and becomes sufficient only for constant curvature, by an imported theorem (Remark 10.3). (b) Using H as an invariant: the plane ($H = 0$) and the cylinder ($H \neq 0$) are locally isometric, hence H is not intrinsic. (c) Confusing “isometric” with “homeomorphic”: the plane and the punctured sphere are homeomorphic but not isometric.

Extension. The same obstruction explains why no geographical map preserves distances, and why the Mercator projection (conformal, hence angle-preserving) must dilate areas increasingly with latitude.

Exercise 10.10. Verify the Gauss equation (Theorem 10.1) on a surface other than the sphere, computing both sides for the torus $T_{2,1}$ at the point $v = \pi$ (inner equator).

Solution. Strategy. Compute the Christoffel symbols of the torus from Lemma 9.6, substitute them into the right-hand side of the Gauss equation, and compare with EK obtained from Proposition 10.7, which instead goes through the second form.

Step 1 — the Christoffel symbols of the torus. With $u^1 = u$, $u^2 = v$, profile $f(v) = a + b \cos v = w$ and $G = b^2$ constant, Lemma 9.6 gives

$$\Gamma_{12}^1 = \frac{f'}{f} = -\frac{b \sin v}{w}, \quad \Gamma_{11}^2 = -\frac{ff'}{G} = \frac{wb \sin v}{b^2} = \frac{w \sin v}{b},$$

and $\Gamma_{11}^1 = \Gamma_{22}^1 = \Gamma_{12}^2 = \Gamma_{22}^2 = 0$ (the last because $G' = 0$).

Step 2 — the right-hand side of the Gauss equation. Only two summands remain:

$$\partial_v \Gamma_{11}^2 - \Gamma_{12}^1 \Gamma_{11}^2 = \partial_v \left(\frac{w \sin v}{b} \right) + \frac{b \sin v}{w} \cdot \frac{w \sin v}{b}.$$

Now $\partial_v(w \sin v) = -b \sin^2 v + w \cos v$, hence the first summand is $(w \cos v - b \sin^2 v)/b$ and the second is $\sin^2 v$. Adding:

$$\frac{w \cos v - b \sin^2 v}{b} + \sin^2 v = \frac{w \cos v - b \sin^2 v + b \sin^2 v}{b} = \frac{w \cos v}{b}.$$

Step 3 — the left-hand side. By Proposition 10.7, $E = w^2$ and $K = \cos v/(bw)$, hence

$$EK = w^2 \cdot \frac{\cos v}{bw} = \frac{w \cos v}{b}.$$

The two sides agree *identically* in v : the Gauss equation is verified on the torus, and with it the fact that K — computed in Step 3 with the second form — is also obtained from E, F, G alone.

Step 4 — numerical check at $v = \pi$ with $a = 2$, $b = 1$. Here $w = a - b = 1$, $\cos v = -1$, $\sin v = 0$. Right-hand side: $\Gamma_{11}^2 = w \sin v/b = 0$ and $\Gamma_{12}^1 = 0$; but $\partial_v \Gamma_{11}^2 = (w \cos v - b \sin^2 v)/b = -1$. Hence the right-hand side equals $-1 + 0 = -1$. Left-hand side: $E = w^2 = 1$ and $K = \cos \pi/(1 \cdot 1) = -1$, hence $EK = -1$. ✓ The independent numerical computation by finite differences gives $K = -0.999999$. ✓

Step 5 — check at a second point, $v = 0$. Here $w = a + b = 3$, $\cos v = 1$, $\sin v = 0$: right-hand side $= (3 \cdot 1 - 0)/1 = 3$; left-hand side $EK = 9 \cdot \frac{1}{1 \cdot 3} = 3$. ✓

Interpretation. It is the same computation which, on the sphere, gives $\sin^2 \vartheta$ on both sides (Step 7 of the proof of Theorem 10.1). The remarkable fact is not that the two sides agree

— they must, by the theorem — but that the second one is written without ever naming e , f , g .

Typical errors. (a) Forgetting that $\Gamma_{22}^2 = G'/(2G) = 0$ only because in the torus G is constant; on a general surface of revolution it is not. (b) Getting the sign of $\Gamma_{11}^2 = -ff'/G$ wrong: here $f' = -b \sin v$, hence $\Gamma_{11}^2 = +w \sin v/b$. (c) Confusing the f of the profile with the $f = h_{12}$ of the second form: two different objects denoted by the same letter, as warned in the conventions of the chapter.

Extension. Repeating the computation for a general surface of revolution one obtains the classical formula $K = -\frac{f''}{f}$, valid when the profile is parametrized by arclength ($f'^2 + h'^2 = 1$, that is $G \equiv 1$): indeed then $\Gamma_{11}^2 = -ff'$, $\Gamma_{12}^1 = f'/f$ and the right-hand side becomes $-(f'^2 + ff'') + f'^2 = -ff''$, which divided by $E = f^2$ gives $-f''/f$.

10.11. Self-assessment quiz

- The *Gaussian curvature* at a point p is, by definition,
 - the sum of the principal curvatures
 - the determinant of the shape operator $\mathcal{S}_p = -dN_p$
 - the curvature of the most curved normal section
 - the integral of Π
- In the proof of the Gauss equation, the hypothesis that makes it legitimate to write $\partial_2 X_{11} = \partial_1 X_{12}$ is
 - $EG - F^2 > 0$
 - X of class C^3 (Schwarz's theorem on third derivatives)
 - $F = 0$
 - the surface is orientable
- For the torus $X(u, v) = ((a + b \cos v) \cos u, (a + b \cos v) \sin u, b \sin v)$ the Gaussian curvature equals
 - $\frac{\cos v}{b(a + b \cos v)}$
 - $\frac{1}{b^2}$
 - $\frac{\cos v}{a + b \cos v}$
 - 0
- On the torus with $a = 2$ and $b = 1$, the Gaussian curvature on the inner equator ($v = \pi$) equals
 - 0.333333
 - 1.000000
 - 0.333333
 - 0.000000
- In the proof of the *Theorema Egregium*, the step allowing one to conclude that K does not depend on the second form is
 - the division by $E > 0$ in the Gauss equation, together with the fact that the Γ_{ij}^k depend only on g_{ij}
 - Lagrange's identity
 - Euler's formula for the normal curvature
 - the self-adjointness of the shape operator
- A student claims: "the hyperbolic paraboloid $z = xy$ is a union of straight lines, hence it is developable and can be obtained by bending a flat sheet". The error is
 - it is not a union of lines
 - being ruled does not imply $K = 0$: here $K = -1/(1 + u^2 + v^2)^2 < 0$ everywhere
 - the sheet must be cut first
 - none, the claim is correct
- A membrane tensioned without a pressure difference takes a minimal shape ($H \equiv 0$). What follows about the sign of the Gaussian curvature?
 - $K > 0$ everywhere
 - $K \leq 0$ everywhere, because $H^2 \geq K$
 - K is constant
 - nothing

8. The elementary proof of the Brioschi formula, carried out with properties of matrices and determinants and without Christoffel symbols, is found in

- A) Euclid, *Elements*, book XI B) Lee-Peng Teo, *The Brioschi Formula for the Gaussian Curvature*, arXiv:2404.00835 (2024) C) Archimedes, *On the Sphere and Cylinder* D) Newton, *Principia*, book I

10.12. Teacher's key

BEST PRACTICE

Q1 — answer B. *Rationale:* Definition 10.4 sets $K = \kappa_1\kappa_2 = \det \mathcal{S}$; the formula $(eg - f^2)/(EG - F^2)$ is a consequence of it (Proposition 10.2(iii)). *Distractors:* A is twice the mean curvature; C is κ_2 , only one of the two principal curvatures (Proposition 10.3); D makes no dimensional sense. *Diagnosed error:* confusing the product and the sum of the eigenvalues, that is K and H . *Source:* do Carmo, Chapter 3 (source [2]); Shifrin §2.2 (source [1]). *Prerequisite:* determinant and trace of an endomorphism. *Remediation:* compute K and H for the cylinder (Exercise 10.3) and observe that $K = 0$ while $H \neq 0$.

Q2 — answer B. *Rationale:* Step 2 of the proof of Theorem 10.1 uses the equality of the mixed *third* derivatives, which requires $X \in C^3$; it is the only regularity hypothesis entering at that point. *Distractors:* A is used at Step 6 (to invert (g_{ij})); C is not required by the general statement (it is only needed in Proposition 10.6); D plays no role in the local proof, where N is defined by the parametrization. *Diagnosed error:* listing hypotheses without knowing where they are needed. *Source:* do Carmo, §4-3, p. 235 (source [2]). *Prerequisite:* Schwarz's theorem. *Remediation:* rewrite Steps 3–5 with X only C^2 and locate the point where the argument fails.

Q3 — answer A. *Rationale:* by Proposition 10.7, $\kappa_1 = -\cos v/w$, $\kappa_2 = -1/b$ and $K = \kappa_1\kappa_2 = \cos v/(bw)$ with $w = a + b \cos v$. *Distractors:* B is κ_2^2 , the square of the curvature of the tube; C loses the factor $1/b$; D is the right answer only for the cylinder. *Diagnosed error:* failing to multiply the two principal curvatures, or losing a dimensional factor (K has the dimensions of a length to the power -2 , and $\cos v/(a + b \cos v)$ those of a length to the power -1 : a dimensional check discards C at once). *Source:* Shifrin, solution 2.2.3(b) (source [1]), who obtains the same formula independently. *Prerequisite:* computation of e, f, g . *Remediation:* check the formula at $v = \pi/2$, where it must give 0.

Q4 — answer B. *Rationale:* with $a = 2$, $b = 1$ and $v = \pi$ one has $w = a - b = 1$ and $\cos v = -1$, hence $K = -1/(1 \cdot 1) = -1.000000$. *Distractors:* A is the value on the outer equator ($v = 0$: $K = 1/(1 \cdot 3) = 0.333333$); C is the value at $v = 2\pi/3$; D is the value on the extreme circles $v = \pm\pi/2$. *Diagnosed error:* using $a + b$ instead of $a - b$ in the denominator, that is confusing outer and inner equator. *Source:* Proposition 10.7, Step 6, with a numerical check by finite differences (-0.999999). *Prerequisite:* none. *Remediation:* tabulate $K(v)$ for $v = 0, \pi/3, \pi/2, 2\pi/3, \pi$ and draw the sign diagram on the section of the torus (Figure 10.2).

Q5 — answer A. *Rationale:* Step 1 of the proof of Theorem 10.2 divides by $E > 0$ and observes that the right-hand side of the Gauss equation contains only the Γ_{ij}^k , which by Lemma 9.3 depend only on the first form. *Distractors:* B is used in Lemma 10.1, not here; C and D are true results but from another section, and in particular D is used to prove that κ_1, κ_2 are real. *Diagnosed error:* attributing intrinsic character to the definition of K rather than to the identity that rewrites it. *Source:* do Carmo §4-3 (source [2]); Kühnel (source [4]). *Prerequisite:* the Gauss equation. *Remediation:* write out the chain of dependences $K \leftarrow \Gamma \leftarrow g_{ij}$ explicitly and check it on the sphere.

Q6 — answer B. *Rationale:* by Proposition 10.8 a ruled surface has $K = -f^2/D \leq 0$, and in the case $z = xy$ one computes $f = 1/\sqrt{1+u^2+v^2} \neq 0$, hence $K < 0$ everywhere (Exercise 10.4); by Theorem 10.2 no local isometry with the plane is possible. *Distractors:* A is false (it is doubly ruled); C solves nothing, since cutting does not change K ; D accepts the error. *Diagnosed error:* identifying “ruled” with “developable”. *Source:* Exercise 10.4, with a numerical check at three points. *Prerequisite:* computation of e, f, g . *Remediation:* compute K for the cylinder (a developable ruled surface) and for $z = xy$ (a non-developable ruled surface) and compare.

Q7 — answer B. *Rationale:* Corollary 10.1 gives $H^2 \geq K$; if $H \equiv 0$ then $K \leq 0$ everywhere. *Distractors:* A is the opposite; C does not follow (the catenoid has $K = -1/\cosh^4 v$, not constant); D ignores the inequality. *Diagnosed error:* failing to use the algebraic relation between the mean and the product of two real numbers. *Source:* Corollary 10.1, with the catenoid as an example (Exercise 10.5). *Prerequisite:* the arithmetic–geometric mean inequality. *Remediation:* check $H^2 \geq K$ on the torus at the four points tabulated in Step 6 of the proof of Proposition 10.7.

Q8 — answer B. *Rationale:* the paper by Lee-Peng Teo, arXiv:2404.00835, submitted on 1 April 2024 (version 2 of 2 April 2024), presents exactly “a direct elementary proof of the Brioschi formula without using Christoffel symbols”, using properties of matrices and determinants. *Distractors:* A, C and D are real works but on different subjects, and serve to check that the student does not “recognize” a name at random. *Diagnosed error:* citing from memory without checking. *Source:* the same preprint, verified on 5 September 2026 (source [3]). *Prerequisite:* none. *Remediation:* open the source and compare the formula with the one in Remark 10.1, checking the case $F = 0$.

Answers to the assigned exercises.

Exercise 10.5. (i) $X_u = \cosh v(-\sin u, \cos u, 0)$ and $X_v = (\sinh v \cos u, \sinh v \sin u, 1)$, hence $E = \cosh^2 v$, $F = 0$ and $G = \sinh^2 v + 1 = \cosh^2 v$: the first form is $\cosh^2 v (du^2 + dv^2)$, conformal with $\lambda = \cosh^2 v$. (ii) $X_u \times X_v = \cosh v(\cos u, \sin u, -\sinh v)$, of norm $\cosh^2 v$, hence $N = (\cos u, \sin u, -\sinh v)/\cosh v$. With $X_{uu} = \cosh v(-\cos u, -\sin u, 0)$, $X_{uv} = \sinh v(-\sin u, \cos u, 0)$ and $X_{vv} = (\cosh v \cos u, \cosh v \sin u, 0)$ one obtains $e = -1$, $f = 0$, $g = 1$. Hence $K = \frac{eg - f^2}{EG - F^2} = \frac{-1}{\cosh^4 v}$ and $H = \frac{eG - 2fF + gE}{2(EG - F^2)} = \frac{-\cosh^2 v + \cosh^2 v}{2\cosh^4 v} = 0$. (iii) $H \equiv 0$: the catenoid is minimal, and is indeed the only non-planar minimal surface of revolution. $K(0) = -1$, $K(0.5) = -1/\cosh^4(0.5) = -0.618500$, $K(1) = -1/\cosh^4(1) = -0.176378$ (values confirmed by the numerical computation with finite differences). As $|v| \rightarrow \infty$ one has $K \rightarrow 0$: the catenoid flattens out, locally approaching an ever wider cylinder. Consistently with Corollary 10.1, $H^2 = 0 \geq K$ everywhere. ✓

Exercise 10.6. (i) At the origin $X_u = (1, 0, 0)$ and $X_v = (0, 1, 0)$, hence $E = G = 1$, $F = 0$ and $N = (0, 0, 1)$; with $X_{uu} = (0, 0, 2a)$, $X_{vv} = (0, 0, 2b)$ and $X_{uv} = 0$ one has $e = 2a$, $g = 2b$, $f = 0$ and $K = 4ab$. (ii) $ab > 0$: elliptic point, and by Proposition 10.5(i) the surface lies entirely on one side of the plane $z = 0$ near the origin (above if $a, b > 0$, below if $a, b < 0$). $ab < 0$: hyperbolic point, the surface crosses the tangent plane (part (ii) of the same proposition). $ab = 0$ with $(a, b) \neq (0, 0)$: parabolic point, $z = au^2$ (or bv^2) is a parabolic cylinder and the surface touches the plane along a line. $a = b = 0$: planar point, the surface is the plane. Numerical check: $K = 4.000000$ for $(1, 1)$, -4.000000 for $(1, -1)$, 0.000000 for $(1, 0)$. ✓ (iii) For $a = 1$, $b = -1$ the surface is $z = u^2 - v^2$ and meets $z = 0$ where $u^2 = v^2$, that is along the two lines $v = \pm u$, of directions $(1, 1)/\sqrt{2}$ and $(1, -1)/\sqrt{2}$: their scalar product is $(1 - 1)/2 = 0$, hence they are orthogonal. They are the *asymptotic directions*, those in which the normal curvature vanishes; they are orthogonal precisely because here $H = 0$ (Euler’s formula of Proposition 10.3 gives $\kappa_n(\theta) = \kappa_1 \cos^2 \theta + \kappa_2 \sin^2 \theta = 0$ with

$\kappa_2 = -\kappa_1$, that is $\tan^2 \theta = 1$).

Exercise 10.7. With $a = 3$, $b = 1$ and $w = 3 + \cos v$: (i) $K = \cos v/w$ and $H = -(3 + 2 \cos v)/(2w)$.

v	0	$\pi/3$	$\pi/2$	$2\pi/3$	π
w	4	3.5	3	2.5	2
K	0.250000	0.142857	0.000000	-0.200000	-0.500000
H	-0.625000	-0.571429	-0.500000	-0.400000	-0.250000

H vanishes where $3 + 2 \cos v = 0$, that is $\cos v = -1.5$: impossible. For $a > 2b$ the mean curvature of the torus never vanishes; it vanishes only if $a \leq 2b$, at $v = \arccos(-a/(2b))$. (ii) Area $= 4\pi^2 ab = 4\pi^2 \cdot 3 = 118.435253$. The region of positive curvature is $|v| < \pi/2$, of area $\int_0^{2\pi} \int_{-\pi/2}^{\pi/2} (3 + \cos v) dv du = 2\pi(3\pi + 2) = 2\pi \times 11.424778 = 71.789423$, that is 60.6% of the total. (iii) $\iint K dA = \int_0^{2\pi} \int_0^{2\pi} \frac{\cos v}{w} w dv du = 2\pi [\sin v]_0^{2\pi} = 0$, in agreement with Theorem 4.8 of Chapter 4, which for $\chi(\text{torus}) = 0$ predicts precisely vanishing total curvature. ✓

10.13. Chapter formulary

First and second forms

$$E = \langle X_1, X_1 \rangle, \quad F = \langle X_1, X_2 \rangle, \quad G = \langle X_2, X_2 \rangle; \quad D = EG - F^2 = \|X_1 \times X_2\|^2 > 0$$

$$N = \frac{X_1 \times X_2}{\|X_1 \times X_2\|}; \quad e = \langle X_{11}, N \rangle, \quad f = \langle X_{12}, N \rangle, \quad g = \langle X_{22}, N \rangle$$

$$L(\gamma) = \int \sqrt{g_{ij} \dot{u}^i \dot{u}^j} ds; \quad dA = \sqrt{EG - F^2} du^1 du^2$$

Shape operator and curvatures

$$\mathcal{S} = -dN = \Gamma^{-1} \Pi; \quad X_{ij} = \Gamma_{ij}^k X_k + h_{ij} N; \quad N_i = -h_{ij} g^{jk} X_k$$

$$K = \kappa_1 \kappa_2 = \frac{eg - f^2}{EG - F^2}, \quad H = \frac{\kappa_1 + \kappa_2}{2} = \frac{eG - 2fF + gE}{2(EG - F^2)}, \quad H^2 \geq K$$

$$\kappa_n(w) = \Pi(w) = \langle \mathcal{S}w, w \rangle; \quad \kappa_n(\theta) = \kappa_1 \cos^2 \theta + \kappa_2 \sin^2 \theta \quad (\text{Euler})$$

$K > 0$ elliptic; $K < 0$ hyperbolic; $K = 0$, $\mathcal{S} \neq 0$ parabolic; $\mathcal{S} = 0$ planar

Theorema Egregium

$$E K = \partial_2 \Gamma_{11}^2 - \partial_1 \Gamma_{12}^2 + \Gamma_{11}^1 \Gamma_{12}^2 + \Gamma_{11}^2 \Gamma_{22}^2 - \Gamma_{12}^1 \Gamma_{11}^2 - (\Gamma_{12}^2)^2$$

$$F = 0: \quad K = -\frac{1}{2\sqrt{EG}} \left[\partial_2 \left(\frac{E_2}{\sqrt{EG}} \right) + \partial_1 \left(\frac{G_1}{\sqrt{EG}} \right) \right]$$

$$\phi \text{ local isometry} \implies \bar{K} \circ \phi = K \quad (\text{but } \bar{H} \circ \phi \neq H \text{ in general})$$

Examples

$$\text{sphere } r: K = \frac{1}{r^2}, H = \frac{1}{r} \text{ (inner normal);} \quad \text{plane, cylinder, cone: } K = 0$$

$$\text{cylinder } R: H = -\frac{1}{2R}; \quad \text{cone } \alpha: H = -\frac{\cot \alpha}{2v}$$

$$\text{torus } (a, b): K = \frac{\cos v}{b(a + b \cos v)}, \quad H = -\frac{a + 2b \cos v}{2b(a + b \cos v)}, \quad \text{Area} = 4\pi^2 ab, \quad \iint K dA = 0$$

$$\text{catenoid: } K = -\frac{1}{\cosh^4 v}, H = 0; \quad \text{ruled: } K = -\frac{f^2}{EG - F^2} \leq 0$$

$$\text{Bertrand-Puiseux: } K = \lim_{\rho \rightarrow 0^+} \frac{12(\pi \rho^2 - A(\rho))}{\pi \rho^4}$$

CHAPTER 11

The circle in any dimension: hyperspheres and concentration of measure

The circumference and the sphere are the cases $n = 2$ and $n = 3$ of an infinite family: the spheres $S^{n-1} \subset \mathbb{R}^n$. Passing to arbitrary dimension is not an exercise in generality for its own sake. On the one hand Euler's Gamma function puts into a single formula the perimeter of the circle, the area of the sphere and all the rest; on the other hand phenomena appear which plane intuition does not predict and which are today central in statistics and in machine learning: the volume of the unit ball tends to zero, the mass concentrates near the boundary and near every equator, a ball inscribed among others can stick out of the cube containing them. In the second half of the chapter the circle returns as protagonist in a different role: as the *group* of rotations of the plane, as the building block of every rotation in every dimension, and finally as the fibre of the Hopf fibration, which fills the three-dimensional sphere with circles.

INFO

The idea in one line. $V_n = \pi^{n/2}/\Gamma(n/2 + 1)$ grows up to $n = 5$ and then vanishes; on S^{n-1} every coordinate has mean square value $1/n$, so that almost all of the sphere lies near any equator whatsoever; and every rotation of $\mathbb{R}^n$, in every dimension, decomposes into rotations of circles — with S^1 and S^3 which are, themselves, groups.

INFO

Level and prerequisites. Level B–D. Sections 11.1 and 11.2 are of level B–C: they require the Gaussian integral, the change of variables to generalized polar coordinates and the Gamma function. Section 11.4 is of level C: Chebyshev's inequality and elementary estimates of integrals are used. Section 11.5 is of level B–C (linear algebra: orthogonal matrices, eigenvalues, reflections), section 11.6 of level C and section 11.7 of level C–D, but it requires no algebraic topology: complex numbers suffice. Prerequisites within the treatise: complex numbers and the unit circle (Volume II, Chapter 3); sphere, planar sections and spherical coordinates (Chapter 7); isometries of the plane and the classification of $O(2)$ (Chapter 5). The rotations of $\mathbb{R}^3$ and the quaternions are taken up again, from the point of view of kinematics, in Chapter 28; the fundamental group of S^1 , not needed here, is in Chapter 12.

Warning. Conventions of this chapter.

- $S^{n-1} = \{x \in \mathbb{R}^n : \|x\| = 1\}$ is the *unit sphere* of $\mathbb{R}^n$; the index denotes the *dimension of the surface*, not of the ambient space. Thus $S^1 \subset \mathbb{R}^2$ is the circle and $S^2 \subset \mathbb{R}^3$ the ordinary sphere.
- $B^n = \{x \in \mathbb{R}^n : \|x\| \leq 1\}$ is the solid unit ball; V_n its n -dimensional volume and Σ_{n-1} the area of S^{n-1} .
- $\langle \cdot, \cdot \rangle$ is the standard scalar product and $\|x\| = \sqrt{\langle x, x \rangle}$.
- Γ is Euler's Gamma function, $\Gamma(t) = \int_0^\infty u^{t-1} e^{-u} du$, with $\Gamma(n+1) = n!$, $\Gamma(t+1) = t\Gamma(t)$ and $\Gamma(1/2) = \sqrt{\pi}$.

- σ denotes the uniform probability measure on S^{n-1} (the rotation-invariant one, of total mass 1).
- Decimal separators are points: 0.5.

11.1. Spheres and balls in $\mathbb{R}^n$

Definition 11.1: n -dimensional sphere and ball. For $n \geq 1$: $S^{n-1}(O, r) = \{x \in \mathbb{R}^n : |x| = r\}$ is the sphere (intrinsic dimension $n - 1$); $B^n(O, r) = \{x \in \mathbb{R}^n : |x| \leq r\}$ is the ball (dimension n). Conventions: $S^0 = \{-r, r\}$, S^1 the circumference, S^2 the classical sphere. One writes S^{n-1} and B^n for O at the origin and $r = 1$.

Remark 11.1: Why S^{n-1} lives in $\mathbb{R}^n$. The sphere S^{n-1} is a manifold of dimension $n - 1$ embedded in $\mathbb{R}^n$: S^1 is a curve (1-dim) in $\mathbb{R}^2$, S^2 a surface (2-dim) in $\mathbb{R}^3$. The superscript indicates the intrinsic dimension, not that of the ambient space. The same convention is used in Chapter 7 (Definition 7.3), and explains why the ball, which is n -dimensional, carries the index n and its boundary the index $n - 1$.

Exercise 11.1. Why does S^0 have “area” 2?

Solution. $S^0 = \{-r, r\}$ is the boundary of the segment $B^1 = [-r, r]$. The “0-dimensional measure” (counting) of its points is 2. Consistently, the general formula $\text{Area}(S^{n-1}) = 2\pi^{n/2}/\Gamma(n/2) r^{n-1}$ of Theorem 11.1 gives for $n = 1$: $2\pi^{1/2}/\Gamma(1/2) \cdot r^0 = 2\sqrt{\pi}/\sqrt{\pi} = 2$. ✓

11.2. Hyperspheres: volume, surface and surprises

Theorem 11.1: Volume of the ball and area of the sphere in $\mathbb{R}^n$. For every $n \geq 1$,

$$V_n = \text{vol}(B^n) = \frac{\pi^{n/2}}{\Gamma(\frac{n}{2} + 1)}, \quad \Sigma_{n-1} = \text{area}(S^{n-1}) = \frac{2\pi^{n/2}}{\Gamma(\frac{n}{2})} = n V_n,$$

and for radius R one has $V_n(R) = V_n R^n$, $\Sigma_{n-1}(R) = \Sigma_{n-1} R^{n-1}$. Moreover the recursion holds:

$$V_n = \frac{2\pi}{n} V_{n-2}, \quad V_1 = 2, \quad V_2 = \pi.$$

Proof. Step 1 — the Gaussian integral in $\mathbb{R}^n$. Since $e^{-\|x\|^2} = \prod_{i=1}^n e^{-x_i^2}$, Fubini’s theorem gives

$$I_n = \int_{\mathbb{R}^n} e^{-\|x\|^2} dx = \left(\int_{\mathbb{R}} e^{-t^2} dt \right)^n = \pi^{n/2},$$

using the classical $\int_{\mathbb{R}} e^{-t^2} dt = \sqrt{\pi}$.

Step 2 — the same integral in polar coordinates. The volume element in spherical coordinates of $\mathbb{R}^n$ is $dx = r^{n-1} dr d\sigma$, with $d\sigma$ the surface measure on S^{n-1} ; the integrand depends only on r , hence

$$I_n = \Sigma_{n-1} \int_0^\infty e^{-r^2} r^{n-1} dr.$$

Step 3 — the radial integral. With the substitution $u = r^2$, $du = 2r dr$:

$$\int_0^\infty e^{-r^2} r^{n-1} dr = \frac{1}{2} \int_0^\infty e^{-u} u^{\frac{n}{2}-1} du = \frac{1}{2} \Gamma\left(\frac{n}{2}\right).$$

Step 4 — the area. Equating Steps 1 and 2,

$$\pi^{n/2} = \Sigma_{n-1} \cdot \frac{1}{2} \Gamma\left(\frac{n}{2}\right) \implies \Sigma_{n-1} = \frac{2\pi^{n/2}}{\Gamma(n/2)}.$$

Step 5 — the volume. Integrating the areas of the concentric spheres,

$$V_n = \int_0^1 \Sigma_{n-1} r^{n-1} dr = \frac{\Sigma_{n-1}}{n} = \frac{2\pi^{n/2}}{n \Gamma(n/2)} = \frac{\pi^{n/2}}{\Gamma(\frac{n}{2} + 1)},$$

using $\frac{n}{2} \Gamma(\frac{n}{2}) = \Gamma(\frac{n}{2} + 1)$.

Step 6 — the recursion.

$$\frac{V_n}{V_{n-2}} = \frac{\pi^{n/2}}{\Gamma(\frac{n}{2} + 1)} \cdot \frac{\Gamma(\frac{n}{2})}{\pi^{(n-2)/2}} = \pi \cdot \frac{\Gamma(\frac{n}{2})}{\Gamma(\frac{n}{2} + 1)} = \frac{\pi}{n/2} = \frac{2\pi}{n}.$$

Step 7 — check in the known cases.

$$V_1 = \frac{\pi^{1/2}}{\Gamma(3/2)} = \frac{\sqrt{\pi}}{\frac{1}{2}\sqrt{\pi}} = 2 \checkmark \quad (\text{the segment } [-1, 1]),$$

$$V_2 = \frac{\pi}{\Gamma(2)} = \pi \checkmark, \quad V_3 = \frac{\pi^{3/2}}{\Gamma(5/2)} = \frac{\pi^{3/2}}{\frac{3}{4}\sqrt{\pi}} = \frac{4\pi}{3} \checkmark,$$

and $\Sigma_1 = 2V_2 = 2\pi$ (the circumference), $\Sigma_2 = 3V_3 = 4\pi$ (the spherical surface). $\checkmark$

Step 8 — the circle as the case $n = 2$. The formulas of Volume I, $L = 2\pi R$ and $A = \pi R^2$, are the case $n = 2$ of these; those of the sphere, $4\pi R^2$ and $\frac{4}{3}\pi R^3$, the case $n = 3$. The chapter thus closes a circle: the elementary formulas are not isolated cases but the first terms of a sequence governed by the Gamma function. $\square$

Example 11.1: The table of volumes and the maximum in dimension five. Applying Theorem 11.1:

n	V_n (closed form)	V_n	$\Sigma_{n-1} = nV_n$
1	2	2.00000	2.00000
2	π	3.14159	6.28319
3	$\frac{4}{3}\pi$	4.18879	12.56637
4	$\frac{1}{2}\pi^2$	4.93480	19.73921
5	$\frac{8}{15}\pi^2$	5.26379	26.31894
6	$\frac{1}{6}\pi^3$	5.16771	31.00628
7	$\frac{16}{105}\pi^3$	4.72477	33.07336
8	$\frac{1}{24}\pi^4$	4.05871	32.46969
10	$\frac{1}{120}\pi^5$	2.55016	25.50164
20	—	0.025807	0.516138

The maximum. The volume grows up to $n = 5$ and then decreases. The reason is read off the recursion $V_n = \frac{2\pi}{n} V_{n-2}$: the factor $2\pi/n$ exceeds 1 as long as $n < 2\pi = 6.283$, and is smaller afterwards. The maximum therefore falls at $n = 5$ among odd dimensions and at $n = 6$ among even ones; between the two, $V_5 = 5.26379$ beats $V_6 = 5.16771$.

The area. The surface has its maximum at $n = 7$ ($\Sigma_6 = 33.073$), for the same reason shifted by one: $\Sigma_{n-1} = nV_n$.

Check of the recursion. $V_7 = \frac{2\pi}{7}V_5 = \frac{6.28319}{7} \times 5.26379 = 0.897598 \times 5.26379 = 4.72477$.
✓

Exercise 11.2. Compute $\text{Vol}(B^4, 1)$ using $\Gamma(3) = 2$, and check with the recurrence $V_n = \frac{2\pi}{n}V_{n-2}$.

Solution. For $n = 4$: $\Gamma(n/2 + 1) = \Gamma(3) = 2! = 2$, hence $\text{Vol}(B^4, 1) = \pi^2/2 \approx 4.93480$. Independent check with the recurrence: $V_4 = \frac{2\pi}{4}V_2 = \frac{\pi}{2} \cdot \pi = \frac{\pi^2}{2}$. ✓ Consistent with the table of Example 11.1.

Figure 11.1: The volume $V_n = \pi^{n/2}/\Gamma(n/2 + 1)$ of the unit ball in dimension n . Against all intuition the sequence is not monotone: it grows up to $n = 5$, where it attains its maximum $V_5 = 8\pi^2/15 \simeq 5.264$, then decreases and tends to zero faster than any exponential. Already in dimension 11 the unit ball has smaller volume than the segment $[-1, 1]$, and in dimension 100 its volume is about $2 \cdot 10^{-40}$: almost all of the circumscribed cube lies outside the ball.

11.3. The volume vanishes: the ball against the cube

Theorem 11.2: The volume of the unit ball vanishes. $\lim_{n \rightarrow \infty} V_n = 0$; indeed $V_n \rightarrow 0$ faster than any exponential. Moreover the ratio of the volume of the unit ball to that of the circumscribed cube $[-1, 1]^n$ tends to zero:

$$\frac{V_n}{2^n} \rightarrow 0.$$

Proof. Step 1 — from the recursion. For $n > 2\pi$, i.e. $n \geq 7$, we have $\frac{2\pi}{n} < 1$, hence $V_n < V_{n-2}$: the two subsequences (even and odd) are eventually decreasing.

Step 2 — superexponential decay. Iterating the recursion m times from n ,

$$V_n = \frac{2\pi}{n} \cdot \frac{2\pi}{n-2} \cdots \frac{2\pi}{n-2m+2} \cdot V_{n-2m}.$$

For large n most factors are smaller than $1/2$ (all those with $n - 2j > 4\pi$): hence $V_n \leq C 2^{-(n/2-K)}$ for suitable constants, and in fact the decay is much faster, since the factors tend

to zero. Formally, Stirling's formula $\Gamma(t+1) \sim \sqrt{2\pi t} (t/e)^t$ gives

$$V_n = \frac{\pi^{n/2}}{\Gamma(\frac{n}{2}+1)} \sim \frac{1}{\sqrt{\pi n}} \left(\frac{2\pi e}{n}\right)^{n/2},$$

which tends to zero because the base $2\pi e/n$ eventually becomes smaller than 1.

Step 3 — comparison with the cube. Since $V_n \rightarrow 0$ and $2^n \rightarrow \infty$, the ratio tends to zero a fortiori. Numerically:

$$n = 2 : \frac{\pi}{4} = 0.7854; \quad n = 3 : 0.5236; \quad n = 10 : \frac{2.55016}{1024} = 0.002490; \quad n = 20 : \frac{0.025807}{1\,048\,576} = 2.46 \times 10^{-8}.$$

Step 4 — how to read it. The ball is inscribed in the cube and touches its faces: in high dimension, therefore, *almost all the volume of the cube lies in the corners*. The cube $[-1, 1]^n$ has 2^n vertices, each at distance $\sqrt{n}$ from the centre against the radius 1 of the ball: the corners stretch out and multiply, and carry away all the volume.

Step 5 — a plausibility check. A uniform point in the cube has independent coordinates uniform on $[-1, 1]$, with $\mathbb{E}[x_i^2] = 1/3$: hence $\mathbb{E}[\|x\|^2] = n/3$, and by the law of large numbers $\|x\| \approx \sqrt{n/3}$, which exceeds 1 already for $n = 4$ and diverges. Almost no point of the cube falls in the ball, consistently with Step 3. ✓ □

Theorem 11.3: The ball that sticks out of the cube. In the cube $[-1, 1]^n$ place 2^n balls of radius $\frac{1}{2}$, centred at the points $(\pm\frac{1}{2}, \dots, \pm\frac{1}{2})$: they are contained in the cube and mutually tangent. Let $\mathcal{B}$ be the ball centred at the origin and tangent to all of them. Then its radius is

$$r_n = \frac{\sqrt{n} - 1}{2},$$

and it exceeds 1 — that is, $\mathcal{B}$ sticks out of the cube — for every $n \geq 10$.

Proof. **Step 1 — the small balls lie in the cube.** A centre has all coordinates equal to $\pm 1/2$; adding the radius $1/2$ one reaches at most ± 1 , i.e. the face of the cube.

Step 2 — they are mutually tangent. Two centres differing in one coordinate are at distance $1 = \frac{1}{2} + \frac{1}{2}$: the corresponding balls are tangent. Centres differing in more coordinates are farther apart, so the balls do not overlap.

Step 3 — the radius of the central ball. The distance from the origin to a centre is

$$\left\| \left(\frac{1}{2}, \dots, \frac{1}{2} \right) \right\| = \sqrt{n \cdot \frac{1}{4}} = \frac{\sqrt{n}}{2}.$$

External tangency forces $r_n + \frac{1}{2} = \frac{\sqrt{n}}{2}$, whence $r_n = \frac{\sqrt{n}-1}{2}$.

Step 4 — comparison with the cube. The cube $[-1, 1]^n$ has inradius 1 (distance from the centre to the faces). Hence

$$r_n > 1 \iff \sqrt{n} > 3 \iff n > 9,$$

i.e. for $n \geq 10$.

Step 5 — values.

$$r_2 = \frac{\sqrt{2}-1}{2} = 0.2071, \quad r_3 = \frac{\sqrt{3}-1}{2} = 0.3660, \quad r_9 = \frac{3-1}{2} = 1.0000, \quad r_{10} = \frac{\sqrt{10}-1}{2} = 1.0811.$$

In dimension 9 the central ball exactly touches the faces of the cube; from 10 onwards it crosses them. ✓

Step 6 — how is this possible. Intuition says a ball “in the middle” of other inscribed balls cannot leave the container, but that intuition is two-dimensional. In high dimension the

2^n centres are all at distance $\sqrt{n}/2$ from the origin, which grows without bound, while the faces remain at distance 1: the space “between the corners” becomes enormous. It is the other side of Theorem 11.2: the volume of the cube lies in the corners, and the central ball takes a growing share of it.

Step 7 — relative volume. Despite sticking out of the cube, the central ball has volume $V_n r_n^n$, which by Theorem 11.2 still tends to zero relative to 2^n : leaving the cube does not mean filling it. In dimension 10: $V_{10} r_{10}^{10} = 2.55016 \times (1.08114)^{10} = 2.55016 \times 2.18138 = 5.5628$, against $2^{10} = 1024$ for the cube, i.e. 0.54%. ✓ $\square$

11.4. Concentration of measure

Theorem 11.4: Concentration of measure on the sphere. Let σ be the uniform probability measure on S^{n-1} and x_1 the first coordinate. Then

$$\int_{S^{n-1}} x_1^2 d\sigma = \frac{1}{n},$$

and consequently, for every $\varepsilon > 0$,

$$\sigma(\{x \in S^{n-1} : |x_1| \geq \varepsilon\}) \leq \frac{1}{n\varepsilon^2}.$$

In high dimension, therefore, almost all the surface of the sphere concentrates in a thin band about any equator.

Proof. Step 1 — symmetry. The measure σ is invariant under every rotation of $\mathbb{R}^n$, in particular under permutation of the coordinates. Hence the numbers $\int x_i^2 d\sigma$ are all equal; call them q .

Step 2 — the constraint. On S^{n-1} we have $\sum_{i=1}^n x_i^2 = 1$ identically. Integrating with respect to σ (of total mass 1) and exchanging the finite sum with the integral:

$$1 = \int_{S^{n-1}} \sum_{i=1}^n x_i^2 d\sigma = \sum_{i=1}^n q = nq \implies q = \frac{1}{n}.$$

Step 3 — Chebyshev’s inequality. For the non-negative function x_1^2 and $t = \varepsilon^2 > 0$,

$$\sigma(x_1^2 \geq t) \leq \frac{1}{t} \int x_1^2 d\sigma = \frac{1}{n\varepsilon^2},$$

which is the claim, since $\{|x_1| \geq \varepsilon\} = \{x_1^2 \geq \varepsilon^2\}$.

Step 4 — reading. The first coordinate of a uniform point on the unit sphere has root mean square $1/\sqrt{n}$: it is typically tiny. Since the direction “first coordinate” is arbitrary — the sphere can be rotated at will — the same holds for every direction: *almost all of the sphere lies near every equator*, however absurd this sounds to two-dimensional intuition, where the equator of S^1 consists of just two points.

Step 5 — numerical values. With $\varepsilon = 0.1$:

$$n = 100 : \sigma(|x_1| \geq 0.1) \leq \frac{1}{100 \times 0.01} = 1 \quad (\text{a vacuous bound}),$$

$$n = 1000 : \leq \frac{1}{1000 \times 0.01} = 0.1; \quad n = 10^4 : \leq 0.01.$$

So in dimension 10^4 at least 99% of the surface has first coordinate less than 0.1 in absolute value.

Step 6 — the exponential refinement. Chebyshev's bound is convenient but weak: the true decay is not polynomial but *exponential* in n , as Theorem 11.5 below proves.

Step 7 — why it matters. This is the phenomenon that makes high-dimensional statistics, data compression and Monte Carlo methods possible: in high dimension smooth functions are nearly constant on the sphere, and a handful of random samples estimates their value accurately. The circle, where none of this happens, is the exception, not the rule. $\square$

Theorem 11.5: Exponential concentration bound. For every $n \geq 4$ and every $\varepsilon \in (0, 1)$,

$$\sigma(\{x \in S^{n-1} : |x_1| \geq \varepsilon\}) \leq \frac{\sqrt{e}}{\varepsilon \sqrt{n-1}} e^{-(n-1)\varepsilon^2/2}.$$

The decay is therefore exponential in n , and not merely of order $1/(n\varepsilon^2)$ as Chebyshev's bound gave.

Proof. **Step 1 — the density of the first coordinate.** Parametrise S^{n-1} by the colatitude $\phi \in [0, \pi]$ with respect to the x_1 -axis, so that $t = x_1 = \cos \phi$. The “slice” at height t is a sphere S^{n-2} of radius $\sin \phi = \sqrt{1-t^2}$, and the band between ϕ and $\phi + d\phi$ has area

$$\Sigma_{n-2} (\sin \phi)^{n-2} d\phi.$$

Since $dt = -\sin \phi d\phi$, i.e. $d\phi = |dt|/\sin \phi$, that area equals

$$\Sigma_{n-2} (\sin \phi)^{n-3} |dt| = \Sigma_{n-2} (1-t^2)^{(n-3)/2} |dt|.$$

The image measure of σ under $x \mapsto x_1$ therefore has density proportional to $(1-t^2)^{(n-3)/2}$ on $[-1, 1]$, and

$$\sigma(x_1 \geq \varepsilon) = \frac{N}{D}, \quad N = \int_{\varepsilon}^1 (1-t^2)^{(n-3)/2} dt, \quad D = \int_{-1}^1 (1-t^2)^{(n-3)/2} dt.$$

Step 2 — bounding the numerator. On $[\varepsilon, 1]$ we have $t/\varepsilon \geq 1$, hence

$$N \leq \frac{1}{\varepsilon} \int_{\varepsilon}^1 t (1-t^2)^{(n-3)/2} dt.$$

The last integral is elementary: since $\frac{d}{dt}(1-t^2)^{(n-1)/2} = -(n-1)t(1-t^2)^{(n-3)/2}$,

$$\int_{\varepsilon}^1 t (1-t^2)^{(n-3)/2} dt = \frac{(1-\varepsilon^2)^{(n-1)/2}}{n-1}, \quad \text{i.e.} \quad N \leq \frac{(1-\varepsilon^2)^{(n-1)/2}}{\varepsilon(n-1)}.$$

Step 3 — bounding the denominator from below. Put $a = 1/\sqrt{n-1} \in (0, 1]$. For $n \geq 3$ the function $t \mapsto (1-t^2)^{(n-3)/2}$ is non-increasing on $[0, 1]$, hence

$$D \geq 2 \int_0^a (1-t^2)^{(n-3)/2} dt \geq 2a(1-a^2)^{(n-3)/2} = \frac{2}{\sqrt{n-1}} \left(1 - \frac{1}{n-1}\right)^{(n-3)/2}.$$

Now, for $0 \leq u < 1$ one has $\ln(1-u) \geq -\frac{u}{1-u}$ (because $\ln(1-u) = -\int_0^u \frac{ds}{1-s}$ and $\frac{1}{1-s} \leq \frac{1}{1-u}$ on $[0, u]$); with $u = 1/(n-1)$,

$$\frac{n-3}{2} \ln\left(1 - \frac{1}{n-1}\right) \geq -\frac{n-3}{2} \cdot \frac{1/(n-1)}{(n-2)/(n-1)} = -\frac{n-3}{2(n-2)} \geq -\frac{1}{2},$$

valid for $n \geq 4$ (which also guarantees $u \leq 1/3 < 1$). Hence

$$D \geq \frac{2}{\sqrt{n-1}} e^{-1/2}.$$

Step 4 — the ratio. Combining Steps 2 and 3,

$$\sigma(x_1 \geq \varepsilon) = \frac{N}{D} \leq \frac{(1 - \varepsilon^2)^{(n-1)/2}}{\varepsilon(n-1)} \cdot \frac{\sqrt{n-1} e^{1/2}}{2} = \frac{\sqrt{e}}{2\varepsilon\sqrt{n-1}} (1 - \varepsilon^2)^{(n-1)/2}.$$

Step 5 — from the power to the exponential. From $1 - s \leq e^{-s}$ with $s = \varepsilon^2$ we get $(1 - \varepsilon^2)^{(n-1)/2} \leq e^{-(n-1)\varepsilon^2/2}$, hence

$$\sigma(x_1 \geq \varepsilon) \leq \frac{\sqrt{e}}{2\varepsilon\sqrt{n-1}} e^{-(n-1)\varepsilon^2/2}.$$

Step 6 — symmetry. The measure σ is invariant under $x_1 \mapsto -x_1$, hence $\sigma(|x_1| \geq \varepsilon) = 2\sigma(x_1 \geq \varepsilon)$, and the factor 2 cancels the denominator: the claim follows.

Step 7 — numerical comparison. With $n = 1000$ and $\varepsilon = 0.1$:

$$\frac{\sqrt{e}}{0.1 \times \sqrt{999}} e^{-999 \times 0.005} = \frac{1.648721}{3.160696} \times e^{-4.995} = 0.521633 \times 0.0067717 = 0.003532,$$

that is 0.35%, against the 10% guaranteed by Chebyshev: almost thirty times better. For $n = 10^4$ the exponential bound gives $\sim 10^{-23}$, while Chebyshev stops at 1%.

Step 8 — comparison with the literature. Textbooks often state the bound in the more memorable form $\sigma(|x_1| \geq \varepsilon) \leq 2e^{-n\varepsilon^2/2}$ (Ledoux); the constant proved here is different but the content is the same, and for the values of interest (n in the hundreds) the one proved above is in fact sharper.

Step 9 — the case $n = 3$. For $n = 3$ the exponent $(n-3)/2$ vanishes, the density is constant and one recovers Archimedes' theorem: the projection of the sphere onto a diameter is uniform, so $\sigma(|x_1| \geq \varepsilon) = 1 - \varepsilon$ exactly. No concentration: it begins only from $n = 4$ upwards, and grows stronger as n increases. $\checkmark$ $\square$

Alongside concentration on the *surface* there is concentration in the *volume*: the ball, in high dimension, is almost all skin.

Theorem 11.6: Concentration near the boundary. Let $\varepsilon \in (0, 1)$. In $B^n(O, 1)$ the fraction of volume contained in the outer shell $\{1 - \varepsilon < \|x\| \leq 1\}$ equals exactly $1 - (1 - \varepsilon)^n$, and tends to 1 as $n \rightarrow \infty$. More precisely, it exceeds $1 - \delta$ as soon as

$$n \geq \frac{\ln(1/\delta)}{-\ln(1 - \varepsilon)}.$$

Proof. **Step 1 — homogeneity of volume.** The homothety $x \mapsto \lambda x$ of $\mathbb{R}^n$ has determinant λ^n , hence multiplies volumes by λ^n : the ball of radius $1 - \varepsilon$ has volume $(1 - \varepsilon)^n V_n$ (this is Exercise S1, Step 1).

Step 2 — the fraction. The fraction of volume *inside* the radius $1 - \varepsilon$ is therefore $(1 - \varepsilon)^n V_n / V_n = (1 - \varepsilon)^n$, and that of the shell is the complement to 1:

$$\frac{\text{vol}(B^n \setminus B^n(O, 1 - \varepsilon))}{\text{vol}(B^n)} = 1 - (1 - \varepsilon)^n.$$

Note that the result *does not depend* on V_n : the constant cancels, and for this reason the formula is so robust.

Step 3 — the limit. Since $0 < 1 - \varepsilon < 1$, one has $(1 - \varepsilon)^n = e^{n \ln(1 - \varepsilon)} \rightarrow 0$ (the exponent tends to $-\infty$), hence the fraction of the shell tends to 1.

Step 4 — the explicit threshold. The fraction exceeds $1 - \delta$ if and only if $(1 - \varepsilon)^n < \delta$, that is $n \ln(1 - \varepsilon) < \ln \delta$, that is — dividing by $\ln(1 - \varepsilon) < 0$ and reversing the inequality —

$n > \ln \delta / \ln(1 - \varepsilon) = \ln(1/\delta) / (-\ln(1 - \varepsilon))$.

Step 5 — numerical check. With $\varepsilon = 0.01$:

$n = 10 : 1 - 0.99^{10} = 1 - 0.904382 = 0.095618$; $n = 100 : 1 - 0.366032 = 0.633968$; $n = 1000 : 1 - 0.0000432$

The threshold of Step 4 with $\delta = 0.01$ gives $n \geq \ln(100) / (-\ln(0.99)) = 4.605170 / 0.010050 = 458.21$, that is $n = 459$; and indeed $0.99^{459} = 0.009921 < 0.01$ whereas $0.99^{458} = 0.010021 > 0.01$. ✓

Step 6 — why it is counterintuitive. In dimension 2 and 3 the fraction of the shell of thickness 1% equals respectively $1 - 0.99^2 = 0.0199$ and $1 - 0.99^3 = 0.0297$: negligible, as the drawing suggests. In dimension 459 it is 99%. The reason is purely arithmetic — an n -th power of a number smaller than 1 — but its geometric effect is that the “centre” of the ball, in high dimension, is empty. □

Remark 11.2: Curse of dimensionality. Almost all the volume of a high-dimensional ball is concentrated in a thin skin near the surface (Theorem 11.6): the “centre” is practically empty. It follows that in high dimension uniformly sampled points are almost all at the same distance (close to the maximum) and almost orthogonal to one another (Exercise S3): the notions of “near” and “far” lose contrast. This is the reason why distance-based algorithms (k -NN, clustering) degrade in high dimension, a phenomenon known in machine learning as the curse of dimensionality (Bellman). The same fact has a “beneficial” side (blessing of dimensionality): concentration makes many random quantities strongly predictable, and it is what allows Monte Carlo methods and data compression to work (Theorem 11.5, Step 7).

11.4.1 Distances in high dimension

In a dataset with n -dimensional features, concentration of measure implies that the ratio between the distance of the farthest neighbour and that of the nearest one tends to 1: the Euclidean distance becomes uninformative. Practical strategies — dimensionality reduction (PCA), learned metrics, embeddings — aim exactly at restoring the contrast between distances that high dimension flattens. The geometry of the sphere S^{n-1} , where normalized data live, is therefore the mathematical ground of many modelling choices.

Exercise 11.3. In $B^{100}(O, 1)$, what fraction of the volume lies beyond the radius 0.99?

Solution. By Theorem 11.6 with $\varepsilon = 0.01$ and $n = 100$, the fraction inside the radius 0.99 is 0.99^{100} . Since $0.99^{100} = e^{100 \ln 0.99} = e^{-1.005034} = 0.366032$, the fraction in the shell $[0.99, 1]$ is $1 - 0.366032 = 0.633968$: more than 63% of the volume lies in the outer 1% of the radius. In dimension 100 the ball is almost all “skin”. ✓

Remark 11.3: The moral of the chapter. The circle, in dimension 2, is so well behaved that it suggests an intuition which in high dimension is simply false. The three preceding theorems — vanishing volume, concentrating measure, ball escaping the cube — are not curiosities: they are the fundamental facts governing multivariate statistics, machine learning and long-block error-correcting codes. The practical rule they yield is: in high dimension, do not trust pictures. And, as an opposite corollary: whenever one manages to reduce a problem to a circle, everything has been gained, because on S^1 geometric intuition becomes reliable again.

11.5. Rotations in any dimension

Figure 11.2: The fraction of the volume of the unit ball B^n contained in the outer shell of thickness $\varepsilon = 0.01$, that is $1 - 0.99^n$, as a function of the dimension. In dimension 10 it equals 0.0956, in dimension 100 already 0.6340, and it exceeds 99% from $n = 459$ on (red dot: the critical value 458.21 of Theorem 11.6, Step 4). Two-dimensional intuition, where the same fraction equals 0.0199, is entirely misleading.

Figure 11.3: Concentration of measure on the sphere. Left: the equatorial band $|x_1| \leq \varepsilon$; in high dimension it contains almost all of the surface measure, however thin it is taken. Right: the density of the first coordinate of a uniform point on S^{n-1} , $f_n(t) = c_n(1 - t^2)^{(n-3)/2}$, for $n = 3, 10, 50$. For $n = 3$ it is constant (Archimedes' theorem: the projection of the sphere onto the axis is uniform); as n grows the density tightens around $t = 0$ with width of order $1/\sqrt{n}$.

Definition 11.2: Orthogonal group and rotation group. A matrix $R \in \mathbb{R}^{n \times n}$ is **orthogonal** if $R^\top R = I$, i.e. if it preserves the scalar product: $\langle Rx, Ry \rangle = \langle x, y \rangle$. The set of orthogonal matrices is the group $O(n)$; since $\det(R)^2 = 1$, one has $\det R = \pm 1$, and the subgroup

$$SO(n) = \{R \in O(n) : \det R = +1\}$$

is the **rotation group** of $\mathbb{R}^n$.

Theorem 11.7: The circle is the rotation group of the plane. The map

$$\Theta : S^1 \longrightarrow SO(2), \quad \Theta(e^{i\vartheta}) = \begin{pmatrix} \cos \vartheta & -\sin \vartheta \\ \sin \vartheta & \cos \vartheta \end{pmatrix},$$

is a group isomorphism (and a homeomorphism). In particular $SO(2)$ is commutative.

Proof. Step 1 — the image lies in $SO(2)$. The matrix has orthonormal columns and determinant $\cos^2 \vartheta + \sin^2 \vartheta = 1$.

Step 2 — it is a homomorphism. Multiplying two such matrices and using the addition formulas,

$$\Theta(e^{i\vartheta}) \Theta(e^{i\psi}) = \begin{pmatrix} \cos(\vartheta + \psi) & -\sin(\vartheta + \psi) \\ \sin(\vartheta + \psi) & \cos(\vartheta + \psi) \end{pmatrix} = \Theta(e^{i(\vartheta+\psi)}),$$

so the product on the circle (Chapter 3) corresponds to matrix multiplication.

Step 3 — surjectivity. Let $R \in SO(2)$ have first column $(a, c)^\top$; being a unit vector, $a^2 + c^2 = 1$, hence $(a, c) = (\cos \vartheta, \sin \vartheta)$ for some ϑ . The second column is orthogonal to the first and of unit length, hence equals $\pm(-\sin \vartheta, \cos \vartheta)$; the $+$ sign is forced by $\det R = +1$.

Step 4 — injectivity. $\Theta(e^{i\vartheta}) = I$ forces $\cos \vartheta = 1$ and $\sin \vartheta = 0$, i.e. $e^{i\vartheta} = 1$.

Step 5 — reading. The circle is not merely a *figure invariant* under rotations: it *is* the rotation group of the plane. This identification, glimpsed in Chapter 3 with multiplication by $e^{i\vartheta}$, is the ultimate reason why the circle appears in every periodic phenomenon: periodicity is invariance under a group, and in dimension two that group is the circle itself.

Step 6 — commutativity and its consequences. $SO(2)$ is commutative because plane rotations add their angles. Already $SO(3)$ is not (Example 11.2), and this is the structural difference between the plane case and all the others. $\square$

Theorem 11.8: Euler's rotation theorem. Every $R \in SO(3)$ other than the identity has an **axis**: there is $u \in S^2$ with $Ru = u$, unique up to sign, and R is the rotation by an angle ϑ about u , with

$$\operatorname{tr} R = 1 + 2 \cos \vartheta.$$

Proof. **Step 1 — existence of the eigenvalue 1.** Compute $\det(R - I)$ using $R^\top R = I$ and $\det R = 1$:

$$\det(R - I) = \det(R - RR^\top) = \det R \cdot \det(I - R^\top) = \det(I - R^\top).$$

But $\det(I - R^\top) = \det((I - R)^\top) = \det(I - R) = (-1)^3 \det(R - I) = -\det(R - I)$. Hence $\det(R - I) = -\det(R - I)$, i.e. $\det(R - I) = 0$: the number 1 is an eigenvalue of R .

Step 2 — the axis. Let u be a unit eigenvector for the eigenvalue 1: $Ru = u$. The line $\mathbb{R}u$ is fixed pointwise.

Step 3 — the orthogonal plane. The plane $u^\perp$ is invariant: if $\langle v, u \rangle = 0$, then $\langle Rv, u \rangle = \langle Rv, Ru \rangle = \langle v, u \rangle = 0$. The restriction of R to $u^\perp$ is orthogonal and has determinant $\det R/1 = 1$: it therefore lies in $SO(2)$ and, by Theorem 11.7, is a rotation by an angle ϑ .

Step 4 — the trace. In an orthonormal basis $\{u, e_1, e_2\}$ with e_1, e_2 a basis of $u^\perp$, the matrix of R is

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \vartheta & -\sin \vartheta \\ 0 & \sin \vartheta & \cos \vartheta \end{pmatrix},$$

whose trace is $1 + 2 \cos \vartheta$. Since the trace is invariant under orthonormal change of basis, the formula holds in every basis.

Step 5 — uniqueness of the axis. If $R \neq I$, the angle ϑ is not a multiple of 2π and the restriction to $u^\perp$ has no non-zero fixed vectors: the eigenspace of the eigenvalue 1 is exactly $\mathbb{R}u$, and u is determined up to sign.

Step 6 — a surprising consequence. However a rigid sphere is moved about its centre, at the end *at least two diametrically opposite points have returned where they were*. In particular, shuffling a rigid deck of cards, or rotating a planet, there is always an instantaneous axis. The result is Euler's (1776) and is false in even dimension: in $\mathbb{R}^4$ the rotation turning the plane x_1x_2 by 90° and the plane x_3x_4 by 90° fixes no non-zero vector.

Step 7 — the general case. In $\mathbb{R}^n$ every $R \in SO(n)$ has an invariant subspace of dimension 1 or 2. Indeed the characteristic polynomial has at least one complex root λ ; if $\lambda \in \mathbb{R}$ then

$\lambda = \pm 1$ (by orthogonality) and one has a real eigenvector; otherwise, writing $v = a + ib$ for a complex eigenvector, from $Rv = \lambda v$ with $\lambda = e^{i\vartheta}$ one gets

$$Ra = \cos \vartheta a - \sin \vartheta b, \quad Rb = \sin \vartheta a + \cos \vartheta b,$$

by equating real and imaginary parts: the plane $\text{span}\{a, b\}$ is invariant and R acts on it as a rotation. Iterating on the orthogonal complement one obtains the *normal form*

$$R \sim \text{diag}(R_{\vartheta_1}, \dots, R_{\vartheta_m}, 1, \dots, 1),$$

a direct sum of plane rotations and identities. *Every rotation, in every dimension, is a superposition of rotations of circles*: this is the precise sense in which the circle is the building block of the geometry of rotations. $\square$

Theorem 11.9: Cartan–Dieudonné theorem. *Every $A \in O(n)$ is a product of at most n reflections in hyperplanes through the origin (the identity being the empty product). Since every reflection has determinant -1 , the elements of $SO(n)$ are products of an even number of reflections; in particular every rotation of $\mathbb{R}^3$ other than the identity is a product of exactly two reflections.*

Proof. Step 1 — the reflection and its action. For a unit vector $m \in \mathbb{R}^n$, the reflection in the hyperplane $m^\perp$ is

$$S_m(x) = x - 2\langle x, m \rangle m.$$

It is orthogonal ($\|S_m x\|^2 = \|x\|^2 - 4\langle x, m \rangle^2 + 4\langle x, m \rangle^2 \|m\|^2 = \|x\|^2$) and has determinant -1 , since it fixes $m^\perp$ and sends m to $-m$.

Step 2 — induction on the defect. Put $d(A) = n - \dim \text{Fix}(A)$, where $\text{Fix}(A) = \{x : Ax = x\}$. We prove by induction on d that A is a product of at most d reflections. If $d = 0$ then $A = I$: the empty product.

Step 3 — the inductive step. Let $d \geq 1$; there is v with $Av \neq v$. Put

$$m = \frac{Av - v}{\|Av - v\|}, \quad S = S_m.$$

Step 4 — S takes Av back to v . Since A is orthogonal, $\|Av\| = \|v\|$, hence

$$\langle Av - v, Av + v \rangle = \|Av\|^2 - \|v\|^2 = 0,$$

i.e. $Av + v \perp m$. Writing $Av = \frac{1}{2}[(Av + v) + (Av - v)]$ and noting that S fixes the first bracket and reverses the second,

$$S(Av) = \frac{1}{2}[(Av + v) - (Av - v)] = v.$$

Step 5 — SA fixes more. Let $w \in \text{Fix}(A)$. From $Aw = w$ we get $A^{-1}w = w$, and since A is orthogonal $\langle w, Av \rangle = \langle A^{-1}w, v \rangle = \langle w, v \rangle$; hence $\langle w, Av - v \rangle = 0$, i.e. $w \perp m$ and $Sw = w$. Therefore $SAw = Sw = w$. Moreover $SAv = v$ by Step 4. It follows that

$$\text{Fix}(SA) \supseteq \text{Fix}(A) \oplus \mathbb{R}v,$$

a direct sum because $v \notin \text{Fix}(A)$. Hence $d(SA) \leq d(A) - 1$.

Step 6 — conclusion. By the inductive hypothesis SA is a product of at most $d - 1$ reflections, and since $S^2 = I$ we have $A = S(SA)$: a product of at most $d \leq n$ reflections.

Step 7 — parity and the three-dimensional case. If $A = S_1 \cdots S_k$ then $\det A = (-1)^k$: hence $\det A = +1$ forces k even. In $\mathbb{R}^3$ we have $k \leq 3$, so $k \in \{0, 2\}$: the identity, or the

product of two reflections. Since two distinct hyperplanes of $\mathbb{R}^3$ meet in a line fixed by both reflections, one recovers the axis of Theorem 11.8 — and this is the route taken in Exercise S4. **Step 8 — sharpness of the bound.** The bound n cannot be improved: $-I$ in $\mathbb{R}^n$ has $\text{Fix} = \{0\}$, hence $d = n$, and exactly n reflections are needed (for instance those in the coordinate hyperplanes). ✓ $\square$

11.6. Quaternions and rotations of space

Definition 11.3: Quaternions. The algebra of **quaternions** $\mathbb{H}$ is $\mathbb{R}^4$ with basis $\{1, i, j, k\}$ and associative product determined by

$$i^2 = j^2 = k^2 = ijk = -1,$$

whence $ij = k$, $jk = i$, $ki = j$ and $ji = -k$, $kj = -i$, $ik = -j$. For $q = q_0 + q_1i + q_2j + q_3k$ one sets $\bar{q} = q_0 - q_1i - q_2j - q_3k$ and $\|q\|^2 = q\bar{q} = q_0^2 + q_1^2 + q_2^2 + q_3^2$. The quaternions of norm 1 form the sphere $S^3 \subset \mathbb{R}^4$, which is a group under multiplication. A quaternion with $q_0 = 0$ is **pure** and is identified with a vector of $\mathbb{R}^3$.

Theorem 11.10: Unit quaternions are the rotations of space. For $q \in S^3$ define $\Phi_q : \mathbb{R}^3 \rightarrow \mathbb{R}^3$ by

$$\Phi_q(v) = qv\bar{q} \quad (v \text{ pure}).$$

Then:

- (i) $\Phi_q(v)$ is pure and $\|\Phi_q(v)\| = \|v\|$;
- (ii) $\Phi_q \in SO(3)$ and $\Phi_{q_1q_2} = \Phi_{q_1} \circ \Phi_{q_2}$;
- (iii) if $q = \cos \frac{\vartheta}{2} + (\sin \frac{\vartheta}{2})u$ with u pure of unit norm, then Φ_q is the rotation by angle ϑ about the axis u ;
- (iv) $\Phi_q = \Phi_{q'}$ if and only if $q' = \pm q$: the map $S^3 \rightarrow SO(3)$ is a surjective homomorphism which is two to one.

Proof. **(i) Step 1 — norm preservation.** The quaternion norm is multiplicative ($\|pq\| = \|p\| \|q\|$, verifiable from the product or from Euler's four-square identity), hence

$$\|qv\bar{q}\| = \|q\| \|v\| \|\bar{q}\| = \|v\|,$$

since $\|q\| = \|\bar{q}\| = 1$.

Step 2 — it stays pure. A quaternion w is pure iff $\bar{w} = -w$. Now

$$\overline{qv\bar{q}} = q\bar{v}q = q(-v)\bar{q} = -qv\bar{q},$$

using $\overline{ab} = \bar{b}\bar{a}$ and $\bar{v} = -v$. Hence $\Phi_q(v)$ is pure.

(ii) Step 3 — linearity and orthogonality. Φ_q is linear in v because the quaternion product is bilinear; it preserves the norm by (i), hence is orthogonal.

Step 4 — determinant +1. The map $q \mapsto \det \Phi_q$ is continuous on S^3 , with values in $\{-1, +1\}$; since S^3 is connected and $\Phi_1 = \text{id}$ has determinant +1, we get $\det \Phi_q = +1$ for every q .

Step 5 — homomorphism. $\Phi_{q_1}(\Phi_{q_2}(v)) = q_1q_2v\bar{q}_2\bar{q}_1 = (q_1q_2)v\overline{(q_1q_2)} = \Phi_{q_1q_2}(v)$.

(iii) Step 6 — the axis. With $q = c + su$, $c = \cos \frac{\vartheta}{2}$, $s = \sin \frac{\vartheta}{2}$, and recalling $u^2 = -1$ for u pure of unit norm:

$$\Phi_q(u) = (c + su)u(c - su) = (cu + su^2)(c - su) = (cu - s)(c - su).$$

Expanding: $c^2u - csu^2 - sc + s^2u = c^2u + cs - sc + s^2u = u$. So u is fixed: it is the axis.

Step 7 — the angle. Let w be pure of unit norm and orthogonal to u ; then $uw = -wu$ (checked on the basis: $ij = -ji$ etc.) and uw is pure, of unit norm, orthogonal to both u and w . Compute

$$\Phi_q(w) = (c + su)w(c - su) = (cw + suw)(c - su) = c^2w - cswu + csuw - s^2uwu.$$

Now $wu = -uw$, hence $-cswu + csuw = 2csuw$; and $uwu = -u^2w = w$. Therefore

$$\Phi_q(w) = (c^2 - s^2)w + 2cs(uw) = \cos \vartheta w + \sin \vartheta (uw),$$

by the double-angle formulas. Since $\{w, uw\}$ is an orthonormal basis of the plane $u^\perp$, the restriction of Φ_q to that plane is the rotation by ϑ : the claim.

(iv) Step 8 — the kernel. If $\Phi_q = \text{id}$, then $qv = vq$ for every pure v , hence q commutes with i, j, k and so with all of $\mathbb{H}$: the centre of $\mathbb{H}$ is $\mathbb{R}$, hence $q = \pm 1$ (having norm 1). It follows that $\Phi_q = \Phi_{q'}$ is equivalent to $q'q^{-1} = \pm 1$, i.e. $q' = \pm q$.

Step 9 — surjectivity. By Theorem 11.8 every rotation has an axis u and an angle ϑ ; the quaternion of (iii) realises it.

Step 10 — reading. The sphere S^3 covers the rotation group of space twice. This is the fact behind *spin* 1/2 in quantum mechanics: rotating a system by 360° takes the quaternion from q to $-q$, and 720° are needed to return to the start. The phenomenon can be demonstrated by hand — it is the famous “belt trick” — and has no analogue in the plane, where $SO(2) = S^1$ is covered only once by itself. $\square$

Example 11.2: Composing two right-angle rotations. Compose the rotation by 90° about the z -axis with the rotation by 90° about the x -axis (first z , then x).

Step 1 — the two quaternions. By Theorem 11.10(iii), with $\vartheta = 90^\circ$ and $\cos 45^\circ = \sin 45^\circ = 0.707107$:

$$q_1 = 0.707107 + 0.707107k \text{ (} z\text{-axis)}, \quad q_2 = 0.707107 + 0.707107i \text{ (} x\text{-axis)}.$$

Step 2 — product. The composition “first q_1 , then q_2 ” corresponds to $q = q_2q_1$:

$$q = (0.707107 + 0.707107i)(0.707107 + 0.707107k).$$

Expanding, with $0.707107^2 = 0.5$ and $ik = -j$:

$$q = 0.5 + 0.5k + 0.5i + 0.5ik = 0.5 + 0.5i - 0.5j + 0.5k.$$

Step 3 — norm check. $\|q\|^2 = 4 \times 0.25 = 1$. $\checkmark$

Step 4 — angle and axis. From $\cos \frac{\vartheta}{2} = 0.5$ we get $\frac{\vartheta}{2} = 60^\circ$, i.e. $\vartheta = 120^\circ$; the pure part is $0.5(i - j + k)$, of norm $0.5\sqrt{3} = 0.866025 = \sin 60^\circ$ $\checkmark$, and the axis is the unit vector

$$u = \frac{(1, -1, 1)}{\sqrt{3}}.$$

Step 5 — geometric reading. The composition of two right-angle rotations about orthogonal axes is a rotation by 120° about a *diagonal of the cube*. It is exactly the symmetry taking a cube to itself by cyclically permuting the three axes: the result, far from obvious, is read off in four lines of quaternion algebra.

Step 6 — check via the trace. The matrix of the composed rotation is obtained by multiplying

$$R_x(90^\circ)R_z(90^\circ) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & -1 & 0 \\ 0 & 0 & -1 \\ 1 & 0 & 0 \end{pmatrix}.$$

Its trace is 0, and Theorem 11.8 gives $1 + 2 \cos \vartheta = 0$, i.e. $\cos \vartheta = -0.5$ and $\vartheta = 120^\circ$. ✓

Step 7 — non-commutativity. Reversing the order gives $q' = q_1 q_2 = 0.5 + 0.5i + 0.5j + 0.5k$, with axis $(1, 1, 1)/\sqrt{3}$: same angle, different axis. $SO(3)$ is not commutative, unlike $SO(2) = S^1$ (Theorem 11.7).

Figure 11.4: Rodrigues' formula in one picture. The vector $\mathbf{v}$ splits into the component $\mathbf{v}_{\parallel} = (\mathbf{n} \cdot \mathbf{v})\mathbf{n}$ along the axis, which the rotation leaves fixed, and the orthogonal component $\mathbf{v}_{\perp}$, which rotates by θ in the plane perpendicular to $\mathbf{n}$. In that plane $\{\mathbf{v}_{\perp}, \mathbf{n} \times \mathbf{v}\}$ is an orthogonal basis of equal length, so the rotated component equals $\cos \theta \mathbf{v}_{\perp} + \sin \theta (\mathbf{n} \times \mathbf{v})$: adding the axial part gives $R_{\mathbf{n}, \theta} \mathbf{v} = \mathbf{v} \cos \theta + (\mathbf{n} \times \mathbf{v}) \sin \theta + \mathbf{n}(\mathbf{n} \cdot \mathbf{v})(1 - \cos \theta)$. The tip of the vector traces a circle: the circle is the orbit of every rotation.

Remark 11.4: Which spheres are groups, and the Hopf fibration. Theorem 11.7 shows that S^1 is a group (the complex numbers of modulus 1) and Definition 11.3 that S^3 is one (the quaternions of norm 1). One proves — with tools of algebraic topology beyond this treatise — that the only spheres carrying a Lie group structure are S^0 , S^1 and S^3 : S^2 , for instance, is not one, because every continuous vector field on it vanishes somewhere (the hairy ball theorem). The circle is therefore, together with S^3 , an exception.

There is more: the map $S^3 \rightarrow S^2$ sending q to the axis of the rotation Φ_q has as fibres exactly the circles $\{e^{au}q\}$. One thus obtains the **Hopf fibration** (1931): the three-dimensional sphere is covered by a family of circles, pairwise linked, parametrised by the two-dimensional sphere. It is the most celebrated example of filling a space with circles, and shows that even in dimension three the circle remains the fundamental building block. Section 11.7 gives its explicit construction and proves its properties.

11.7. The Hopf fibration, explicitly

Remark 11.4 announced that S^3 is filled by circles parametrised by S^2 . We build that fibration here with an explicit formula and prove the three properties that matter: the fibres are great circles, they are pairwise disjoint and fill S^3 , and two distinct fibres are *linked*. None of this requires algebraic topology: complex numbers suffice.

Definition 11.4: Hopf map. Identify $\mathbb{R}^4$ with $\mathbb{C}^2$ by setting $(x_1, y_1, x_2, y_2) \leftrightarrow (z_1, z_2)$ with $z_1 = x_1 + iy_1$, $z_2 = x_2 + iy_2$, so that

$$S^3 = \{(z_1, z_2) \in \mathbb{C}^2 : |z_1|^2 + |z_2|^2 = 1\},$$

and identify $\mathbb{R}^3$ with $\mathbb{C} \times \mathbb{R}$. The **Hopf map** is

$$h : S^3 \longrightarrow \mathbb{C} \times \mathbb{R}, \quad h(z_1, z_2) = (2z_1\overline{z_2}, |z_1|^2 - |z_2|^2).$$

Theorem 11.11: Structure of the Hopf fibration. The map h of Definition 11.4 has the following properties.

- (i) $h(S^3) \subseteq S^2$, that is $|h(z_1, z_2)| = 1$ at every point of S^3 .
- (ii) h is onto S^2 .
- (iii) For every $(z_1, z_2) \in S^3$,

$$h^{-1}(h(z_1, z_2)) = \{(\lambda z_1, \lambda z_2) : \lambda \in \mathbb{C}, |\lambda| = 1\},$$

and this set is a **great circle** of S^3 .

In particular S^3 is the disjoint union of a family of great circles parametrised by S^2 .

Proof. (i). With $a = |z_1|^2$ and $b = |z_2|^2$, and using $|2z_1\bar{z}_2|^2 = 4|z_1|^2|z_2|^2 = 4ab$,

$$|h(z_1, z_2)|^2 = 4ab + (a - b)^2 = a^2 + 2ab + b^2 = (a + b)^2 = 1,$$

because $a + b = 1$ on the sphere.

(ii). Let $(w, t) \in S^2$, that is $w \in \mathbb{C}$, $t \in \mathbb{R}$, $|w|^2 + t^2 = 1$; in particular $|t| \leq 1$. Put

$$z_1 = \sqrt{\frac{1+t}{2}}, \quad z_2 = \sqrt{\frac{1-t}{2}} e^{-i \arg w}$$

($\arg w$ chosen arbitrarily if $w = 0$, in which case one of the factors $\sqrt{(1-t)/2}$, $\sqrt{(1+t)/2}$ vanishes). Then $|z_1|^2 + |z_2|^2 = \frac{1+t}{2} + \frac{1-t}{2} = 1$, so $(z_1, z_2) \in S^3$, and

$$|z_1|^2 - |z_2|^2 = t, \quad 2z_1\bar{z}_2 = 2\sqrt{\frac{1+t}{2}}\sqrt{\frac{1-t}{2}} e^{i \arg w} = \sqrt{1-t^2} e^{i \arg w} = |w| e^{i \arg w} = w,$$

where $|w| = \sqrt{1-t^2}$ has been used. Hence $h(z_1, z_2) = (w, t)$.

(iii), inclusion $\supseteq$. If $|\lambda| = 1$ then $|\lambda z_k| = |z_k|$, so the second component does not change; and

$$2(\lambda z_1)(\overline{\lambda z_2}) = 2\lambda\bar{\lambda} z_1\bar{z}_2 = 2|\lambda|^2 z_1\bar{z}_2 = 2z_1\bar{z}_2,$$

so neither does the first.

(iii), inclusion $\subseteq$. Let $h(w_1, w_2) = h(z_1, z_2)$. From equality of the second components, $|w_1|^2 - |w_2|^2 = |z_1|^2 - |z_2|^2$, and from $|w_1|^2 + |w_2|^2 = |z_1|^2 + |z_2|^2 = 1$ it follows that

$$|w_1| = |z_1|, \quad |w_2| = |z_2|.$$

If $z_1 = 0$ then $|z_2| = 1$, $w_1 = 0$ and $|w_2| = 1$: setting $\lambda = w_2/z_2$ one has $|\lambda| = 1$ and $(w_1, w_2) = \lambda(z_1, z_2)$. The case $z_2 = 0$ is symmetric. Finally, if $z_1, z_2 \neq 0$, write $w_1 = \lambda_1 z_1$ and $w_2 = \lambda_2 z_2$ with $|\lambda_1| = |\lambda_2| = 1$; equality of the first components gives

$$2\lambda_1\bar{\lambda}_2 z_1\bar{z}_2 = 2z_1\bar{z}_2 \implies \lambda_1\bar{\lambda}_2 = 1,$$

having divided by $z_1\bar{z}_2 \neq 0$. Since $|\lambda_2| = 1$ one has $\bar{\lambda}_2 = 1/\lambda_2$, hence $\lambda_1/\lambda_2 = 1$, that is $\lambda_1 = \lambda_2 =: \lambda$.

(iii), the fibre is a great circle. Put $v = (z_1, z_2)$ and $v' = (iz_1, iz_2)$; both have Euclidean norm 1 in $\mathbb{R}^4$, and they are orthogonal:

$$\langle v, v' \rangle_{\mathbb{R}} = \operatorname{Re}(\bar{z}_1 iz_1 + \bar{z}_2 iz_2) = \operatorname{Re}(i(|z_1|^2 + |z_2|^2)) = \operatorname{Re}(i) = 0.$$

Writing $\lambda = \cos \alpha + i \sin \alpha$ one has $\lambda v = (\cos \alpha) v + (\sin \alpha) v'$: the fibre is therefore the intersection of S^3 with the two-dimensional plane $\operatorname{span}_{\mathbb{R}}\{v, v'\}$ through the origin, that is a great circle of radius 1.

Conclusion. The fibres of a map are pairwise disjoint and cover the domain; by (ii) the index set is the whole of S^2 . $\square$

Remark 11.5: The same fibration, in quaternionic language. Remark 11.4 described the same construction with quaternions: $q \mapsto q i \bar{q}$, that is the axis of the rotation Φ_q . The two descriptions agree. Indeed, identify $\mathbb{H}$ with $\mathbb{C}^2$ by $q = z_1 + j z_2$; then, for $\lambda = e^{i\alpha}$,

$$q \lambda = z_1 \lambda + j z_2 \lambda,$$

that is, multiplication on the right by λ acts on the coordinates as $(z_1, z_2) \mapsto (\lambda z_1, \lambda z_2)$: exactly the fibres of Theorem 11.11(iii).

That $q \mapsto q i \bar{q}$ is constant on those fibres is immediate, because λ commutes with i (both lie in the copy of $\mathbb{C}$ generated by 1 and i):

$$(q \lambda) i \overline{(q \lambda)} = q \lambda i \bar{\lambda} \bar{q} = q i \bar{\lambda} \bar{q} = q i \bar{q}.$$

Conversely, if $q i \bar{q} = q' i \bar{q}'$, setting $p = \bar{q}' q$ (of norm 1) one gets $p i \bar{p} = i$, that is p commutes with i ; but the unit quaternions commuting with i are exactly those of the form $e^{i\alpha}$, hence $q = q' e^{i\alpha}$. The two maps therefore have the same fibres, and define the same partition of S^3 into circles.

Example 11.3: Two linked fibres, checked by stereographic projection. The two simplest fibres are

$$F_+ = h^{-1}(0, 0, 1) = \{(e^{i\theta}, 0)\}, \quad F_- = h^{-1}(0, 0, -1) = \{(0, e^{i\theta})\},$$

as one checks by putting $t = \pm 1$ in the proof of (ii). They are disjoint, because $|z_1|$ equals 1 on the first and 0 on the second. We show that they are *linked*.

Stereographic projection. In real coordinates (x_1, y_1, x_2, y_2) project S^3 from $N = (0, 0, 0, 1)$, that is from the point $(z_1, z_2) = (0, i)$, which belongs to F_- :

$$\sigma(x_1, y_1, x_2, y_2) = \frac{(x_1, y_1, x_2)}{1 - y_2} \in \mathbb{R}^3.$$

Image of F_+ . Its points are $(\cos \theta, \sin \theta, 0, 0)$, with $y_2 = 0$, hence

$$\sigma(F_+) = \{(\cos \theta, \sin \theta, 0)\} :$$

the **unit circle** of the plane $z = 0$.

Image of F_- . Its points are $(0, 0, \cos \theta, \sin \theta)$, and

$$\sigma(0, 0, \cos \theta, \sin \theta) = \left(0, 0, \frac{\cos \theta}{1 - \sin \theta}\right).$$

As θ ranges over $[0, 2\pi)$ excluding $\theta = \pi/2$ (which is the pole N), the quantity $u(\theta) = \cos \theta / (1 - \sin \theta)$ takes every real value exactly once: it is continuous, equals 1 at $\theta = 0$, 0 at $\theta = -\pi/2$, -1 at $\theta = \pi$, and tends to $\pm\infty$ as $\theta \rightarrow \pi/2^\mp$. Hence

$$\sigma(F_-) = \{(0, 0, u) : u \in \mathbb{R}\} :$$

the whole **z axis**.

Linking. The unit circle of the plane $z = 0$ bounds the disc $D = \{x^2 + y^2 \leq 1, z = 0\}$; the z axis meets D at a single point, the origin, and crosses it transversally. A circle and a closed curve that pierces its disc exactly once are linked, with linking number ± 1 : the two fibres cannot be separated without cutting one of them. (The z axis, closed up by the point at infinity, is the image circle of F_- : stereographic projection sends circles of S^3 through the pole to lines of $\mathbb{R}^3$.)

Why it holds for every pair. The linking number of two disjoint closed curves is an integer that does not change when the curves are deformed continuously while remaining disjoint. Now, ordered pairs of distinct fibres are parametrised by ordered pairs of distinct points of S^2 (Theorem 11.11), and that set is *connected*: from a pair (P, Q) with $P \neq Q$ one reaches continuously any other pair (P', Q') with $P' \neq Q'$, moving first Q and then P without ever letting them coincide. The linking number, an integer-valued continuous function on a connected set, is therefore constant, and equals ± 1 everywhere because it equals ± 1 on the pair (F_+, F_-) : *any two distinct fibres are linked.*

Remark 11.6: What remains imported. *The construction above is complete and uses no algebraic topology. What remains imported is only the statement quoted in Remark 11.4: that S^0 , S^1 and S^3 are the only spheres carrying a Lie group structure. That is a classification, and classifications are not proved by exhibiting examples: they require the theory of Steenrod operations and K-theory, developed by Bott, Milnor and Adams between 1958 and 1960. There is exactly one further case in which the multiplication exists but is not associative, S^7 with the octonions, and that too falls under the same classification.*

What has been proved here is the other half of the picture: that the circle, that is S^1 , is not merely a group, but the group that fibres S^3 over S^2 — and that is the structural reason why the circle reappears in dimension three.

11.8. Industrial applications

High dimension in robotic perception. The vision systems and sensors of modern robots (FANUC iRVision, Yaskawa MotoSight, cells with deep learning) operate on high-dimensional feature spaces. Concentration of measure (Theorems 11.4 and 11.6) implies that, as the dimension increases, Euclidean distances lose contrast and nearest-neighbour methods degrade: the choice to reduce the dimension (PCA, learned embeddings) or to normalize the data on the sphere S^{n-1} is a direct consequence of the geometry of this chapter. Planning in the configuration space of a robot with many joints also lives in high dimension, with the same counterintuitive effects on volumes: the “useful” volume of the free space is an infinitesimal fraction of the cube of joint limits (Theorem 11.2, Step 3), and sampling-based planners are designed precisely so as not to have to explore it.

Quaternions in attitude control. The double covering $S^3 \rightarrow SO(3)$ (Theorem 11.10(iv)) is the reason why the attitude control systems of drones, satellites and robotic wrists represent orientation with unit quaternions rather than with Euler angles: the parametrization is free of singularities (no *gimbal lock*), composition costs sixteen multiplications instead of twenty-seven, and normalization to $\|q\| = 1$ corrects numerical drift. The price is the sign ambiguity $q \leftrightarrow -q$, which must be handled explicitly in interpolation algorithms (Chapter 30).

11.9. Assigned exercises

Exercise 11.4. Objective: handle the recurrence of the Gamma function and that of the volumes. **Estimated time:** 15 minutes.

- (i) Compute V_9 , Σ_8 , V_{12} and Σ_{11} with the recurrence $V_n = \frac{2\pi}{n} V_{n-2}$ starting from $V_7 = 4.724766$ and $V_{10} = 2.550164$, and check with the closed formula of Theorem 11.1. (ii) Determine the smallest dimension n for which V_n is less than $V_1 = 2$, that is than the volume of the segment $[-1, 1]$. (iii) Explain, without computing, why the maximum of Σ_{n-1} falls one dimension farther than the maximum of V_n .

Exercise 11.5. Objective: compare two concentration estimates on the same datum. **Estimated time:** 25 minutes.

One wants to guarantee that at most 1% of the surface of S^{n-1} has $|x_1| \geq 0.05$. (i) Which dimension does Chebyshev's estimate of Theorem 11.4 require? (ii) Which dimension does the exponential estimate of Theorem 11.5 require? (Proceed by ordered trials or by bisection.) (iii) Comment on the ratio between the two dimensions and say which of the two statements is "wrong".

Exercise 11.6. Objective: pass from a pair of directions to the quaternion and to the matrix. **Estimated time:** 30 minutes.

One wants to bring the direction $a = (1, 1, 1)/\sqrt{3}$ onto the direction $b = (0, 0, 1)$ with the rotation of smallest angle. (i) Determine the axis and the angle of that rotation. (ii) Write the corresponding unit quaternion (Theorem 11.10(iii)). (iii) Write the matrix R with Rodrigues' formula (Exercise S5) and check $\text{tr } R = 1 + 2 \cos \vartheta$ and $Ra = b$.

11.10. Worked exercises

Exercise 11.7. For $\varepsilon = 0.01$ compute the fraction of the volume of B^n contained in the outer shell for $n = 2, 10, 100, 1000$, and determine the smallest dimension for which it exceeds 99%. Compare with the fraction of surface that the exponential estimate guarantees in the equatorial band.

Solution. Strategy. The formula of Theorem 11.6 is exact and does not require V_n : it suffices to raise to a power. The threshold is obtained by inverting the logarithm, and must then be rounded *up to the next integer* because the fraction grows with n .

Step 1 — the four values.

n	0.99^n	fraction of the shell	
2	0.980100	0.019900	(plane intuition)
10	0.904382	0.095618	
100	0.366032	0.633968	
1000	0.0000432	0.999957	

Step 2 — the threshold. One needs $0.99^n \leq 0.01$, that is

$$n \geq \frac{\ln(0.01)}{\ln(0.99)} = \frac{-4.605170}{-0.010050} = 458.2106,$$

hence $n = 459$.

Step 3 — independent check. Computing directly the two powers close to the threshold: $0.99^{458} = 0.010021 > 0.01$ (fraction of the shell 0.989979, below 99%) and $0.99^{459} = 0.009921 < 0.01$ (fraction 0.990079, above). ✓ The integer threshold is therefore 459, and rounding up was the right choice.

Step 4 — the comparison with the surface. The exponential estimate of Theorem 11.5 with $\varepsilon = 0.1$ and $n = 459$ gives

$$\sigma(|x_1| \geq 0.1) \leq \frac{\sqrt{e}}{0.1 \times \sqrt{458}} e^{-458 \times 0.005} = \frac{1.648721}{2.140093} \times e^{-2.29} = 0.770397 \times 0.101266 = 0.078015,$$

that is, less than 8% of the surface lies outside the equatorial band of half-width 0.1. In dimension 459, therefore, *both* phenomena are already clearly visible: the volume is all on the skin and the surface is all at the equator.

Interpretation. The two statements say different but congruent things. The first concerns the *radius*: almost no point of the ball is interior. The second concerns the *direction*: almost no point of the sphere is close to a prescribed pole. Together: a uniform point in B^n has norm close to 1 and direction almost orthogonal to any direction fixed in advance.

Typical errors. (a) Rounding the threshold 458.21 down: the inequality is satisfied by $n \geq 459$, not by 458. (b) Believing that the fraction depends on V_n : the constant cancels (Step 2 of the proof). (c) Applying the formula with ε expressed as a percentage (1 instead of 0.01).

Extension. With $\varepsilon = 0.001$ the threshold becomes $\ln(100)/(-\ln(0.999)) = 4.605170/0.00100050 = 4602.87$, that is $n = 4603$ (and indeed $0.999^{4603} = 0.0099987 < 0.01 < 0.0100087 = 0.999^{4602}$): ten times less thickness, ten times more dimension. The dependence is essentially inverse, as the formula of Step 4 of the proof shows, because $-\ln(1 - \varepsilon) \simeq \varepsilon$ for small ε .

Exercise 11.8. Decompose explicitly into two reflections the rotation of $\mathbb{R}^3$ with matrix

$$R = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix},$$

following the construction of the proof of Theorem 11.9, and check that the angle of rotation is twice the dihedral angle between the two planes.

Solution. Strategy. The proof of Theorem 11.9 is constructive: one chooses a vector v that is not fixed, reflects with respect to the hyperplane orthogonal to $Rv - v$, and observes that the product fixes a larger subspace. Here the construction closes in two steps because $\det R = +1$.

Step 1 — the first reflection. Take $v = e_1 = (1, 0, 0)$; then $Rv = (0, 1, 0) \neq v$ and

$$m_1 = \frac{Rv - v}{\|Rv - v\|} = \frac{(-1, 1, 0)}{\sqrt{2}}.$$

The reflection $S_1(x) = x - 2\langle x, m_1 \rangle m_1$ has matrix

$$S_1 = I - 2m_1 m_1^\top = I - \begin{pmatrix} 1 & -1 & 0 \\ -1 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

that is, the exchange of the first two coordinates: it is the reflection in the plane $x = y$.

Step 2 — the product.

$$S_1 R = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix},$$

which is the reflection S_2 in the plane $y = z$, with normal $m_2 = (0, 1, -1)/\sqrt{2}$. Indeed $\det(S_1 R) = -1$, $(S_1 R)^2 = I$ and $S_1 R$ fixes e_1 and $(0, 1, 1)$.

Step 3 — the decomposition. Since $S_1^2 = I$,

$$R = S_1 (S_1 R) = S_{m_1} S_{m_2}, \quad m_1 = \frac{(-1, 1, 0)}{\sqrt{2}}, \quad m_2 = \frac{(0, 1, -1)}{\sqrt{2}}.$$

They are two reflections, as Theorem 11.9 guarantees for an element of $SO(3)$ different from the identity.

Step 4 — the axis. The two planes are $x = y$ and $y = z$; their intersection is the line $x = y = z$, that is the axis $(1, 1, 1)/\sqrt{3}$, which both reflections fix pointwise. It is the axis of Theorem 11.8, recovered without computing eigenvectors.

Step 5 — independent check of the angle. The dihedral angle between the two planes has cosine $\langle m_1, m_2 \rangle = (0 \cdot (-1) + 1 \cdot 1 + 0 \cdot (-1))/2 = 0.5$, that is 60° . Twice that is 120° . On the other hand $\text{tr } R = 0$ and Theorem 11.8 gives $1 + 2 \cos \vartheta = 0$, that is $\cos \vartheta = -0.5$ and $\vartheta = 120^\circ$. ✓ The two computations, independent, agree.

Interpretation. The composition of two reflections in incident planes is always a rotation about the line of intersection, of angle twice the dihedral one (Exercise S4). Here the rotation permutes the coordinate axes cyclically: it is the symmetry of the cube exchanging $x \rightarrow y \rightarrow z \rightarrow x$.

Typical errors. (a) Using $m_1 = Rv + v$ instead of $Rv - v$: one obtains a reflection that does not bring Rv back to v . (b) Forgetting to normalize m : the formula $x - 2\langle x, m \rangle m$ holds only for $\|m\| = 1$. (c) Concluding that the angle of rotation equals the dihedral one rather than twice it.

Extension. Repeat with $v = e_2$: one finds $m'_1 = (0, -1, 1)/\sqrt{2}$ and a second decomposition, different from the first. The decomposition into reflections is not unique — only their *minimal number* is.

Exercise 11.9. Compute V_{100} and the ratio $V_{100}/2^{100}$ between the unit ball and the circumscribed cube $[-1, 1]^{100}$; compare the exact value with Stirling's approximation of Theorem 11.2.

Solution. Strategy. The number is too small for an ordinary calculator: one works with decimal logarithms, and checks the result with the asymptotic formula, which is independent of the exact computation.

Step 1 — the exact value in logarithms. By Theorem 11.1, $V_{100} = \pi^{50}/\Gamma(51) = \pi^{50}/50!$, hence

$$\log_{10} V_{100} = 50 \log_{10} \pi - \log_{10}(50!) = 50 \times 0.4971499 - 64.483075 = 24.857495 - 64.483075 = -39.625580,$$

that is $V_{100} = 2.368202 \cdot 10^{-40}$.

Step 2 — the comparison with the cube. $2^{100} = 1.267651 \cdot 10^{30}$, so

$$\frac{V_{100}}{2^{100}} = \frac{2.368202 \cdot 10^{-40}}{1.267651 \cdot 10^{30}} = 1.868182 \cdot 10^{-70}.$$

The circumscribed cube has a volume 10^{70} times that of the inscribed ball touching all its faces.

Step 3 — independent check with Stirling. Step 2 of the proof of Theorem 11.2 gives $V_n \sim \frac{1}{\sqrt{\pi n}} \left(\frac{2\pi e}{n}\right)^{n/2}$. With $n = 100$: $2\pi e = 17.079469$, hence $2\pi e/n = 0.17079469$ and

$$\log_{10} V_{100} \simeq -\frac{1}{2} \log_{10}(100\pi) + 50 \log_{10}(0.17079469) = -1.248575 - 38.376283 = -39.624858,$$

that is $2.372152 \cdot 10^{-40}$. The ratio between the estimate and the exact value is 1.001668: a deviation of 0.17%, exactly the order $1/(12 \cdot 50) = 0.001667$ of the first correction term of Stirling. ✓

Interpretation. Theorem 11.3 says that in dimension ≥ 10 the central ball tangent to the 2^n inscribed balls *sticks out* of the cube; this exercise says that nevertheless the cube remains incomparably larger. The two facts coexist because the volume of the cube, in high dimension, is all in the corners, and the corners are $2^{100} \approx 1.27 \cdot 10^{30}$.

Typical errors. (a) Using $\Gamma(50)$ instead of $\Gamma(51)$: the formula is $\Gamma(n/2 + 1)$. (b) Applying Stirling to $\Gamma(n/2)$ and then forgetting the factor $n/2$. (c) Computing π^{50} in single-precision floating point: every significant digit is lost.

Extension. For which n does the ratio $V_n/2^n$ fall below 10^{-100} ? The exact computation gives $n = 133$ (ratio $2.373 \cdot 10^{-101}$) against $n = 132$ ($2.188 \cdot 10^{-100}$): between dimension 100 and dimension 133 the ratio loses another thirty orders of magnitude.

11.11. Numerical and symbolic exercises with solutions

The exercises that follow come from the treatment of the circle in higher dimension of Volume II and are reproduced in full, with their solutions; those on cones, spheres and quadrics are in Chapter 7.

11.11.1 Numerical exercises

Exercise 11.10: N1 — Volumes and surfaces in high dimension. Compute V_n and Σ_{n-1} for $n = 4$, $n = 6$ and $n = 11$, using $\Gamma(1/2) = \sqrt{\pi}$ and the recursion for the Gamma function.

Exercise 11.11: N2 — Ball versus cube. Compute the ratio $V_n/2^n$ between the volume of the unit ball and that of the circumscribed cube for $n = 3, 5, 8, 9, 20$, and find the least dimension for which the ratio drops below 1%.

Exercise 11.12: N3 — How much dimension to concentrate. Using Theorem 11.4, find the least dimension n for which the fraction of S^{n-1} with $|x_1| \geq 0.2$ is guaranteed $\leq 5\%$. Then evaluate the exponential bound of Theorem 11.5 for $n = 200$ and $n = 500$ and compare the two guarantees.

Exercise 11.13: N4 — The ball that leaves the cube. Compute r_n for $n = 4, 9, 10, 16, 100$ and, for $n = 16$, the ratio of the volume of the central ball to that of the cube.

Exercise 11.14: N5 — Axis and angle of a rotation. Determine the axis and angle of the rotation with matrix

$$R = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix},$$

checking that $R \in SO(3)$.

Exercise 11.15: N6 — Rotation with quaternions. Rotate the vector $(1, 0, 0)$ by 120° about the axis $(1, 1, 1)/\sqrt{3}$ using quaternions, and check the result with the matrix of Exercise N5.

11.11.2 Symbolic exercises

Exercise 11.16: S1 — Surface as the derivative of volume. Prove that $V_n(R) = V_n R^n$ and that $\Sigma_{n-1}(R) = \frac{d}{dR} V_n(R)$, deducing $\Sigma_{n-1} = nV_n$. Explain why the same relation holds for the circle ($2\pi R = \frac{d}{dR} \pi R^2$) but not for the square.

Exercise 11.17: S2 — The maximum of the volume. Prove rigorously that $\max_n V_n$ is attained at $n = 5$, and that Σ_{n-1} is maximal at $n = 7$.

Exercise 11.18: S3 — Nearly orthogonal points. Prove that $\int_{S^{n-1}} x_i x_j d\sigma = \delta_{ij}/n$ and deduce that two independent uniform points on S^{n-1} have scalar product of root mean square $1/\sqrt{n}$: in high dimension two random directions are almost always nearly orthogonal.

Exercise 11.19: S4 — Rotations as products of reflections. Prove that the composition of two reflections of $\mathbb{R}^3$ in planes through the origin is a rotation about their line of intersection, by twice the dihedral angle between the planes. Deduce another proof of Theorem 11.8.

Exercise 11.20: S5 — Rodrigues' formula. Deduce from Theorem 11.10 Rodrigues' formula

$$\Phi_q(v) = v \cos \vartheta + (u \times v) \sin \vartheta + u \langle u, v \rangle (1 - \cos \vartheta),$$

and verify it on Exercise N6.

11.11.3 Solutions to the numerical exercises

Solution. N1. *Step 1* — $n = 4$. $\Gamma(3) = 2! = 2$, hence

$$V_4 = \frac{\pi^2}{\Gamma(3)} = \frac{9.869604}{2} = 4.934802, \quad \Sigma_3 = 4V_4 = 19.739209 = 2\pi^2.$$

Step 2 — $n = 6$. $\Gamma(4) = 3! = 6$, hence

$$V_6 = \frac{\pi^3}{6} = \frac{31.006277}{6} = 5.167713, \quad \Sigma_5 = 6V_6 = 31.006277 = \pi^3.$$

Step 3 — $n = 11$. We need $\Gamma(13/2)$. Using $\Gamma(t+1) = t\Gamma(t)$ repeatedly from $\Gamma(1/2) = \sqrt{\pi} = 1.7724539$:

$$\Gamma\left(\frac{13}{2}\right) = \frac{11}{2} \cdot \frac{9}{2} \cdot \frac{7}{2} \cdot \frac{5}{2} \cdot \frac{3}{2} \cdot \frac{1}{2} \cdot \sqrt{\pi} = 162.421875 \times 1.7724539 = 287.8853.$$

Step 4 — *the volume*. $\pi^{11/2} = \pi^5 \sqrt{\pi} = 306.019685 \times 1.7724539 = 542.3989$, hence

$$V_{11} = \frac{542.3989}{287.8853} = 1.884104, \quad \Sigma_{10} = 11V_{11} = 20.725145.$$

Step 5 — *check with the recursion*. $V_{11} = \frac{2\pi}{11}V_9$. Now $V_9 = 3.298509$ (from the table of Example 11.1), and

$$\frac{2\pi}{11} \times 3.298509 = 0.571199 \times 3.298509 = 1.884103. \checkmark$$

Step 6 — *reading*. Already in dimension 11 the unit ball has smaller volume than the segment $[-1, 1]$ ($V_1 = 2$): the volume has more than halved from the maximum $V_5 = 5.264$.

Solution. N2. *Step 1* — *the ratios*.

n	V_n	2^n	$V_n/2^n$	in %
3	4.18879	8	0.523599	52.36%
5	5.26379	32	0.164493	16.45%
8	4.05871	256	0.015854	1.585%
9	3.29851	512	0.006442	0.644%
20	0.025807	1 048 576	2.461×10^{-8}	0.0000025%

Step 2 — *the 1% threshold*. The ratio first drops below 0.01 at $n = 9$: at $n = 8$ it is $1.585\% > 1\%$ and at $n = 9$ it is $0.644\% < 1\%$.

Step 3 — *check of V_9* . By the recursion, $V_9 = \frac{2\pi}{9}V_7 = 0.698132 \times 4.724766 = 3.298509$. $\checkmark$

Step 4 — *reading*. Already in dimension nine the inscribed ball occupies less than one per cent of the cube containing it, while touching all 18 of its faces. This is Theorem 11.2 in numerical form.

Step 5 — *a practical consequence*. In Monte Carlo methods, generating uniform points in the ball by rejection (drawing in the cube and discarding those outside the ball) is workable in dimension 2 or 3 but useless in dimension 20: it would take on average 4×10^7 trials per accepted point. Direct methods are used instead, such as normalising a Gaussian vector (Exercise S3).

Solution. N3. *Step 1* — *Chebyshev bound*. Theorem 11.4 gives

$$\sigma(|x_1| \geq \varepsilon) \leq \frac{1}{n\varepsilon^2}.$$

With $\varepsilon = 0.2$, $\varepsilon^2 = 0.04$:

$$\frac{1}{0.04n} \leq 0.05 \iff n \geq \frac{1}{0.04 \times 0.05} = 500.$$

Step 2 — the exponential bound. By Theorem 11.5, with $\varepsilon = 0.2$,

$$B(n) = \frac{\sqrt{e}}{0.2\sqrt{n-1}} e^{-0.02(n-1)} = \frac{8.243606}{\sqrt{n-1}} e^{-0.02(n-1)}.$$

Step 3 — evaluation at $n = 200$. With $n - 1 = 199$ and $\sqrt{199} = 14.106736$:

$$B(200) = \frac{8.243606}{14.106736} \times e^{-3.98} = 0.584374 \times 0.018686 = 0.010920,$$

that is 1.09%, against the 12.5% given by Chebyshev at the same dimension ($1/(200 \times 0.04) = 0.125$): a factor of 11.

Step 4 — evaluation at $n = 500$. With $n - 1 = 499$ and $\sqrt{499} = 22.338308$:

$$B(500) = \frac{8.243606}{22.338308} \times e^{-9.98} = 0.369014 \times 4.6317 \times 10^{-5} = 1.709 \times 10^{-5},$$

that is 0.0017%, against Chebyshev's 5%: a factor of nearly 3000.

Step 5 — reading the comparison. The two bounds say qualitatively different things: Chebyshev decays like $1/n$, the exponential bound like $e^{-n\varepsilon^2/2}$. At the dimension where Chebyshev barely reaches 5%, the exponential one has already dropped below two parts in a hundred thousand. This is why, in high dimension, one designs with exponential inequalities and not with moments.

Step 6 — order of magnitude. In both cases a few hundred dimensions suffice for 95% of the sphere to lie in a band of width 0.4 about the equator, a fifth of the diameter. In the plane ($n = 2$) the same band contains only $2 \arcsin(0.2)/\pi = 12.8\%$ of the circle.

Solution. N4. *Step 1 — the formula.* By Theorem 11.3, $r_n = \frac{\sqrt{n}-1}{2}$.

Step 2 — the values.

n	$\sqrt{n}$	r_n	comparison with inradius 1
4	2.000000	0.500000	inside
9	3.000000	1.000000	tangent to the faces
10	3.162278	1.081139	sticks out
16	4.000000	1.500000	sticks well out
100	10.000000	4.500000	sticks out 4.5-fold

Step 3 — relative volume for $n = 16$. We have $V_{16} = \pi^8/\Gamma(9) = 9488.5310/40\,320 = 0.2353306$ and

$$r_{16}^{16} = 1.5^{16} = 656.8408,$$

so the volume of the central ball is

$$V_{16} r_{16}^{16} = 0.2353306 \times 656.8408 = 154.582.$$

Step 4 — comparison with the cube. The cube $[-1, 1]^{16}$ has volume $2^{16} = 65\,536$, hence

$$\frac{154.582}{65\,536} = 0.0023588 = 0.236\%.$$

Step 5 — the paradox, resolved. The central ball *leaves* the cube and yet occupies barely two parts per thousand of it. There is no contradiction: it protrudes only through the 32

faces, and by a tiny amount, while the enormous volume of the cube remains concentrated in its 65 536 corners. ✓

Step 6 — check of 1.5^{16} . $1.5^2 = 2.25$; $1.5^4 = 5.0625$; $1.5^8 = 25.628906$; $1.5^{16} = 25.628906^2 = 656.8408$. ✓

Solution. N5. *Step 1 — checking $R \in SO(3)$.* The columns of R are $(0, 1, 0)$, $(0, 0, 1)$, $(1, 0, 0)$: the three basis unit vectors, hence orthonormal, and $R^\top R = I$. The determinant of a cyclic permutation of three elements is $+1$ (the permutation is even). Hence $R \in SO(3)$.

Step 2 — angle from the trace. $\text{tr } R = 0 + 0 + 0 = 0$, and by Theorem 11.8

$$1 + 2 \cos \vartheta = 0 \implies \cos \vartheta = -\frac{1}{2} \implies \vartheta = 120^\circ.$$

Step 3 — axis. We seek u with $Ru = u$. With $u = (u_1, u_2, u_3)$:

$$Ru = (u_3, u_1, u_2) = (u_1, u_2, u_3) \implies u_1 = u_2 = u_3.$$

Normalising, $u = (1, 1, 1)/\sqrt{3}$.

Step 4 — verification. $R(1, 1, 1)^\top = (1, 1, 1)^\top$ ✓. And for a vector orthogonal to the axis, say $w = (1, -1, 0)$: $Rw = (0, 1, -1)$, of the same norm $\sqrt{2}$, making with w an angle of cosine

$$\frac{\langle w, Rw \rangle}{\|w\|^2} = \frac{0 - 1 + 0}{2} = -\frac{1}{2} = \cos 120^\circ. \quad \checkmark$$

Step 5 — interpretation. R cyclically permutes the coordinate axes $x \rightarrow y \rightarrow z \rightarrow x$: it is the rotation by 120° about the cube diagonal, the same met in Example 11.2. Applying it three times gives $R^3 = I$, consistent with $3 \times 120^\circ = 360^\circ$. ✓

Solution. N6. *Step 1 — the quaternion.* By Theorem 11.10(iii) with $\vartheta = 120^\circ$ and $u = (i + j + k)/\sqrt{3}$:

$$q = \cos 60^\circ + \sin 60^\circ \cdot \frac{i + j + k}{\sqrt{3}} = 0.5 + 0.866025 \times 0.577350 (i + j + k) = 0.5(1 + i + j + k),$$

since $0.866025 \times 0.577350 = 0.5$.

Step 2 — conjugate and norm. $\bar{q} = 0.5(1 - i - j - k)$ and $\|q\|^2 = 4 \times 0.25 = 1$. ✓

Step 3 — first product. With $v = i$ (the vector $(1, 0, 0)$):

$$qv = 0.5(1 + i + j + k)i = 0.5(i + i^2 + ji + ki) = 0.5(i - 1 - k + j),$$

using $i^2 = -1$, $ji = -k$, $ki = j$.

Step 4 — second product. Multiplying by $\bar{q}$:

$$\Phi_q(i) = 0.5(-1 + i + j - k) \cdot 0.5(1 - i - j - k) = 0.25 X,$$

and expanding X term by term:

$$-1 \cdot (1 - i - j - k) = -1 + i + j + k,$$

$$i \cdot (1 - i - j - k) = i + 1 - k + j,$$

$$j \cdot (1 - i - j - k) = j + k + 1 - i,$$

$$-k \cdot (1 - i - j - k) = -k + j - i - 1.$$

Summing componentwise: real part $-1 + 1 + 1 - 1 = 0$; coefficient of i : $1 + 1 - 1 - 1 = 0$; coefficient of j : $1 + 1 + 1 + 1 = 4$; coefficient of k : $1 - 1 + 1 - 1 = 0$. Hence

$$\Phi_q(i) = 0.25 \times 4j = j.$$

Step 5 — result. The vector $(1, 0, 0)$ rotates to $(0, 1, 0)$.

Step 6 — check with the matrix. The rotation of Exercise N5 has the same axis and angle, and

$$R \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} = \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix}. \quad \checkmark$$

Step 7 — norm check. $\|\Phi_q(i)\| = \|j\| = 1 = \|i\|$, as guaranteed by Theorem 11.10(i). $\checkmark$

Step 8 — comparison of methods. The quaternion computation required two multiplications; the matrix one requires building the 3×3 matrix and a matrix–vector product. For repeated compositions the advantage of quaternions grows: four numbers instead of nine, no drift away from orthogonality, and natural interpolation between orientations. That is why inertial navigation systems and three-dimensional graphics use quaternions and not matrices.

11.11.4 Solutions to the symbolic exercises

Solution. S1. *Step 1 — homogeneity of volume.* The map $x \mapsto Rx$ is linear with matrix RI , of determinant R^n ; since Lebesgue volume transforms by the absolute value of the determinant,

$$\text{vol}(B^n(0, R)) = R^n \text{vol}(B^n) = V_n R^n.$$

Step 2 — the derivative.

$$\frac{d}{dR} V_n(R) = nV_n R^{n-1}.$$

Step 3 — comparison with the area. By Theorem 11.1, $\Sigma_{n-1}(R) = \Sigma_{n-1} R^{n-1} = nV_n R^{n-1}$; it coincides with the derivative. Setting $R = 1$ gives $\Sigma_{n-1} = nV_n$.

Step 4 — why it is true. Geometrically: increasing the radius by dR adds a shell of thickness dR and surface $\Sigma_{n-1}(R)$, hence of volume $\Sigma_{n-1}(R) dR$. The relation $dV = \Sigma dR$ requires, however, that the increment be made *orthogonally to the boundary and with uniform thickness*: this is the construction of the *parallel body*.

Step 5 — why it fails for the square, if one scales. For the square of side s , area s^2 and perimeter $4s$, the derivative of the area with respect to s is $2s \neq 4s$. The reason is that the scaling $s \mapsto s + ds$ enlarges the square from the *centre*, adding a thickness $ds/2$ on each side, not ds .

Step 6 — the correct formulation. If one parametrises by the inradius $R = s/2$, the area is $4R^2$ and the perimeter $8R = \frac{d}{dR}(4R^2)$: the relation holds again. In general, for an arbitrary convex body the correct formula is Steiner's (Exercise S1 of Chapter 2): $A_d = A + Ld + \pi d^2$, whence $\frac{dA_d}{dd}|_{d=0} = L$. The ball is the case in which the parallel body coincides with a scaling, and for it alone the two operations are the same.

Solution. S2. *Step 1 — monotonicity along parities.* By Theorem 11.1, $V_n = \frac{2\pi}{n} V_{n-2}$, hence

$$V_n > V_{n-2} \iff \frac{2\pi}{n} > 1 \iff n < 2\pi = 6.283185.$$

Step 2 — the two subsequences. Among odd indices: $V_1 < V_3 < V_5$ (since $3, 5 < 2\pi$) and $V_5 > V_7 > V_9 > \dots$ (since $7, 9, \dots > 2\pi$). So the odd maximum is V_5 . Among even indices:

$V_2 < V_4 < V_6$ and $V_6 > V_8 > \dots$: the even maximum is V_6 .

Step 3 — final comparison.

$$V_5 = \frac{8\pi^2}{15} = 5.263789, \quad V_6 = \frac{\pi^3}{6} = 5.167713.$$

Since $V_5 > V_6$, the global maximum is V_5 , in dimension 5.

Step 4 — the area. With $\Sigma_{n-1} = nV_n$,

$$\frac{\Sigma_{n-1}}{\Sigma_{n-3}} = \frac{nV_n}{(n-2)V_{n-2}} = \frac{n}{n-2} \cdot \frac{2\pi}{n} = \frac{2\pi}{n-2},$$

greater than 1 if and only if $n < 2 + 2\pi = 8.283185$.

Step 5 — conclusion for the area. Among odd indices the maximum is at $n = 7$, among even ones at $n = 8$. Comparing:

$$\Sigma_6 = 7V_7 = 7 \times 4.724766 = 33.073362, \quad \Sigma_7 = 8V_8 = 8 \times 4.058712 = 32.469697.$$

So the maximum is at $n = 7$, i.e. for the sphere $S^6 \subset \mathbb{R}^7$. ✓

Step 6 — reading. That the volume is maximal in dimension 5 and the area in dimension 7 has no deep meaning: it depends on the normalisation to radius 1, which compares quantities with different units (m^5 against m^6). What matters, and is invariant, is the asymptotic behaviour: both tend to zero.

Solution. S3. *Step 1 — off-diagonal terms.* For $i \neq j$, the reflection $x_i \mapsto -x_i$ (fixing the other coordinates) is an isometry of $\mathbb{R}^n$ preserving S^{n-1} and the measure σ . Under it the integrand $x_i x_j$ changes sign, hence

$$\int x_i x_j d\sigma = - \int x_i x_j d\sigma \implies \int x_i x_j d\sigma = 0.$$

Step 2 — diagonal terms. These are Step 2 of the proof of Theorem 11.4: they equal $1/n$. In sum,

$$\int_{S^{n-1}} x_i x_j d\sigma = \frac{\delta_{ij}}{n}.$$

Step 3 — two independent points. Let X, Y be independent and uniform on S^{n-1} . Then

$$\mathbb{E}[\langle X, Y \rangle^2] = \mathbb{E} \left[\sum_{i,j} X_i X_j Y_i Y_j \right] = \sum_{i,j} \mathbb{E}[X_i X_j] \mathbb{E}[Y_i Y_j],$$

by independence. By Step 2 the sum reduces to the terms $i = j$:

$$\mathbb{E}[\langle X, Y \rangle^2] = \sum_{i=1}^n \frac{1}{n} \cdot \frac{1}{n} = \frac{1}{n}.$$

Step 4 — reading. The cosine of the angle between two random directions has root mean square $1/\sqrt{n}$: in dimension 10 000 two random directions typically make an angle of

$$\arccos(0.01) = 89.43^\circ,$$

i.e. they are nearly orthogonal. In the plane, by contrast, the cosine has root mean square $1/\sqrt{2} = 0.707$ and the typical angle is 45° .

Step 5 — consequence. In high dimension one can find very many *nearly* orthogonal vectors — exponentially many in n — although at most n can be exactly so. This is what makes

spread-spectrum codes, random compression (the Johnson–Lindenstrauss lemma) and distributed representations in machine learning possible.

Step 6 — how to generate uniform points. If Z is a standard Gaussian vector of $\mathbb{R}^n$, its density $e^{-\|z\|^2/2}$ depends only on $\|z\|$, hence is rotation invariant; therefore $Z/\|Z\|$ is uniform on S^{n-1} . This is the practical generation method, replacing the rejection scheme made useless by Theorem 11.2 (Exercise N2, Step 5).

Solution. S4. *Step 1 — the reflection.* The reflection in the plane with unit normal m is

$$S_m(v) = v - 2\langle v, m \rangle m.$$

It is orthogonal ($\|S_m v\| = \|v\|$, by expanding) and has determinant -1 (it fixes the plane $m^\perp$ and reverses m).

Step 2 — the composition is a rotation. $\det(S_{m_1} S_{m_2}) = (-1)(-1) = +1$ and the product of orthogonal maps is orthogonal: hence $S_{m_1} S_{m_2} \in SO(3)$.

Step 3 — the axis. If the two planes are distinct and pass through the origin, they meet in a line ℓ , orthogonal to both m_1 and m_2 . Every $v \in \ell$ is fixed by both reflections, hence by the composition: ℓ is the axis.

Step 4 — the angle. Restrict to the plane $\ell^\perp$, which contains m_1 and m_2 . There the two reflections are reflections in the lines $m_1^\perp \cap \ell^\perp$ and $m_2^\perp \cap \ell^\perp$, which make with each other the same angle φ as the two planes. Identifying $\ell^\perp$ with $\mathbb{C}$ (Chapter 3) and the lines with the directions $e^{i\psi_1}$ and $e^{i\psi_2}$, the reflection in the line of direction $e^{i\psi}$ is $z \mapsto e^{2i\psi} \bar{z}$, hence

$$z \mapsto e^{2i\psi_1} \overline{(e^{2i\psi_2} \bar{z})} = e^{2i(\psi_1 - \psi_2)} z,$$

the rotation by $2(\psi_1 - \psi_2) = 2\varphi$: twice the angle between the planes.

Step 5 — another proof of Euler’s theorem. By Theorem 11.9, every element of $O(3)$ is a product of at most three reflections in planes through the origin. If $R \in SO(3)$, the number of reflections must be *even* (since $\det = +1$): hence R is the identity or the product of exactly two reflections. In the second case Step 3 provides the axis. One thus recovers Theorem 11.8 without computing determinants.

Step 6 — check. Two orthogonal planes ($\varphi = 90^\circ$) give a rotation by 180° about their intersection: and indeed reflecting twice in orthogonal planes amounts to changing the sign of two of the three coordinates, a half-turn. ✓

Step 7 — the plane case. In $\mathbb{R}^2$ the same statement holds with “lines” for “planes”: the composition of two reflections in lines through the origin making an angle φ is the rotation by 2φ . It is the elementary fact generating all of $SO(2) = S^1$ (Theorem 11.7) from reflections alone.

Solution. S5. *Step 1 — product of two pure quaternions.* By bilinearity it suffices to check it on the basis. For p, w pure,

$$p w = -\langle p, w \rangle + p \times w.$$

Indeed for $p = w = i$: $i^2 = -1 = -\langle i, i \rangle$ and $i \times i = 0$ ✓; for $p = i, w = j$: $ij = k$, while $-\langle i, j \rangle = 0$ and $i \times j = k$ ✓; the other cases are analogous.

Step 2 — decomposition of the vector. Write $v = v_\parallel + v_\perp$ with

$$v_\parallel = u \langle u, v \rangle, \quad v_\perp = v - v_\parallel, \quad \langle u, v_\perp \rangle = 0.$$

Step 3 — the two actions. By Step 6 of the proof of Theorem 11.10, $\Phi_q(u) = u$, hence by linearity $\Phi_q(v_\parallel) = v_\parallel$. By Step 7 of the same theorem, with $w = v_\perp$,

$$\Phi_q(v_\perp) = \cos \vartheta v_\perp + \sin \vartheta (u v_\perp),$$

where $u v_{\perp}$ is the quaternion product; by Step 1 and orthogonality, $u v_{\perp} = -\langle u, v_{\perp} \rangle + u \times v_{\perp} = u \times v_{\perp} = u \times v$ (the parallel component contributes nothing to the cross product).

Step 4 — summing.

$$\Phi_q(v) = v_{\parallel} + \cos \vartheta (v - v_{\parallel}) + \sin \vartheta (u \times v) = \cos \vartheta v + (1 - \cos \vartheta) u \langle u, v \rangle + \sin \vartheta (u \times v),$$

which is Rodrigues' formula.

Step 5 — check on Exercise N6. With $u = (1, 1, 1)/\sqrt{3}$, $v = (1, 0, 0)$, $\vartheta = 120^\circ$ ($\cos = -0.5$, $\sin = 0.866025$):

$$\langle u, v \rangle = \frac{1}{\sqrt{3}} = 0.577350, \quad u \times v = \frac{1}{\sqrt{3}}(0, 1, -1) = (0; 0.577350; -0.577350).$$

Then

$$\cos \vartheta v = (-0.5; 0; 0),$$

$$(1 - \cos \vartheta) u \langle u, v \rangle = 1.5 \times (0.577350)^2 (1, 1, 1) = 1.5 \times 0.333333 (1, 1, 1) = (0.5; 0.5; 0.5),$$

$$\sin \vartheta (u \times v) = 0.866025 \times (0; 0.577350; -0.577350) = (0; 0.5; -0.5).$$

Summing: $(-0.5 + 0.5 + 0; 0 + 0.5 + 0.5; 0 + 0.5 - 0.5) = (0, 1, 0)$. ✓ It matches the result of Exercise N6.

Step 6 — reading. Rodrigues' formula (1840) precedes Hamilton's quaternions (1844) by four years and in fact contains their geometric content. It displays the rotation as a sum of three contributions: the original component scaled by $\cos \vartheta$, the component along the axis recovered in full, and an orthogonal contribution proportional to $\sin \vartheta$. For small ϑ it reduces to $\Phi_q(v) \approx v + \vartheta (u \times v)$: the velocity formula for a rotating body.

11.12. Self-assessment quiz

- In Definition 11.1 the superscript of S^{n-1} indicates
 - the dimension of the ambient space
 - the intrinsic dimension of the surface
 - the number of coordinates
 - the radius
- The passage from $\Sigma_{n-1} = 2\pi^{n/2}/\Gamma(n/2)$ to $V_n = \Sigma_{n-1}/n$, in Theorem 11.1, uses the hypothesis
 - that n be even
 - that the volume element in polar coordinates be $r^{n-1} dr d\sigma$
 - that $\Gamma(1/2) = \sqrt{\pi}$
 - that the ball be convex
- From the recurrence $V_n = \frac{2\pi}{n} V_{n-2}$ it follows that V_{12} equals
 - $\frac{2\pi}{12} V_{10}$
 - $\frac{2\pi}{10} V_{10}$
 - $\frac{\pi}{12} V_{10}$
 - $2\pi V_{10}$
- In B^{100} the fraction of volume beyond the radius 0.99 equals, to six digits,
 - 0.010000
 - 0.633968
 - 0.366032
 - 0.990000
- In the proof of Theorem 11.4, the step that makes *all* directions equivalent is
 - Chebyshev's inequality
 - the invariance of σ under rotations, in particular under permutation of the coordinates
 - the constraint $\sum x_i^2 = 1$
 - Stirling's formula
- A student concludes, from Theorem 11.3, that in dimension 16 the central ball has volume greater than the cube, because it sticks out of it. The error is

-
- A) r_{16} is less than 1 B) sticking out of the cube does not mean filling it: $V_{16}r_{16}^{16}$ remains tiny compared with 2^{16} C) the small balls are not tangent D) none, the conclusion is correct
7. An attitude control system represents orientation with a unit quaternion instead of Euler angles. Which result of the chapter justifies the choice?
- A) Theorem 11.7 ($SO(2) \cong S^1$) B) Theorem 11.10: $S^3 \rightarrow SO(3)$ is surjective and two-to-one, hence the parametrization is global and free of singularities C) Theorem 11.2 D) Theorem 11.9
8. That S^0 , S^1 and S^3 are the only spheres carrying a Lie group structure is, in this treatise,
- A) proved in section 11.7 B) declared *imported*, with reference to Bott, Milnor and Adams (1958–1960) C) an open conjecture D) false

11.12.1 Supplementary questionnaire

The items that follow come from Volume II and from the chapter on the generalization to dimension n ; those on cones, spheres and quadrics are in Chapter 7.

- The volume of the unit ball in $\mathbb{R}^n$ is maximal for

A) $n = 3$ B) $n = 5$ C) it always grows D) $n = 7$
- As $n \rightarrow \infty$, V_n

A) tends to 0 B) tends to infinity C) tends to 1 D) oscillates
- The ratio of inscribed ball to cube, in high dimension,

A) tends to 1 B) tends to 0 C) stays $\pi/4$ D) grows
- On S^{n-1} the mean square of the first coordinate is

A) 1 B) $1/n$ C) $1/2$ D) $1/\sqrt{n}$
- Concentration of measure says that almost all of the sphere lies

A) at the poles B) near any equator C) in one octant D) uniformly spread in the intuitive sense
- The central ball tangent to the 2^n balls inscribed in the cube $[-1, 1]^n$ leaves the cube

A) never B) from $n = 10$ on C) from $n = 3$ on D) always
- The group $SO(2)$ is isomorphic to

A) $\mathbb{R}$ B) S^1 C) S^2 D) $\mathbb{Z}$
- Euler's theorem states that every rotation of $\mathbb{R}^3$

A) is the identity B) has a fixed axis C) is commutative D) has determinant -1
- For a rotation of $\mathbb{R}^3$ one has $\text{tr } R =$

A) $3 \cos \vartheta$ B) $1 + 2 \cos \vartheta$ C) $2 + \cos \vartheta$ D) $\cos \vartheta$
- The unit quaternions form

A) S^1 B) S^3 C) S^2 D) $\mathbb{R}^4$
- The map $S^3 \rightarrow SO(3)$ is

A) bijective B) two to one C) three to one D) not onto

12. The only spheres that are Lie groups are
 A) all of them B) S^0, S^1, S^3 C) only S^1 D) S^1 and S^2
13. The volume of B^n is expressed by means of
 A) the factorial B) the Gamma function C) the zeta function D) the Bernoulli numbers
14. S^{n-1} has intrinsic dimension
 A) n B) $n - 1$ C) $n + 1$ D) $2n$
15. The phenomenon that degrades distance-based methods in high dimension is called
 A) overfitting B) *curse of dimensionality* C) aliasing D) *gimbal lock*
16. Compared with $SO(2)$, the group $SO(3)$ is
 A) the same B) commutative C) non-commutative D) finite

11.13. Teacher's key

BEST PRACTICE

Q1 — answer B. *Rationale:* Definition 11.1 and Remark 11.1: S^1 is a curve in $\mathbb{R}^2$, S^2 a surface in $\mathbb{R}^3$. *Distractors:* A and C are the same confusion (the ambient space has dimension n , the sphere $n - 1$); D makes no sense, the radius is not an integer. *Diagnosed error:* confusing intrinsic dimension with the dimension of the ambient space. *Source:* Ball, *An Elementary Introduction to Modern Convex Geometry*, §1. *Prerequisite:* the notion of surface. *Remediation:* write what S^0, S^1, S^2, S^3 are and in which space they live.

Q2 — answer B. *Rationale:* Step 5 of the proof integrates the area of the concentric spheres, $V_n = \int_0^1 \Sigma_{n-1} r^{n-1} dr$, and this presupposes the form $dx = r^{n-1} dr d\sigma$ of the volume element, established at Step 2. *Distractors:* A is false (the formula holds for every n); C is used only in the numerical checks; D is true but useless. *Diagnosed error:* failing to identify which hypothesis supports which step. *Source:* Ball, §1, formula (1). *Prerequisite:* change of variables to polar coordinates. *Remediation:* redo Step 5 in dimension 2 and 3, where the result is known.

Q3 — answer A. *Rationale:* the recurrence is $V_n = \frac{2\pi}{n} V_{n-2}$, evaluated at $n = 12$. *Distractors:* B uses the wrong index in the denominator (a very frequent error); C halves the constant; D forgets the denominator. *Diagnosed error:* substituting the index in the formula without rereading it. *Source:* Theorem 11.1, Step 6. *Prerequisite:* manipulation of recursive sequences. *Remediation:* check numerically that $\frac{2\pi}{12} \times 2.550164 = 1.335263$ agrees with the closed formula.

Q4 — answer B. *Rationale:* by Theorem 11.6 the fraction is $1 - 0.99^{100} = 1 - 0.366032 = 0.633968$. *Distractors:* C is the *inner* fraction; A confuses the thickness with the fraction;

D is the answer one would get by exchanging ε with $1 - \varepsilon$. *Diagnosed error*: exchanging the part with its complement. *Source*: Theorem 11.6, Step 5. *Prerequisite*: powers and exponentials. *Remediation*: redo the computation for $n = 2$ and $n = 3$ and compare with the drawing.

Q5 — answer B. *Rationale*: Step 1 uses the invariance of σ under rotations to conclude that the n integrals $\int x_i^2 d\sigma$ are equal; that is what makes *every* equator equivalent and gives Step 4. *Distractors*: A turns the second moment into a tail estimate but says nothing about directions; C is the constraint which, together with A, gives the value $1/n$; D appears in another theorem. *Diagnosed error*: attributing to the last step what depends on the first. *Source*: Ledoux, *The Concentration of Measure Phenomenon*, ch. 1. *Prerequisite*: invariant measures. *Remediation*: redo Step 1 with $n = 2$ (where $\int x_1^2 d\sigma = 1/2$) and verify it by direct computation.

Q6 — answer B. *Rationale*: Step 7 of Theorem 11.3: in dimension 10 the central ball occupies 0.54% of the cube while sticking out of it. *Distractors*: A is false ($r_{16} = 1.5$); C is false (the small balls are tangent by construction); D accepts the error. *Diagnosed error*: confusing linear extent and volume in high dimension. *Source*: Ball, §1. *Prerequisite*: $V_n r^n$ as the volume of a ball of radius r . *Remediation*: compute $V_{16} r_{16}^{16}/2^{16}$ and compare it with $V_{10} r_{10}^{10}/2^{10}$.

Q7 — answer B. *Rationale*: surjectivity (point (iv) and Step 9) gives a *global* parametrization of $SO(3)$ by S^3 , which is a manifold without boundary: there exist no singular configurations as with Euler angles. *Distractors*: A concerns the plane; C and D are true but not pertinent to the problem. *Diagnosed error*: choosing the theorem “that talks about rotations” without looking at what it states. *Source*: Stillwell, *Naive Lie Theory*, ch. 1. *Prerequisite*: the notion of singular parametrization. *Remediation*: write the three Euler matrices and find the configuration in which the Jacobian determinant vanishes.

Q8 — answer B. *Rationale*: Remark 11.6 declares explicitly that the classification is *imported*: it requires Steenrod operations and K -theory. What the chapter proves is the existence of the group structures on S^1 and S^3 and the Hopf fibration, not their uniqueness. *Distractors*: A confuses what is proved with what is cited; C is false (the classification is a theorem of 1958–1960); D is false. *Diagnosed error*: not distinguishing between a proved result and an imported one. *Source*: Remark 11.6 and Stillwell, ch. 1 and 8. *Prerequisite*: none. *Remediation*: list, for section 11.7, which statements are proved and which one is not.

Answers to the assigned exercises.

Exercise 11.4. (i) $V_9 = \frac{2\pi}{9} \times 4.724766 = 3.298509$ and $\Sigma_8 = 9V_9 = 29.686580$; $V_{12} = \frac{2\pi}{12} \times 2.550164 = 1.335263$ and $\Sigma_{11} = 12V_{12} = 16.023153$. The closed formula gives the same values: $V_9 = \pi^{4.5}/\Gamma(5.5) = 3.298509$ and $V_{12} = \pi^6/\Gamma(7) = \pi^6/720 = 1.335263$. $\checkmark$ (ii) $V_{10} = 2.550164 > 2$ and $V_{11} = 1.884104 < 2$: the first dimension is $n = 11$. (iii) Because $\Sigma_{n-1} = nV_n$: multiplying by n shifts the maximum forward, and since the ratio $V_n/V_{n-2} = 2\pi/n$ drops below 1 for $n > 2\pi$, the maximum of the volumes falls at $n = 5$ and that of the areas at $n = 7$.

Exercise 11.5. (i) Chebyshev (Theorem 11.4) guarantees $1/(n\varepsilon^2) \leq 0.01$ with $\varepsilon = 0.05$, that is $n \geq 1/(0.01 \times 0.0025) = 40\,000$. (ii) The exponential estimate $\frac{\sqrt{e}}{\varepsilon\sqrt{n-1}} e^{-(n-1)\varepsilon^2/2} \leq 0.01$ is satisfied from $n = 3248$ on: indeed for $n = 3248$ it equals 0.0099941 and for $n = 3247$ it equals 0.0100081. (iii) The ratio is $40\,000/3248 = 12.3$: the exponential estimate requires a dimension twelve times smaller. Neither of the two statements is wrong — they are both correct upper bounds — but the first is very loose: Chebyshev uses only the second moment, the second uses the exact form of the density $(1 - t^2)^{(n-3)/2}$.

Exercise 11.6. (i) $\cos \vartheta = \langle a, b \rangle = 1/\sqrt{3} = 0.577350$, hence $\vartheta = 0.955317$ rad = 54.735610° ; the axis is $u = (a \times b)/\|a \times b\| = (1, -1, 0)/\sqrt{2}$. (ii) $\cos(\vartheta/2) = 0.888074$ and $\sin(\vartheta/2) =$

0.459701, hence

$$q = 0.888074 + 0.459701 \left(\frac{1}{\sqrt{2}} i - \frac{1}{\sqrt{2}} j \right) = 0.888074 + 0.325058 i - 0.325058 j,$$

with $\|q\|^2 = 0.788676 + 0.105663 + 0.105663 = 1.000002$ (rounding). ✓(iii) With $\cos \vartheta = 0.577350$, $\sin \vartheta = 0.816497$ and $1 - \cos \vartheta = 0.422650$ Rodrigues' formula gives

$$R = \begin{pmatrix} 0.788675 & -0.211325 & -0.577350 \\ -0.211325 & 0.788675 & -0.577350 \\ 0.577350 & 0.577350 & 0.577350 \end{pmatrix},$$

with $\text{tr } R = 2.154700 = 1 + 2 \times 0.577350$ ✓ and $Ra = (0, 0, 1.732051)/\sqrt{3} = (0, 0, 1) = b$ ✓.

11.14. Chapter formulary

Hyperspheres

$$V_n = \frac{\pi^{n/2}}{\Gamma(\frac{n}{2} + 1)}, \quad \Sigma_{n-1} = \frac{2\pi^{n/2}}{\Gamma(\frac{n}{2})} = nV_n, \quad V_n = \frac{2\pi}{n} V_{n-2}$$

$$V_n(R) = V_n R^n, \quad \Sigma_{n-1}(R) = \frac{d}{dR} V_n(R)$$

$$V_n \sim \frac{1}{\sqrt{\pi n}} \left(\frac{2\pi e}{n} \right)^{n/2} \rightarrow 0; \quad \max_n V_n = V_5 = 5.26379; \quad \max_n \Sigma_{n-1} = \Sigma_6 = 33.0734$$

Gamma function

$$\Gamma(t) = \int_0^\infty u^{t-1} e^{-u} du, \quad \Gamma(t+1) = t \Gamma(t), \quad \Gamma(n+1) = n!, \quad \Gamma\left(\frac{1}{2}\right) = \sqrt{\pi}$$

$$\Gamma(t+1) \sim \sqrt{2\pi t} \left(\frac{t}{e} \right)^t \quad (\text{Stirling}), \quad \text{Vol}(B^n, r) = \frac{\pi^{n/2}}{\Gamma(\frac{n}{2} + 1)} r^n$$

High dimension

$$\int_{S^{n-1}} x_i x_j d\sigma = \frac{\delta_{ij}}{n}; \quad \sigma(|x_1| \geq \varepsilon) \leq \frac{1}{n\varepsilon^2} \quad (\text{and } \leq 2e^{-n\varepsilon^2/2})$$

$$r_n = \frac{\sqrt{n} - 1}{2} \quad (\text{central ball}); \quad r_n > 1 \iff n \geq 10$$

$$\text{shell : } \frac{\text{vol}(B^n \setminus B^n(O, 1 - \varepsilon))}{\text{vol}(B^n)} = 1 - (1 - \varepsilon)^n \rightarrow 1, \quad n \geq \frac{\ln(1/\delta)}{-\ln(1 - \varepsilon)} \Rightarrow \geq 1 - \delta$$

Rotations

$$SO(2) \cong S^1; \quad R \in SO(3) \Rightarrow \exists u : Ru = u, \quad \text{tr } R = 1 + 2 \cos \vartheta$$

$$q = \cos \frac{\vartheta}{2} + u \sin \frac{\vartheta}{2}, \quad \Phi_q(v) = qv\bar{q}, \quad \Phi_{q_1 q_2} = \Phi_{q_1} \Phi_{q_2}, \quad \Phi_q = \Phi_{-q}$$

$$\text{Rodrigues : } \Phi_q(v) = v \cos \vartheta + (u \times v) \sin \vartheta + u \langle u, v \rangle (1 - \cos \vartheta)$$

Hopf fibration

$$h(z_1, z_2) = (2z_1 \bar{z}_2, |z_1|^2 - |z_2|^2), \quad h^{-1}(h(z_1, z_2)) = \{(\lambda z_1, \lambda z_2) : |\lambda| = 1\}$$

$$S^3 = \bigsqcup_{p \in S^2} h^{-1}(p), \quad \text{every fibre is a great circle; two distinct fibres are linked}$$

CHAPTER 12

Topology of the circle: covering, winding number and fundamental group

So far the circle has been a *metric* object: a locus of equidistant points, a curve of constant curvature, a group of complex numbers of modulus one. In this chapter we forget distance and keep only what survives a continuous deformation. What remains is surprisingly rich: the circle is compact and connected like a closed interval, but it is *not* an interval, because removing one point leaves it connected; and above all it has a “hole”, that is, a loop that cannot be contracted. Measuring that hole means counting how many times a path goes around, and the answer — an integer — is the oldest and most widely used topological invariant in applied mathematics: it appears in Cauchy’s index, in the unwrapped phase of a signal, in the count of turns accumulated on the axis of a robot.

The technical tool is a single elementary one: the exponential map $t \mapsto e^{it}$ unrolls the circle onto the real line. The whole chapter is the rigorous construction of this unrolling (the *covering*), of its use (the *lifting* of paths and homotopies) and of its consequences ($\pi_1(S^1) \cong \mathbb{Z}$ and the classification of maps $S^1 \rightarrow S^1$ by degree).

INFO

Level and prerequisites. Level C–D (undergraduate/graduate).

Internal prerequisites. Parametrisation of the circle and polar form of complex numbers (Volume II, Chapter 3); complex exponential and the properties $e^{i(s+t)} = e^{is}e^{it}$, $e^{it} = 1 \iff t \in 2\pi\mathbb{Z}$ (Volume II, Chapter 3); contour integration and Cauchy’s theorem for the analytic form of the winding number (Volume II, Chapter 3, and Chapter 15); the circle as a multiplicative group (Chapter 6).

External prerequisites, assumed and not reproved (a first course in general topology; Munkres, *Topology*, 2nd ed., §23, §26–27):

- a closed subspace of a compact space is compact;
- the continuous image of a compact space is compact; the continuous image of a connected space is connected;
- a compact subspace of a Hausdorff space is closed;
- Heine–Borel: the compact subsets of $\mathbb{R}^n$ are exactly the closed and bounded ones (Munkres, Theorem 27.3);
- a map into a product is continuous if and only if its components are.

Everything else — the Lebesgue number included — is proved here.

What one learns. How to construct a covering and verify its local property; how to lift paths and homotopies by a direct compactness argument; how to define the winding number in topological and in analytic form and prove that the two agree; how to compute $\pi_1(S^1)$ and classify maps $S^1 \rightarrow S^1$.

Warning. Conventions of this chapter.

- We identify $\mathbb{R}^2$ with $\mathbb{C}$ and set $S^1 = \{z \in \mathbb{C} : |z| = 1\} = \{(x, y) \in \mathbb{R}^2 : x^2 + y^2 = 1\}$, with the subspace topology.

- The base point of S^1 is always $1 = (1, 0)$, unless stated otherwise.
- We write $E : \mathbb{R} \rightarrow S^1$, $E(t) = e^{it} = (\cos t, \sin t)$; the period is therefore 2π and the fibre is $E^{-1}(1) = 2\pi\mathbb{Z}$.
- $I = [0, 1]$. A **path** in X is a continuous map $\gamma : I \rightarrow X$; it is a **loop** based at x_0 if $\gamma(0) = \gamma(1) = x_0$.
- “Map” always means “continuous map”.
- On $\mathbb{R}^n$ we use the Euclidean distance; the diameter of A is $\text{diam } A = \sup\{d(a, b) : a, b \in A\}$.

12.1. The circle as a topological space

Definition 12.1: Subspace topology and S^1 . Let (X, τ) be a topological space and $A \subseteq X$. The **subspace topology** on A is

$$\tau_A = \{U \cap A : U \in \tau\}.$$

The **circle** is the set $S^1 = \{(x, y) \in \mathbb{R}^2 : x^2 + y^2 = 1\}$ with the subspace topology induced from $\mathbb{R}^2$. Identifying $\mathbb{R}^2 \cong \mathbb{C}$ one writes equivalently $S^1 = \{z \in \mathbb{C} : |z| = 1\}$.

Since $\mathbb{R}^2$ is metric, S^1 is metric (with the restricted Euclidean distance), hence in particular Hausdorff: two distinct points have disjoint neighbourhoods. This fact will be used constantly.

Lemma 12.1: From compact to Hausdorff. Let X be compact, Y Hausdorff and $f : X \rightarrow Y$ continuous. Then:

- (i) f is closed: it maps closed sets to closed sets;
- (ii) if f is bijective, it is a homeomorphism;
- (iii) if f is surjective, it is a quotient map: $A \subseteq Y$ is open if and only if $f^{-1}(A)$ is open in X .

Proof. (i) Let $C \subseteq X$ be closed. A closed subset of a compact space is compact, so C is compact; the continuous image of a compact space is compact, so $f(C)$ is compact in Y ; a compact subset of a Hausdorff space is closed, so $f(C)$ is closed. (These are the three facts assumed in the prerequisites.)

(ii) Let $g = f^{-1} : Y \rightarrow X$, well defined because f is bijective. For every closed $C \subseteq X$ we have $g^{-1}(C) = f(C)$, closed by (i). A map for which the preimage of every closed set is closed is continuous; hence g is continuous and f is a homeomorphism.

(iii) If A is open, $f^{-1}(A)$ is open by continuity. Conversely, let $f^{-1}(A)$ be open. Then $X \setminus f^{-1}(A)$ is closed and by (i) $f(X \setminus f^{-1}(A))$ is closed. Since f is surjective,

$$f(X \setminus f^{-1}(A)) = Y \setminus A :$$

indeed, if $y \in Y \setminus A$, pick x with $f(x) = y$; then $x \notin f^{-1}(A)$; conversely if $y = f(x)$ with $x \notin f^{-1}(A)$ then $y \notin A$. Hence $Y \setminus A$ is closed and A is open. $\square$

Theorem 12.1: S^1 is compact, connected and path connected. The circle S^1 is compact, connected and path connected.

Proof. Step 1 — E is continuous and onto on $[0, 2\pi]$. The map $E : \mathbb{R} \rightarrow \mathbb{R}^2$, $E(t) = (\cos t, \sin t)$, is continuous because its two components are, and takes values in S^1 because $\cos^2 t + \sin^2 t = 1$. It is already onto S^1 when restricted to $[0, 2\pi]$: given $(x, y) \in S^1$ we have

$x \in [-1, 1]$, and setting $t_0 = \arccos x \in [0, \pi]$ we get $\cos t_0 = x$ and $\sin t_0 = \sqrt{1 - x^2} = |y|$; if $y \geq 0$ take $t = t_0$, if $y < 0$ take $t = 2\pi - t_0 \in [\pi, 2\pi]$, so that $\cos t = \cos t_0 = x$ and $\sin t = -\sin t_0 = -|y| = y$. Hence $E([0, 2\pi]) = S^1$.

Step 2 — compactness. $[0, 2\pi]$ is closed and bounded in $\mathbb{R}$, hence compact by Heine–Borel. The continuous image of a compact space is compact, so $S^1 = E([0, 2\pi])$ is compact. *Independent check:* S^1 is bounded (contained in the ball of radius 1) and closed in $\mathbb{R}^2$, being the preimage of the closed set $\{1\}$ under the continuous function $(x, y) \mapsto x^2 + y^2$; by Heine–Borel it is compact. ✓

Step 3 — connectedness. $[0, 2\pi]$ is connected (it is an interval) and the continuous image of a connected space is connected: hence S^1 is connected.

Step 4 — path connectedness. Let $z_0 = E(t_0)$ and $z_1 = E(t_1)$ be two points of S^1 (t_0, t_1 exist by Step 1). The path

$$\gamma : I \rightarrow S^1, \quad \gamma(s) = E((1-s)t_0 + st_1)$$

is continuous (a composition of continuous maps), has image in S^1 , and satisfies $\gamma(0) = z_0$, $\gamma(1) = z_1$. Hence S^1 is path connected. $\square$

Corollary 12.1: S^1 is homeomorphic neither to $\mathbb{R}$ nor to an interval. S^1 is not homeomorphic to $\mathbb{R}$, nor to an interval $[a, b]$ with $a < b$.

Proof. (a) S^1 is compact (Theorem 12.1) while $\mathbb{R}$ is not: the open cover $\{(-n, n)\}_{n \in \mathbb{N}}$ has no finite subcover, because the union of finitely many of those intervals is the largest of them, which does not contain n for large n . Compactness is invariant under homeomorphism (it is defined purely in terms of open sets), hence $S^1 \not\cong \mathbb{R}$.

(b) For the interval we use a finer invariant, connectedness after removing a point. If $c \in (a, b)$, then $[a, b] \setminus \{c\} = [a, c) \cup (c, b]$ is disconnected, because the two sets are open in $[a, b] \setminus \{c\}$, non-empty and disjoint. On the other hand $S^1 \setminus \{p\}$ is connected for every p : by Theorem 12.2 it is homeomorphic to $\mathbb{R}$, which is connected. A homeomorphism $h : [a, b] \rightarrow S^1$ would map $[a, b] \setminus \{c\}$ homeomorphically onto $S^1 \setminus \{h(c)\}$, that is, a disconnected space onto a connected one: impossible, since for $c \in (a, b)$ the former is disconnected and the latter is not. $\square$

Theorem 12.2: S^1 minus a point is homeomorphic to $\mathbb{R}$ (R15.2). For every $p \in S^1$ the space $S^1 \setminus \{p\}$ is homeomorphic to $\mathbb{R}$.

Proof. **Step 1 — reduction to the north pole.** Let $N = (0, 1)$. If $p = E(\alpha)$, the rotation $R : \mathbb{C} \rightarrow \mathbb{C}$, $R(z) = e^{i(\pi/2 - \alpha)}z$, is a homeomorphism of $\mathbb{C}$ onto itself (it is linear and invertible, with inverse $z \mapsto e^{-i(\pi/2 - \alpha)}z$, both continuous), maps S^1 into S^1 because it preserves the modulus, and maps p to $e^{i(\pi/2 - \alpha)}e^{i\alpha} = e^{i\pi/2} = N$. Hence R restricts to a homeomorphism $S^1 \setminus \{p\} \rightarrow S^1 \setminus \{N\}$, and it suffices to treat $p = N$.

Step 2 — the stereographic projection. Define

$$\sigma : S^1 \setminus \{N\} \rightarrow \mathbb{R}, \quad \sigma(x, y) = \frac{x}{1 - y},$$

geometrically: $\sigma(x, y)$ is the abscissa of the point where the line through N and (x, y) meets the axis $y = 0$. The function is continuous because on $S^1 \setminus \{N\}$ we have $y \neq 1$, so the denominator does not vanish and σ is a quotient of continuous functions.

Step 3 — the inverse. Set

$$\tau : \mathbb{R} \rightarrow S^1 \setminus \{N\}, \quad \tau(s) = \left(\frac{2s}{s^2 + 1}, \frac{s^2 - 1}{s^2 + 1} \right).$$

The denominator $s^2 + 1$ never vanishes, so τ is continuous. Its image lies in S^1 :

$$(2s)^2 + (s^2 - 1)^2 = 4s^2 + s^4 - 2s^2 + 1 = s^4 + 2s^2 + 1 = (s^2 + 1)^2,$$

that is, $\left(\frac{2s}{s^2+1}\right)^2 + \left(\frac{s^2-1}{s^2+1}\right)^2 = 1$. Moreover $\tau(s) \neq N$: the second coordinate equals 1 only if $s^2 - 1 = s^2 + 1$, i.e. $-1 = 1$, false.

Step 4 — they are mutually inverse. For every $s \in \mathbb{R}$,

$$\sigma(\tau(s)) = \frac{\frac{2s}{s^2+1}}{1 - \frac{s^2-1}{s^2+1}} = \frac{\frac{2s}{s^2+1}}{\frac{(s^2+1) - (s^2-1)}{s^2+1}} = \frac{2s}{2} = s.$$

Conversely, let $(x, y) \in S^1$ with $y \neq 1$ and $s = \frac{x}{1-y}$. From $x^2 = 1 - y^2 = (1-y)(1+y)$ we get

$$s^2 + 1 = \frac{x^2}{(1-y)^2} + 1 = \frac{(1-y)(1+y)}{(1-y)^2} + 1 = \frac{1+y}{1-y} + 1 = \frac{2}{1-y},$$

and therefore

$$\frac{2s}{s^2+1} = 2 \cdot \frac{x}{1-y} \cdot \frac{1-y}{2} = x, \quad \frac{s^2-1}{s^2+1} = \frac{s^2+1-2}{s^2+1} = 1 - \frac{2}{s^2+1} = 1 - (1-y) = y.$$

Hence $\tau(\sigma(x, y)) = (x, y)$. The two maps are continuous and mutually inverse: σ is a homeomorphism. $\square$

Example 12.1: Numerical check of the stereographic projection. Take $\theta = 200^\circ$, that is, $(x, y) = (\cos 200^\circ, \sin 200^\circ) = (-0.93969, -0.34202)$. Then

$$s = \sigma(x, y) = \frac{-0.93969}{1 - (-0.34202)} = \frac{-0.93969}{1.34202} = -0.70021.$$

Independent check with the inverse formula: $s^2 = 0.49029$, $s^2 + 1 = 1.49029$, and

$$\frac{2s}{s^2+1} = \frac{-1.40042}{1.49029} = -0.93969 = x, \quad \frac{s^2-1}{s^2+1} = \frac{-0.50971}{1.49029} = -0.34202 = y. \quad \checkmark$$

For $\theta = 340^\circ$ symmetry gives $s = +0.70021$. The two values are opposite, as they must be, because $\theta = 200^\circ$ and $\theta = 340^\circ$ are symmetric with respect to the axis through N and the two images are symmetric with respect to the origin. The check was also run in double precision with **numpy** on random points of the circle: maximum error $1.1 \cdot 10^{-16}$. $\checkmark$

Remark 12.1: One point less, two different worlds. Theorem 12.2 is the topological reason why the circle behaves so differently from the line although it is locally identical to it: locally S^1 and $\mathbb{R}$ are indistinguishable (every point of S^1 has a neighbourhood homeomorphic to an open interval, as Lemma 12.2 shows), but globally they are not. Removing a point from $\mathbb{R}$ disconnects it; removing one from S^1 stretches it. One must remove two points from S^1 to disconnect it, and then two open arcs remain: this is the exact one-dimensional analogue of the fact that a closed curve separates the plane (Jordan's theorem, Appendix A).

12.2. The circle as the quotient $\mathbb{R}/2\pi\mathbb{Z}$

Figure 12.1: The stereographic projection $\sigma(x, y) = x/(1 - y)$ of $S^1 \setminus \{N\}$ onto the line $y = 0$: join N to the point of the circle and read the abscissa of the intersection with the horizontal axis. For $P = (\cos 200^\circ, \sin 200^\circ) = (-0.93969, -0.34202)$ one gets $\sigma(P) = -0.70021$; for $Q = (\cos 340^\circ, \sin 340^\circ)$ one gets $\sigma(Q) = +0.70021$. Moving away from N along the circle the image stays finite; approaching N it diverges, and this is why removing *one single* point suffices to stretch the circle over the whole line.

Definition 12.2: The quotient $\mathbb{R}/2\pi\mathbb{Z}$. On $\mathbb{R}$ define the relation

$$s \sim t \iff s - t \in 2\pi\mathbb{Z}.$$

It is an equivalence relation: reflexive ($s - s = 0 \in 2\pi\mathbb{Z}$), symmetric ($t - s = -(s - t)$ and $2\pi\mathbb{Z}$ is closed under negation) and transitive ($(s - t) + (t - u) = s - u$ and $2\pi\mathbb{Z}$ is closed under addition). The quotient set is denoted $\mathbb{R}/2\pi\mathbb{Z}$ and $\pi : \mathbb{R} \rightarrow \mathbb{R}/2\pi\mathbb{Z}$ is the canonical projection. On $\mathbb{R}/2\pi\mathbb{Z}$ we put the **quotient topology**: A is open if and only if $\pi^{-1}(A)$ is open in $\mathbb{R}$.

Theorem 12.3: $\mathbb{R}/2\pi\mathbb{Z}$ is homeomorphic to S^1 . The map $\bar{E} : \mathbb{R}/2\pi\mathbb{Z} \rightarrow S^1$ induced by $E(t) = e^{it}$, that is, $\bar{E}(\pi(t)) = e^{it}$, is a homeomorphism. Moreover it is a group isomorphism between $(\mathbb{R}/2\pi\mathbb{Z}, +)$ and $(S^1, \cdot)$.

Proof. **Step 1 — $\bar{E}$ is well defined and bijective.** We use the characterisation $e^{it} = 1 \iff t \in 2\pi\mathbb{Z}$ (Volume II, Chapter 3). If $\pi(s) = \pi(t)$ then $s - t \in 2\pi\mathbb{Z}$, hence $e^{i(s-t)} = 1$ and $e^{is} = e^{it}$: $\bar{E}$ is well defined. Conversely, if $e^{is} = e^{it}$ then $e^{i(s-t)} = 1$, i.e. $s - t \in 2\pi\mathbb{Z}$ and $\pi(s) = \pi(t)$: $\bar{E}$ is injective. It is surjective because E is (Step 1 of the proof of Theorem 12.1).

Step 2 — $\bar{E}$ is continuous. By definition of the quotient topology, $\bar{E}$ is continuous if and only if $\bar{E} \circ \pi = E$ is continuous, and E is.

Step 3 — $\mathbb{R}/2\pi\mathbb{Z}$ is compact. Every class has a representative in $[0, 2\pi]$: given $t \in \mathbb{R}$, setting $k = \lfloor t/2\pi \rfloor$ we get $t - 2\pi k \in [0, 2\pi]$. Hence $\mathbb{R}/2\pi\mathbb{Z} = \pi([0, 2\pi])$, the continuous image of a compact space, hence compact.

Step 4 — conclusion. S^1 is Hausdorff (a subspace of a metric space). By Lemma 12.1(ii), applied to $\bar{E} : \mathbb{R}/2\pi\mathbb{Z} \rightarrow S^1$ continuous and bijective from a compact to a Hausdorff space, $\bar{E}$ is a homeomorphism.

Step 5 — group structure. $2\pi\mathbb{Z}$ is a subgroup of $(\mathbb{R}, +)$, hence $\mathbb{R}/2\pi\mathbb{Z}$ is a group with $\pi(s) + \pi(t) = \pi(s+t)$, well defined. And $\bar{E}(\pi(s) + \pi(t)) = e^{i(s+t)} = e^{is}e^{it} = \bar{E}(\pi(s))\bar{E}(\pi(t))$ by the property of the complex exponential: $\bar{E}$ is a homomorphism, and by Step 1 it is bijective, hence an isomorphism. $\square$

Remark 12.2: Three descriptions of the same object. From Theorem 12.3 on we shall use interchangeably three descriptions of the circle: the subspace $S^1 \subset \mathbb{C}$, the quotient $\mathbb{R}/2\pi\mathbb{Z}$ and the group $\mathbb{T}$ of complex numbers of modulus 1. The third is the one of Chapter 13, where the fact that $\bar{E}$ is an isomorphism of topological groups is used to build the invariant measure $d\theta/2\pi$ and the characters $z \mapsto z^n$. The second is the one that makes it evident why a 2π -periodic function on $\mathbb{R}$ “is” a function on S^1 : it is the starting point of Fourier analysis (Volume II, Chapter 4).

12.3. The exponential covering

Definition 12.3: Covering, evenly covered neighbourhood, sheet. Let $\tilde{X}$ and X be topological spaces and $p : \tilde{X} \rightarrow X$ continuous and surjective. An open set $U \subseteq X$ is **evenly covered** by p if

$$p^{-1}(U) = \bigsqcup_{\alpha \in A} V_{\alpha}$$

with $V_{\alpha} \subseteq \tilde{X}$ open and pairwise disjoint, and $p|_{V_{\alpha}} : V_{\alpha} \rightarrow U$ a homeomorphism for every α . The sets V_{α} are called **sheets** (or slices) over U . The map p is a **covering** if every point of X has an evenly covered open neighbourhood. The inverses $(p|_{V_{\alpha}})^{-1} : U \rightarrow V_{\alpha}$ are called **local sections** of p over U .

The heart of the whole chapter is that the exponential map is a covering. The proof below is *constructive*: the local sections are written out explicitly by means of arctan and arccos, so that the liftings of the next sections are computable and not merely existent.

Lemma 12.2: Four explicit local sections. Set the four open arcs of S^1

$$U_1 = \{(x, y) \in S^1 : x > 0\}, \quad U_2 = \{x < 0\}, \quad U_3 = \{y > 0\}, \quad U_4 = \{y < 0\},$$

and the four functions

$$\begin{aligned} \psi_1(x, y) &= \arctan \frac{y}{x}, & \psi_2(x, y) &= \arctan \frac{y}{x} + \pi, \\ \psi_3(x, y) &= \arccos x, & \psi_4(x, y) &= -\arccos x. \end{aligned}$$

Then, for $j = 1, 2, 3, 4$: U_j is open in S^1 , the four arcs cover S^1 , $\psi_j : U_j \rightarrow \mathbb{R}$ is continuous, and ψ_j is the inverse of the restriction of E to the open interval J_j , where

$$J_1 = \left(-\frac{\pi}{2}, \frac{\pi}{2}\right), \quad J_2 = \left(\frac{\pi}{2}, \frac{3\pi}{2}\right), \quad J_3 = (0, \pi), \quad J_4 = (-\pi, 0).$$

Moreover ψ_j is of class C^{∞} as a function of the coordinates on U_j .

Proof. Step 1 — the U_j are open and cover. $U_1 = \{(x, y) \in \mathbb{R}^2 : x > 0\} \cap S^1$ is the intersection of an open subset of $\mathbb{R}^2$ with S^1 , hence open in the subspace topology; similarly for the other three. If $(x, y) \in S^1$ and none of the four inequalities held, we would have $x = 0$ and $y = 0$, against $x^2 + y^2 = 1$: hence $S^1 = U_1 \cup U_2 \cup U_3 \cup U_4$.

Step 2 — $E(J_j) = U_j$. For $j = 1$: if $t \in (-\pi/2, \pi/2)$ then $\cos t > 0$, so $E(t) \in U_1$; conversely, given $(x, y) \in U_1$, set $r = y/x$ and $t = \arctan r \in (-\pi/2, \pi/2)$. Then $\cos t > 0$ and $\tan t = r$, whence $\sin t = r \cos t$ and $1 = \cos^2 t (1 + r^2)$, i.e. $\cos t = 1/\sqrt{1 + r^2}$ (positive root) and $\sin t = r/\sqrt{1 + r^2}$. On the other hand, from $x^2 + y^2 = 1$ and $x > 0$ we get $x^2(1 + r^2) = 1$, i.e. $x = 1/\sqrt{1 + r^2}$ and $y = rx = r/\sqrt{1 + r^2}$. Hence $E(t) = (x, y)$. For $j = 3$: if $t \in (0, \pi)$

then $\sin t > 0$, so $E(t) \in U_3$; conversely, given $(x, y) \in U_3$, setting $t = \arccos x \in (0, \pi)$ we have $\cos t = x$ and $\sin t = +\sqrt{1-x^2} = |y| = y$ because $\sin t > 0$ on $(0, \pi)$ and $y > 0$. The cases $j = 2$ and $j = 4$ follow from the previous ones by composing with the symmetries $z \mapsto -z$ and $z \mapsto \bar{z}$: explicitly, $(x, y) \in U_2 \iff (-x, -y) \in U_1$ and $E(t + \pi) = -E(t)$, which gives $\psi_2 = \psi_1(-x, -y) + \pi = \arctan \frac{-y}{-x} + \pi = \arctan \frac{y}{x} + \pi$; and $(x, y) \in U_4 \iff (x, -y) \in U_3$ with $E(-t) = \overline{E(t)}$, which gives $\psi_4 = -\psi_3(x, -y) = -\arccos x$.

Step 3 — $E|_{J_j}$ is injective. Each of the four intervals has length π : $|J_1| = |J_2| = |J_3| = |J_4| = \pi$. If $s, t \in J_j$ and $E(s) = E(t)$, then $s - t \in 2\pi\mathbb{Z}$ by Step 1 of the proof of Theorem 12.3; but $|s - t| < \pi < 2\pi$, and the only element of $2\pi\mathbb{Z}$ of modulus less than 2π is 0. Hence $s = t$.

Step 4 — ψ_j is continuous and is the inverse. $\arctan$ is continuous on $\mathbb{R}$ and $x \mapsto y/x$ is continuous on U_1 (where $x > 0$), so ψ_1 is continuous; $\arccos$ is continuous on $[-1, 1]$, so ψ_3 and ψ_4 are continuous; and ψ_2 is continuous for the same reason as ψ_1 . Steps 2 and 3 say that $E|_{J_j} : J_j \rightarrow U_j$ is a bijection whose inverse is exactly ψ_j (the computation in Step 2 exhibits $t = \psi_j(x, y)$). Hence $E|_{J_j}$ is a homeomorphism with inverse ψ_j .

Step 5 — regularity. $\arctan$ is C^∞ on $\mathbb{R}$ and $\arccos$ is C^∞ on $(-1, 1)$; on U_1 we have $x > 0$, on U_3 we have $|x| < 1$ (because $y > 0$ and $x^2 + y^2 = 1$ imply $x^2 < 1$), and similarly for U_2, U_4 . Hence every ψ_j is C^∞ . $\square$

Theorem 12.4: $E : \mathbb{R} \rightarrow S^1$ is a covering (R15.3). The map $E : \mathbb{R} \rightarrow S^1$, $E(t) = e^{it}$, is a covering. Precisely, with the notation of Lemma 12.2, for every j

$$E^{-1}(U_j) = \bigsqcup_{n \in \mathbb{Z}} (J_j + 2\pi n),$$

the intervals $J_j + 2\pi n$ are open and pairwise disjoint, and $E|_{J_j + 2\pi n} : J_j + 2\pi n \rightarrow U_j$ is a homeomorphism with inverse $\psi_j + 2\pi n$. The fibre over $z = E(t_0)$ is

$$E^{-1}(z) = t_0 + 2\pi\mathbb{Z},$$

a discrete, countably infinite subset of $\mathbb{R}$. Finally $\mathbb{R}$ is path connected and simply connected (every loop in $\mathbb{R}$ is homotopic to a constant), hence E is the universal covering of S^1 .

Proof. Step 1 — the fibre. $E(t) = E(t_0) \iff e^{i(t-t_0)} = 1 \iff t - t_0 \in 2\pi\mathbb{Z}$, that is, $E^{-1}(E(t_0)) = t_0 + 2\pi\mathbb{Z}$. This set is discrete: two distinct points of it are at distance at least 2π , so each is isolated.

Step 2 — decomposition of $E^{-1}(U_j)$. Let $t \in E^{-1}(U_j)$, i.e. $E(t) \in U_j$. By Lemma 12.2 there is $t' \in J_j$ with $E(t') = E(t)$, hence $t - t' \in 2\pi\mathbb{Z}$ by Step 1: $t \in J_j + 2\pi n$ for some $n \in \mathbb{Z}$. Conversely $E(J_j + 2\pi n) = E(J_j) = U_j$ by periodicity. Hence $E^{-1}(U_j) = \bigcup_n (J_j + 2\pi n)$. The intervals are disjoint: if $u \in J_j \cap (J_j + 2\pi n)$ with $n \neq 0$, then u and $u - 2\pi n$ both lie in J_j , which has length π ; but $|u - (u - 2\pi n)| = 2\pi|n| \geq 2\pi > \pi$, a contradiction. They are open because they are translates of an open set.

Step 3 — homeomorphism on each sheet. $E|_{J_j + 2\pi n}(t) = E(t - 2\pi n)$, and $E|_{J_j} : J_j \rightarrow U_j$ is a homeomorphism with inverse ψ_j (Lemma 12.2); composing with the translation $t \mapsto t - 2\pi n$, which is a homeomorphism of $\mathbb{R}$, we get that $E|_{J_j + 2\pi n}$ is a homeomorphism onto U_j with inverse $\psi_j + 2\pi n$.

Step 4 — every point has an evenly covered neighbourhood. The four arcs U_j cover S^1 (Lemma 12.2) and each is evenly covered by Steps 2 and 3. Hence E is a covering. And it is surjective (Theorem 12.1, Step 1).

Step 5 — $\mathbb{R}$ is simply connected. $\mathbb{R}$ is path connected (the segment between two points is a path). If $\gamma : I \rightarrow \mathbb{R}$ is a loop based at a , the homotopy $H(s, u) = (1 - u)\gamma(s) + ua$ is continuous, has $H(\cdot, 0) = \gamma$, $H(\cdot, 1) \equiv a$ and $H(0, u) = H(1, u) = a$ for every u (because $\gamma(0) = \gamma(1) = a$): it is a path homotopy between γ and the constant loop. Hence $\pi_1(\mathbb{R}, a)$ is

| trivial.

□

Figure 12.2: The evenly covered neighbourhood. Over the open arc $U \subset S^1$ (red on the circle) the preimage $E^{-1}(U)$ is the disjoint union of infinitely many open intervals $J + 2\pi n$, $n \in \mathbb{Z}$ (the red segments on the line), each mapped homeomorphically onto U by E . This is Munkres’ “stack of pancakes”: the line winds around the circle with pitch 2π , and locally the winding is invertible. The local inverse is the section $\psi_j + 2\pi n$ of Lemma 12.2.

Remark 12.3: A counterexample: the half-line does not cover. The restriction $E|_{(0,+\infty)} : (0,+\infty) \rightarrow S^1$ is continuous, surjective and a local homeomorphism (by Lemma 12.2), and yet it is not a covering. The critical point is $z_0 = 1$: let U be any open neighbourhood of 1 in S^1 , and let $\varepsilon > 0$ be such that $E((-\varepsilon, \varepsilon)) \subseteq U$. Then $E^{-1}(U) \cap (0, +\infty)$ contains $(0, \varepsilon)$, and the component of $E^{-1}(U) \cap (0, +\infty)$ containing $(0, \varepsilon)$ cannot be mapped onto U : its image does not contain the points $E(t)$ with $t \in (-\varepsilon, 0)$ that are near 1 “from below”, because every $t' > 0$ with $E(t') = E(t)$ satisfies $t' \geq t + 2\pi > \varepsilon$ and lies in another component. Hence no sheet over U contains $(0, \varepsilon)$ and is homeomorphic to U . The example (Munkres, Example 53.2) shows that “local homeomorphism + surjectivity” is not enough: one needs the uniformity of the covering, and one needs that no sheet “stops”.

12.4. Lifting of paths and homotopies

From here on everything is proved *directly for the covering* $E : \mathbb{R} \rightarrow S^1$, without invoking the general theory of covering spaces: the only ingredients are the compactness of I and of $I \times I$ (through the Lebesgue number), the pasting lemma and the discrete structure of the fibre $2\pi\mathbb{Z}$.

Definition 12.4: Lifting. Let $f : Y \rightarrow S^1$ be continuous. A **lifting** of f is a continuous map $\tilde{f} : Y \rightarrow \mathbb{R}$ such that $E \circ \tilde{f} = f$, i.e. $f(y) = e^{i\tilde{f}(y)}$ for every $y \in Y$. In the case $Y = I$ one speaks of the lifting of a path; the value $\tilde{f}(y)$ is also called the **unwrapped phase** of f at y .

Lemma 12.3: Pasting lemma. Let $Y = A_1 \cup \dots \cup A_m$ with $A_1, \dots, A_m$ closed in Y , and let $g_k : A_k \rightarrow Z$ be continuous with $g_k = g_l$ on $A_k \cap A_l$ for all k, l . Then the function $g : Y \rightarrow Z$ defined by $g|_{A_k} = g_k$ is well defined and continuous.

Proof. Well-definedness is the compatibility hypothesis. For continuity, let $C \subseteq Z$ be closed. Then

$$g^{-1}(C) = \bigcup_{k=1}^m (g^{-1}(C) \cap A_k) = \bigcup_{k=1}^m g_k^{-1}(C).$$

Each $g_k^{-1}(C)$ is closed in A_k by continuity of g_k , and A_k is closed in Y , so $g_k^{-1}(C)$ is closed in Y . A finite union of closed sets is closed, so $g^{-1}(C)$ is closed and g is continuous. $\square$

Lemma 12.4: Lebesgue number. *Let (X, d) be a compact metric space and let $\mathcal{U}$ be an open cover of it. Then there is $\delta > 0$ (a **Lebesgue number** for $\mathcal{U}$) such that every subset $B \subseteq X$ with $\text{diam } B < \delta$ is contained in some element of $\mathcal{U}$.*

Proof. For every $x \in X$ there is $U_x \in \mathcal{U}$ with $x \in U_x$, and since U_x is open there is $\varepsilon_x > 0$ with $B(x, 2\varepsilon_x) \subseteq U_x$. The family $\{B(x, \varepsilon_x)\}_{x \in X}$ is an open cover of X ; by compactness there are $x_1, \dots, x_m$ with

$$X = \bigcup_{i=1}^m B(x_i, \varepsilon_{x_i}).$$

Set $\delta = \min\{\varepsilon_{x_1}, \dots, \varepsilon_{x_m}\} > 0$ (the minimum of a finite set of positive numbers). Now let $B \subseteq X$ be non-empty with $\text{diam } B < \delta$ and let $b \in B$. There is i with $b \in B(x_i, \varepsilon_{x_i})$. For every $a \in B$,

$$d(a, x_i) \leq d(a, b) + d(b, x_i) < \delta + \varepsilon_{x_i} \leq 2\varepsilon_{x_i},$$

so $B \subseteq B(x_i, 2\varepsilon_{x_i}) \subseteq U_{x_i} \in \mathcal{U}$. If $B = \emptyset$ the statement is trivial. $\square$

Lemma 12.5: Uniqueness of the lifting on a connected space. *Let Y be connected and let $\tilde{f}_1, \tilde{f}_2 : Y \rightarrow \mathbb{R}$ be two liftings of the same map $f : Y \rightarrow S^1$. If $\tilde{f}_1(y_0) = \tilde{f}_2(y_0)$ for some $y_0 \in Y$, then $\tilde{f}_1 = \tilde{f}_2$.*

Proof. Set $d = \tilde{f}_1 - \tilde{f}_2 : Y \rightarrow \mathbb{R}$, continuous. For every y , $e^{i\tilde{f}_1(y)} = f(y) = e^{i\tilde{f}_2(y)}$, so $e^{id(y)} = 1$ and $d(y) \in 2\pi\mathbb{Z}$. Hence $d(Y) \subseteq 2\pi\mathbb{Z}$. But $d(Y)$ is connected (continuous image of a connected space) and the connected subsets of $2\pi\mathbb{Z}$ — which is discrete — are the singletons and the empty set: indeed, if $2\pi n \neq 2\pi m$ both belonged to $d(Y)$, taking $c = \pi(n + m)$ we would get a partition of $d(Y)$ into the two non-empty disjoint open sets $d(Y) \cap (-\infty, c)$ and $d(Y) \cap (c, +\infty)$ (no element of $2\pi\mathbb{Z}$ equals c when $n + m$ is odd; if $n + m$ is even take $c = \pi(n + m) + \pi = \pi(n + m + 1)$, which is not a multiple of 2π because $n + m + 1$ is odd), contradicting connectedness. Hence d is constant, and it equals $d(y_0) = 0$: $\tilde{f}_1 = \tilde{f}_2$. $\square$

Lemma 12.6: Path lifting (R15.4). *Let $\gamma : I \rightarrow S^1$ be a path and let $a \in \mathbb{R}$ with $E(a) = \gamma(0)$. Then there is one and only one lifting $\tilde{\gamma} : I \rightarrow \mathbb{R}$ of γ with $\tilde{\gamma}(0) = a$.*

Proof. Uniqueness. I is connected, so this follows from Lemma 12.5.

Step 1 — an adapted subdivision. The family $\{\gamma^{-1}(U_j)\}_{j=1,\dots,4}$, with the U_j of Lemma 12.2, is an open cover of I (the U_j cover S^1 and γ is continuous). I is metric and compact, so by Lemma 12.4 there is a Lebesgue number $\delta > 0$. Choose $m \in \mathbb{N}$ with $1/m < \delta$ and set $t_k = k/m$ for $k = 0, \dots, m$. Each interval $I_k = [t_{k-1}, t_k]$ has diameter $1/m < \delta$, hence $I_k \subseteq \gamma^{-1}(U_{j(k)})$ for a suitable index $j(k)$, that is,

$$\gamma(I_k) \subseteq U_{j(k)} \quad (k = 1, \dots, m).$$

Step 2 — construction by induction. We build by induction on k continuous functions $g_k : I_k \rightarrow \mathbb{R}$ with $E \circ g_k = \gamma|_{I_k}$ and $g_k(t_{k-1}) = g_{k-1}(t_{k-1})$ (with the convention $g_0(t_0) = a$). Let $k \geq 1$ and let the value $b_{k-1} := g_{k-1}(t_{k-1})$ be known (for $k = 1$, $b_0 = a$), satisfying $E(b_{k-1}) = \gamma(t_{k-1})$. Since $\gamma(t_{k-1}) \in U_{j(k)}$, the number b_{k-1} belongs to $E^{-1}(U_{j(k)}) = \bigsqcup_n (J_{j(k)} + 2\pi n)$ (Theorem 12.4), hence to one and only one sheet $V = J_{j(k)} + 2\pi n_k$. Set

$$g_k = (E|_V)^{-1} \circ \gamma|_{I_k} = \psi_{j(k)} \circ \gamma|_{I_k} + 2\pi n_k,$$

a composition of continuous functions, hence continuous; and $E \circ g_k = \gamma|_{I_k}$ because $E|_V$ is bijective onto $U_{j(k)}$. Finally $g_k(t_{k-1}) = (E|_V)^{-1}(\gamma(t_{k-1})) = b_{k-1}$ because $b_{k-1} \in V$ and $E(b_{k-1}) = \gamma(t_{k-1})$.

Step 3 — pasting. The I_k are closed in I , their union is I , and two of them meet in at most one point: $I_k \cap I_{k+1} = \{t_k\}$ and $I_k \cap I_l = \emptyset$ if $|k - l| \geq 2$. At the common points the g_k agree by construction. By Lemma 12.3 the function $\tilde{\gamma}$ defined by $\tilde{\gamma}|_{I_k} = g_k$ is continuous; it satisfies $E \circ \tilde{\gamma} = \gamma$ and $\tilde{\gamma}(0) = g_1(t_0) = a$. $\square$

Lemma 12.7: Homotopy lifting. Let $F : I \times I \rightarrow S^1$ be continuous and let $a \in \mathbb{R}$ with $E(a) = F(0, 0)$. Then there is one and only one continuous lifting $\tilde{F} : I \times I \rightarrow \mathbb{R}$ of F with $\tilde{F}(0, 0) = a$.

Proof. Uniqueness. $I \times I$ is connected (it is convex, hence path connected), and Lemma 12.5 applies.

Step 1 — adapted grid. $I \times I$ is metric and compact (closed and bounded in $\mathbb{R}^2$, Heine–Borel); $\{F^{-1}(U_j)\}_{j=1,\dots,4}$ is an open cover of it. Let $\delta > 0$ be a Lebesgue number (Lemma 12.4) and choose m with $\sqrt{2}/m < \delta$. The small squares

$$Q_{k,l} = \left[\frac{k-1}{m}, \frac{k}{m}\right] \times \left[\frac{l-1}{m}, \frac{l}{m}\right], \quad k, l = 1, \dots, m,$$

have diameter $\sqrt{2}/m < \delta$, hence $F(Q_{k,l}) \subseteq U_{j(k,l)}$ for a suitable index.

Step 2 — ordering and induction. Order the squares row by row: $Q_{1,1}, Q_{2,1}, \dots, Q_{m,1}, Q_{1,2}, \dots, Q_{m,m}$, and call this sequence $R_1, R_2, \dots, R_{m^2}$. Let $A_r = R_1 \cup \dots \cup R_r$. We build by induction on r a continuous map $G_r : A_r \rightarrow \mathbb{R}$ with $E \circ G_r = F|_{A_r}$ and $G_r(0, 0) = a$, extending the previous one.

Base $r = 1$. $R_1 = Q_{1,1}$ contains $(0, 0)$ and $F(R_1) \subseteq U$ with $U = U_{j(1,1)}$. The point a lies in one and only one sheet V over U (Theorem 12.4), because $E(a) = F(0, 0) \in U$. Set $G_1 = (E|_V)^{-1} \circ F|_{R_1}$: continuous, lifting $F|_{R_1}$, with $G_1(0, 0) = a$.

Inductive step. Let $r \geq 2$, let $R = R_r$ be the current square and $C = A_{r-1} \cap R$. Because of the row-by-row construction, C is: the left edge of R , if R is not the first of its row and lies in the first row; the bottom edge of R , if R is the first of its row (with row index ≥ 2); the union of the left edge and of the bottom edge, otherwise. In all cases C is non-empty and *connected*: in the third case the two edges are segments meeting at the lower-left vertex of R , and the union of two connected sets with a common point is connected.

Let $U = U_{j(k,l)}$ with $F(R) \subseteq U$, and let $c \in C$. The value $G_{r-1}(c)$ lies in one and only one sheet V over U . Set $g = (E|_V)^{-1} \circ F|_R$, continuous on R , with $E \circ g = F|_R$ and $g(c) = G_{r-1}(c)$. On C , both $g|_C$ and $G_{r-1}|_C$ are continuous liftings of $F|_C$ agreeing at c ; since C is connected, by Lemma 12.5 they agree on all of C . The sets A_{r-1} and R are closed in A_r (finite unions of closed subsets of $\mathbb{R}^2$ intersected with A_r), so by Lemma 12.3 the function G_r equal to G_{r-1} on A_{r-1} and to g on R is well defined and continuous, and lifts $F|_{A_r}$.

Step 3 — conclusion. $A_{m^2} = I \times I$, and $\tilde{F} = G_{m^2}$ is the required lifting. $\square$

Corollary 12.2: Path homotopies lift to path homotopies. Let $F : I \times I \rightarrow S^1$ be a path homotopy, i.e. with $F(0, u) = z_0$ and $F(1, u) = z_1$ constant in u . Let $\tilde{F}$ be the lifting of Lemma 12.7. Then $u \mapsto \tilde{F}(0, u)$ and $u \mapsto \tilde{F}(1, u)$ are constant; in particular the lifted paths $\tilde{\gamma}_u = \tilde{F}(\cdot, u)$ all have the same endpoints.

Proof. The map $u \mapsto \tilde{F}(0, u)$ is continuous and lifts the constant path $u \mapsto z_0$. The constant function $u \mapsto \tilde{F}(0, 0)$ is also a lifting of the same constant path, and the two agree at $u = 0$. Since I is connected, by Lemma 12.5 they agree everywhere: $\tilde{F}(0, u) = \tilde{F}(0, 0)$ for every u . The same argument applied to $u \mapsto \tilde{F}(1, u)$ gives the second assertion. $\square$

Corollary 12.3: Lifting of maps defined on $\mathbb{R}$. Let $f : \mathbb{R} \rightarrow S^1$ be continuous and let $a \in \mathbb{R}$ with $E(a) = f(0)$. Then there is one and only one continuous lifting $\tilde{f} : \mathbb{R} \rightarrow \mathbb{R}$ with $\tilde{f}(0) = a$.

Proof. For every $n \in \mathbb{N}$, the restriction of f to $[-n, n]$ is a path up to the affine reparametrisation $s \mapsto -n + 2ns$ of I onto $[-n, n]$; by Lemma 12.6 applied first to $f|_{[0, n]}$ (with initial datum a at 0) and then to $f|_{[-n, 0]}$ (traversed backwards, with the same datum at 0), we obtain a continuous lifting $h_n : [-n, n] \rightarrow \mathbb{R}$ with $h_n(0) = a$. For $n < n'$, the restrictions $h_{n'}|_{[-n, n]}$ and h_n are liftings of the same map on a connected set and agree at 0, hence agree everywhere (Lemma 12.5). One then defines $\tilde{f}(t) = h_n(t)$ for any $n \geq |t|$: the definition does not depend on n , and $\tilde{f}$ is continuous because it is continuous on every $(-n, n)$, and these are open and cover $\mathbb{R}$. Uniqueness follows from Lemma 12.5, $\mathbb{R}$ being connected. $\square$

12.5. The winding number

Definition 12.5: Winding number of a loop in S^1 . Let $\gamma : I \rightarrow S^1$ be a loop (i.e. $\gamma(0) = \gamma(1)$) and let $\tilde{\gamma}$ be a lifting of γ (Lemma 12.6). The **winding number** (or index, or degree) of γ is

$$w(\gamma) = \frac{\tilde{\gamma}(1) - \tilde{\gamma}(0)}{2\pi}.$$

Theorem 12.5: The winding number is an integer invariant under homotopy (R15.5). Let $\gamma : I \rightarrow S^1$ be a loop. Then:

- (i) $w(\gamma) \in \mathbb{Z}$ and does not depend on the chosen lifting;
- (ii) if $\gamma \simeq \gamma'$ as paths (homotopy with fixed endpoints), then $w(\gamma) = w(\gamma')$;
- (iii) $w(\gamma \cdot \gamma') = w(\gamma) + w(\gamma')$ for loops with the same base point, where $(\gamma \cdot \gamma')(s) = \gamma(2s)$ for $s \leq \frac{1}{2}$ and $\gamma'(2s - 1)$ for $s \geq \frac{1}{2}$;
- (iv) $w(\bar{\gamma}) = -w(\gamma)$, where $\bar{\gamma}(s) = \gamma(1 - s)$, and $w(\text{constant}) = 0$;
- (v) $w(\omega_n) = n$, where $\omega_n(s) = e^{2\pi i n s}$.

Proof. (i) From $E(\tilde{\gamma}(1)) = \gamma(1) = \gamma(0) = E(\tilde{\gamma}(0))$ we get $\tilde{\gamma}(1) - \tilde{\gamma}(0) \in 2\pi\mathbb{Z}$ (Theorem 12.4, Step 1), hence $w(\gamma) \in \mathbb{Z}$. If $\tilde{\gamma}_1, \tilde{\gamma}_2$ are two liftings, their difference is constant and equal to some $2\pi n$ (proof of Lemma 12.5: the difference is continuous with values in $2\pi\mathbb{Z}$ on a connected set), hence $\tilde{\gamma}_2(1) - \tilde{\gamma}_2(0) = (\tilde{\gamma}_1(1) + 2\pi n) - (\tilde{\gamma}_1(0) + 2\pi n) = \tilde{\gamma}_1(1) - \tilde{\gamma}_1(0)$: the value of w does not change.

(ii) Let $F : I \times I \rightarrow S^1$ be a path homotopy with $F(\cdot, 0) = \gamma$, $F(\cdot, 1) = \gamma'$, $F(0, u) = F(1, u) = z_0$ for every u (the endpoints agree because the loops have the same base point). Let $\tilde{F}$ be the lifting with $\tilde{F}(0, 0) = a$ (Lemma 12.7). For every u , the map $\tilde{\gamma}_u = \tilde{F}(\cdot, u)$ is a lifting of the loop $F(\cdot, u)$, so by (i)

$$w(F(\cdot, u)) = \frac{\tilde{F}(1, u) - \tilde{F}(0, u)}{2\pi}.$$

By Corollary 12.2, $\tilde{F}(0, u)$ and $\tilde{F}(1, u)$ are constant in u ; hence the right-hand side does not depend on u , and taking $u = 0, 1$ gives $w(\gamma) = w(\gamma')$.

(iii) Let $\tilde{\gamma}$ be the lifting of γ with $\tilde{\gamma}(0) = a$ and $\tilde{\gamma}'$ the lifting of γ' with $\tilde{\gamma}'(0) = \tilde{\gamma}(1)$ (legitimate because $E(\tilde{\gamma}(1)) = \gamma(1) = \gamma'(0)$). The function

$$\eta(s) = \begin{cases} \tilde{\gamma}(2s), & 0 \leq s \leq \frac{1}{2}, \\ \tilde{\gamma}'(2s - 1), & \frac{1}{2} \leq s \leq 1, \end{cases}$$

is well defined at $s = \frac{1}{2}$ (both expressions give $\tilde{\gamma}(1)$) and continuous by Lemma 12.3; moreover $E \circ \eta = \gamma \cdot \gamma'$. Hence

$$w(\gamma \cdot \gamma') = \frac{\eta(1) - \eta(0)}{2\pi} = \frac{\tilde{\gamma}'(1) - \tilde{\gamma}'(0)}{2\pi} = \frac{(\tilde{\gamma}'(1) - \tilde{\gamma}'(0)) + (\tilde{\gamma}(1) - \tilde{\gamma}(0))}{2\pi} = w(\gamma') + w(\gamma).$$

(iv) If $\tilde{\gamma}$ lifts γ , then $s \mapsto \tilde{\gamma}(1-s)$ lifts $\bar{\gamma}$, and the difference of the endpoints changes sign. For the constant loop $\gamma \equiv z_0$ a lifting is the constant a , and $w = 0$.

(v) The path $\tilde{\omega}_n(s) = 2\pi ns$ is continuous and $E(\tilde{\omega}_n(s)) = e^{2\pi i ns} = \omega_n(s)$: it is a lifting, and $w(\omega_n) = (2\pi n - 0)/2\pi = n$. $\square$

Definition 12.6: Winding number of a loop in $\mathbb{C} \setminus \{0\}$. Let $\gamma : I \rightarrow \mathbb{C} \setminus \{0\}$ be a loop. Its **winding number about the origin** is

$$w(\gamma) = w\left(\frac{\gamma}{|\gamma|}\right),$$

where $\gamma/|\gamma| : I \rightarrow S^1$ is a loop in S^1 (it is continuous because $|\gamma|$ is continuous and never zero). For a point $z_0 \notin \gamma(I)$ one sets $w(\gamma, z_0) = w(\gamma - z_0)$.

Theorem 12.6: Analytic form of the winding number. Let $\gamma : [0, 1] \rightarrow \mathbb{C} \setminus \{0\}$ be a loop of class C^1 (i.e. γ differentiable with continuous derivative and $\gamma(0) = \gamma(1)$, $\gamma'(0) = \gamma'(1)$). Then

$$\frac{1}{2\pi i} \oint_{\gamma} \frac{dz}{z} = \frac{1}{2\pi i} \int_0^1 \frac{\gamma'(t)}{\gamma(t)} dt = w(\gamma) \in \mathbb{Z}.$$

Proof. Step 1 — a primitive of the logarithm along γ . The function $t \mapsto \gamma'(t)/\gamma(t)$ is continuous on $[0, 1]$ (a quotient of continuous functions with non-vanishing denominator). Set

$$h(t) = \int_0^t \frac{\gamma'(u)}{\gamma(u)} du,$$

which is of class C^1 with $h' = \gamma'/\gamma$ and $h(0) = 0$ (fundamental theorem of calculus).

Step 2 — $\gamma(t) = \gamma(0)e^{h(t)}$. Consider $\varphi(t) = \gamma(t)e^{-h(t)}$. It is differentiable and

$$\varphi'(t) = \gamma'(t)e^{-h(t)} - \gamma(t)h'(t)e^{-h(t)} = \gamma'(t)e^{-h(t)} - \gamma(t)\frac{\gamma'(t)}{\gamma(t)}e^{-h(t)} = 0.$$

Since $[0, 1]$ is connected and $\varphi' \equiv 0$ (real and imaginary parts have zero derivative), φ is constant: $\varphi(t) = \varphi(0) = \gamma(0)$. Hence $\gamma(t) = \gamma(0)e^{h(t)}$.

Step 3 — the integral lies in $2\pi i\mathbb{Z}$. From $\gamma(1) = \gamma(0) \neq 0$ we get $e^{h(1)} = 1$, hence $h(1) \in 2\pi i\mathbb{Z}$: writing $h(1) = i\theta$ with θ real (because $|e^{h(1)}| = e^{\operatorname{Re} h(1)} = 1$ forces $\operatorname{Re} h(1) = 0$), we have $e^{i\theta} = 1$ and therefore $\theta \in 2\pi\mathbb{Z}$. Hence $\frac{1}{2\pi i} \int_0^1 \frac{\gamma'}{\gamma} dt = \frac{h(1)}{2\pi i} \in \mathbb{Z}$.

Step 4 — it agrees with the topological winding number. Set $\rho(t) = |\gamma(t)| > 0$ and $\beta(t) = \gamma(t)/\rho(t) \in S^1$. From $\gamma = \gamma(0)e^h$ we get $\rho(t) = |\gamma(0)|e^{\operatorname{Re} h(t)}$ and

$$\beta(t) = \frac{\gamma(0)}{|\gamma(0)|} e^{i\operatorname{Im} h(t)}.$$

Choosing $a \in \mathbb{R}$ with $e^{ia} = \gamma(0)/|\gamma(0)|$ (possible by surjectivity of E), the function

$$\tilde{\beta}(t) = a + \operatorname{Im} h(t)$$

is continuous and satisfies $E(\tilde{\beta}(t)) = \beta(t)$: it is a lifting of β . Hence

$$w(\gamma) = w(\beta) = \frac{\tilde{\beta}(1) - \tilde{\beta}(0)}{2\pi} = \frac{\operatorname{Im} h(1)}{2\pi} = \frac{h(1)}{2\pi i}$$

(the last equality because $h(1)$ is purely imaginary, by Step 3). This concludes the proof. $\square$

Remark 12.4: The bridge with Cauchy. Theorem 12.6 is the point where the topology of the circle enters complex analysis. In Cauchy's integral formula and in the residue theorem (Volume II, Chapter 3, and Chapter 15) exactly the expression

$$\operatorname{Ind}_{\gamma}(z_0) = \frac{1}{2\pi i} \oint_{\gamma} \frac{dz}{z - z_0}$$

appears, called the index (or winding number) of γ about z_0 : the proof just given shows that it is an integer and that it is the topological invariant $w(\gamma - z_0)$, not an arbitrary number. This is why Cauchy's formula $f(z_0) \operatorname{Ind}_{\gamma}(z_0) = \frac{1}{2\pi i} \oint_{\gamma} \frac{f(z)}{z - z_0} dz$ counts turns: the integer factor in front of $f(z_0)$ is the degree of the loop. The topological form (Definition 12.5) is however more general, because it requires no regularity: it holds for merely continuous loops, where the integral makes no sense.

Lemma 12.8: Dominant term lemma. Let $a, b \in \mathbb{C}$ with $|b| > |a|$ and $n, m \in \mathbb{Z}$. The loop

$$\gamma(t) = a e^{2\pi i n t} + b e^{2\pi i m t}, \quad t \in I,$$

never vanishes and has $w(\gamma) = m$.

Proof. For every t , $|\gamma(t)| \geq |b e^{2\pi i m t}| - |a e^{2\pi i n t}| = |b| - |a| > 0$: γ does not vanish. Consider

$$H(t, u) = u a e^{2\pi i n t} + b e^{2\pi i m t}, \quad (t, u) \in I \times I.$$

H is continuous and never vanishes, by the same estimate: $|H(t, u)| \geq |b| - u|a| \geq |b| - |a| > 0$. Moreover $H(0, u) = ua + b = H(1, u)$ for every u , so $H/|H| : I \times I \rightarrow S^1$ is a path homotopy of loops between $\gamma/|\gamma|$ (for $u = 1$) and $\beta(t) = b e^{2\pi i m t}/|b|$ (for $u = 0$). By Theorem 12.5(ii), $w(\gamma) = w(\beta)$. Finally $\beta(t) = e^{i\varphi_0} e^{2\pi i m t}$ with $e^{i\varphi_0} = b/|b|$, which lifts to $\varphi_0 + 2\pi m t$, so $w(\beta) = m$. $\square$

Example 12.2: Two loops and their winding numbers, checked twice. Consider

$$\gamma_1(t) = e^{6\pi i t} + \frac{1}{2}e^{-4\pi i t}, \quad \gamma_2(t) = e^{4\pi i t} + 2e^{-2\pi i t}, \quad t \in [0, 1].$$

Closed formula. For γ_1 the dominant term is $e^{6\pi i t} = e^{2\pi i \cdot 3t}$ (coefficient $1 > \frac{1}{2}$), hence $w(\gamma_1) = 3$ by Lemma 12.8. For γ_2 the dominant term is $2e^{-2\pi i t} = 2e^{2\pi i(-1)t}$ (coefficient $2 > 1$), hence $w(\gamma_2) = -1$.

Independent numerical check. Sampling $N + 1$ equispaced points and (a) unwrapping the phase, (b) approximating $\frac{1}{2\pi i} \int_0^1 \gamma'/\gamma dt$ by the trapezoidal rule with centred difference quotients for the derivative:

loop	N	unwrapped phase	integral
γ_1	200	3.000000	2.995561
γ_1	2 000	3.000000	2.999956
γ_1	20 000	3.000000	2.999999
γ_2	200	-1.000000	-0.999836
γ_2	2 000	-1.000000	-0.999998
γ_2	20 000	-1.000000	-1.000000

The two methods agree with the closed formula. ✓ Note the difference in nature: the unwrapped phase gives the *exact* integer already with $N = 200$, because it counts discrete jumps; the integral converges only with order $O(N^{-2})$, because it is a quadrature. This is the numerical translation of the fact that w is a topological invariant and not a metric quantity.

12.6. The fundamental group of S^1

Definition 12.7: Path homotopy and fundamental group. Let $\gamma, \gamma' : I \rightarrow X$ be paths with the same endpoints ($\gamma(0) = \gamma'(0) = x_0$, $\gamma(1) = \gamma'(1) = x_1$). A **path homotopy** between them is a continuous map $F : I \times I \rightarrow X$ with

$$F(s, 0) = \gamma(s), \quad F(s, 1) = \gamma'(s), \quad F(0, u) = x_0, \quad F(1, u) = x_1$$

for all $s, u \in I$. One writes $\gamma \simeq \gamma'$. The set of homotopy classes of loops based at x_0 , with the operation induced by concatenation $[\gamma][\gamma'] = [\gamma \cdot \gamma']$, is called the **fundamental group** $\pi_1(X, x_0)$.

Proposition 12.1: $\pi_1(X, x_0)$ is a group. The relation $\simeq$ is an equivalence relation; concatenation descends to the quotient; and $\pi_1(X, x_0)$ with that operation is a group, with identity the class of the constant loop c_{x_0} and inverse $[\gamma]^{-1} = [\bar{\gamma}]$, $\bar{\gamma}(s) = \gamma(1 - s)$.

Proof. Step 1 — $\simeq$ is an equivalence relation. *Reflexive:* $F(s, u) = \gamma(s)$. *Symmetric:* if F is a homotopy from γ to γ' , then $F(s, 1 - u)$ goes from γ' to γ . *Transitive:* given F from γ to γ' and G from γ' to γ'' , set $H(s, u) = F(s, 2u)$ for $u \leq \frac{1}{2}$ and $G(s, 2u - 1)$ for $u \geq \frac{1}{2}$; the two definitions agree at $u = \frac{1}{2}$ (both give $\gamma'(s)$) and $I \times [0, \frac{1}{2}]$, $I \times [\frac{1}{2}, 1]$ are closed, so H is continuous by Lemma 12.3.

Step 2 — concatenation descends to the quotient. If F is a homotopy from γ to γ_1 and G from δ to δ_1 (with $\gamma(1) = \delta(0)$), set $H(s, u) = F(2s, u)$ for $s \leq \frac{1}{2}$ and $G(2s - 1, u)$ for $s \geq \frac{1}{2}$: at $s = \frac{1}{2}$ both equal $\gamma(1) = \delta(0)$, which does not depend on u because the homotopies have fixed endpoints; by Lemma 12.3 H is continuous and is a path homotopy between $\gamma \cdot \delta$ and $\gamma_1 \cdot \delta_1$.

Step 3 — reparametrisations. Let $\varphi : I \rightarrow I$ be continuous with $\varphi(0) = 0$, $\varphi(1) = 1$. Then $\gamma \circ \varphi \simeq \gamma$: the homotopy is

$$H(s, u) = \gamma((1 - u)\varphi(s) + us),$$

continuous (composition of continuous maps, with argument in I because I is convex), with $H(\cdot, 0) = \gamma \circ \varphi$, $H(\cdot, 1) = \gamma$, $H(0, u) = \gamma(0)$ and $H(1, u) = \gamma(1)$.

Step 4 — associativity. One checks that $(\gamma \cdot \delta) \cdot \varepsilon = (\gamma \cdot (\delta \cdot \varepsilon)) \circ \varphi$ with

$$\varphi(s) = \begin{cases} \frac{s}{2}, & 0 \leq s \leq \frac{1}{2}, \\ s - \frac{1}{4}, & \frac{1}{2} \leq s \leq \frac{3}{4}, \\ 2s - 1, & \frac{3}{4} \leq s \leq 1, \end{cases}$$

which is continuous (the three expressions agree at the junction points: at $s = \frac{1}{2}$ they give $\frac{1}{4}$; at $s = \frac{3}{4}$ they give $\frac{1}{2}$), with $\varphi(0) = 0$, $\varphi(1) = 1$. By Step 3 the two concatenations are homotopic.

Step 5 — identity. $\gamma \cdot c_{x_1} = \gamma \circ \varphi$ with $\varphi(s) = 2s$ for $s \leq \frac{1}{2}$ and $\varphi(s) = 1$ for $s \geq \frac{1}{2}$: continuous, with $\varphi(0) = 0$ and $\varphi(1) = 1$. By Step 3, $\gamma \cdot c_{x_1} \simeq \gamma$; similarly $c_{x_0} \cdot \gamma \simeq \gamma$.

Step 6 — inverse. Set

$$H(s, u) = \begin{cases} \gamma(2s(1-u)), & 0 \leq s \leq \frac{1}{2}, \\ \gamma(2(1-s)(1-u)), & \frac{1}{2} \leq s \leq 1. \end{cases}$$

At $s = \frac{1}{2}$ both give $\gamma(1-u)$: H is well defined and continuous (Lemma 12.3). We have $H(s, 0) = (\gamma \cdot \bar{\gamma})(s)$, $H(s, 1) = \gamma(0) = x_0$ for every s , $H(0, u) = \gamma(0) = x_0$ and $H(1, u) = \gamma(0) = x_0$. Hence $\gamma \cdot \bar{\gamma} \simeq c_{x_0}$; exchanging the roles, $\bar{\gamma} \cdot \gamma \simeq c_{x_0}$. $\square$

Theorem 12.7: $\pi_1(S^1) \cong \mathbb{Z}$ (R15.6). The maps

$$\Phi : \pi_1(S^1, 1) \rightarrow \mathbb{Z}, \quad \Phi([\gamma]) = w(\gamma), \quad \Psi : \mathbb{Z} \rightarrow \pi_1(S^1, 1), \quad \Psi(n) = [\omega_n], \quad \omega_n(s) = e^{2\pi i n s},$$

are group homomorphisms, inverse to one another. In particular $\pi_1(S^1, 1) \cong \mathbb{Z}$ and it is infinite cyclic, generated by $[\omega_1]$.

Proof. **Step 1 — Φ is well defined and a homomorphism.** The number $w(\gamma)$ does not depend on the lifting (Theorem 12.5(i)) nor on the representative of the homotopy class (item (ii)); it is therefore a function on $\pi_1(S^1, 1)$. It is a homomorphism by item (iii): $\Phi([\gamma][\gamma']) = w(\gamma \cdot \gamma') = w(\gamma) + w(\gamma') = \Phi([\gamma]) + \Phi([\gamma'])$.

Step 2 — Ψ is a homomorphism. We show $\omega_n \cdot \omega_m \simeq \omega_{n+m}$. A lifting of $\omega_n \cdot \omega_m$ with initial value 0 is, by item (iii) of the proof of Theorem 12.5, the path η equal to $2\pi n \cdot 2s$ on $[0, \frac{1}{2}]$ and to $2\pi n + 2\pi m(2s - 1)$ on $[\frac{1}{2}, 1]$; the lifting of ω_{n+m} with initial value 0 is $s \mapsto 2\pi(n+m)s$. Both go from 0 to $2\pi(n+m)$, so the linear homotopy $L(s, u) = (1-u)\eta(s) + 2\pi(n+m)su$ is continuous, has fixed endpoints ($L(0, u) = 0$, $L(1, u) = 2\pi(n+m)$) and $E \circ L$ is a path homotopy between $\omega_n \cdot \omega_m$ and ω_{n+m} . Hence $\Psi(n)\Psi(m) = [\omega_n \cdot \omega_m] = [\omega_{n+m}] = \Psi(n+m)$.

Step 3 — $\Phi \circ \Psi = \text{id}_{\mathbb{Z}}$. This is item (v) of Theorem 12.5: $\Phi(\Psi(n)) = w(\omega_n) = n$. In particular Φ is surjective and Ψ is injective.

Step 4 — $\Psi \circ \Phi = \text{id}$. Let $[\gamma] \in \pi_1(S^1, 1)$ and $n = w(\gamma)$. Let $\tilde{\gamma}$ be the lifting with $\tilde{\gamma}(0) = 0$; then $\tilde{\gamma}(1) = 2\pi n$. The path $\tilde{\omega}_n(s) = 2\pi ns$ has the same endpoints. The linear homotopy

$$L(s, u) = (1-u)\tilde{\gamma}(s) + u2\pi ns$$

is continuous, with $L(0, u) = 0$ and $L(1, u) = 2\pi n$ for every u : it is a path homotopy in $\mathbb{R}$. Hence $E \circ L$ is a path homotopy in S^1 between $\gamma = E \circ \tilde{\gamma}$ and $\omega_n = E \circ \tilde{\omega}_n$ (the endpoints are $E(0) = 1$ and $E(2\pi n) = 1$, constant). Therefore $[\gamma] = [\omega_n] = \Psi(n) = \Psi(\Phi([\gamma]))$.

Step 5 — conclusion. Φ and Ψ are mutually inverse homomorphisms, hence isomorphisms. Since $\Psi(n) = [\omega_1]^n$ (Step 2 with induction on n and $\Psi(-1) = [\omega_{-1}] = [\bar{\omega}_1] = [\omega_1]^{-1}$), the group is cyclic generated by $[\omega_1]$, and infinite because Φ is injective. $\square$

Corollary 12.4: *There is no retraction $D^2 \rightarrow S^1$. Let $D^2 = \{z \in \mathbb{C} : |z| \leq 1\}$. There is no continuous map $r : D^2 \rightarrow S^1$ with $r(z) = z$ for every $z \in S^1$.*

Proof. Suppose r exists and consider the loop $\omega_1(s) = e^{2\pi is}$ in S^1 . In D^2 the loop ω_1 is path homotopic to the constant 1: the linear homotopy

$$K(s, u) = (1 - u)\omega_1(s) + u \cdot 1$$

takes values in D^2 because D^2 is convex, and has fixed endpoints because $K(0, u) = K(1, u) = (1 - u) + u = 1$. Composing with r , the map $r \circ K$ is a path homotopy in S^1 between $r \circ \omega_1 = \omega_1$ (because r is the identity on S^1) and the constant loop $r(1) = 1$. Hence $[\omega_1] = [c_1]$ in $\pi_1(S^1, 1)$, that is, $1 = w(\omega_1) = w(c_1) = 0$ by Theorem 12.5: absurd. $\square$

Corollary 12.5: *Brouwer fixed point theorem in dimension 2. Every continuous map $h : D^2 \rightarrow D^2$ has a fixed point.*

Proof. Suppose $h(x) \neq x$ for every $x \in D^2$. Define $r(x)$ as the point where the ray issuing from $h(x)$ and passing through x meets S^1 . Explicitly, setting $v(x) = \frac{x - h(x)}{|x - h(x)|}$ (well defined and continuous because $x \neq h(x)$), one seeks $\lambda \geq 0$ with $|x + \lambda v(x)| = 1$, that is,

$$\lambda^2 + 2\lambda\langle x, v(x) \rangle + |x|^2 - 1 = 0,$$

whose unique non-negative root is

$$\lambda(x) = -\langle x, v(x) \rangle + \sqrt{\langle x, v(x) \rangle^2 + 1 - |x|^2}$$

(the radicand is ≥ 0 because $|x| \leq 1$; the root is ≥ 0 because the product of the two roots is $|x|^2 - 1 \leq 0$). The function λ is continuous, so $r(x) = x + \lambda(x)v(x)$ is continuous with values in S^1 . If $x \in S^1$, then $|x| = 1$ and $\lambda(x) = -\langle x, v \rangle + |\langle x, v \rangle|$: we have $\langle x, v(x) \rangle \geq 0$, because $\langle x, x - h(x) \rangle = 1 - \langle x, h(x) \rangle \geq 1 - |x||h(x)| \geq 0$, hence $\lambda(x) = 0$ and $r(x) = x$. Thus r is a retraction of D^2 onto S^1 , which does not exist by Corollary 12.4: absurd. Hence h has a fixed point. $\square$

Remark 12.5: *What we import: $\pi_1(S^n)$ for $n \geq 2$. For $n \geq 2$ one has $\pi_1(S^n) = 0$: every loop on a sphere of dimension at least two contracts to a point. This statement is here **imported** and not proved. The proof (Hatcher, Algebraic Topology, Proposition 1.14, p. 35) needs two ingredients that have not been built in this chapter: the lemma on decomposing loops with respect to an open cover (Hatcher, Lemma 1.15, p. 35), which is the combinatorial core of the Seifert–van Kampen theorem; and the fact that a loop in S^n can be homotoped to a non-surjective one, so as to contract it inside $S^n \setminus \{p\} \cong \mathbb{R}^n$ via stereographic projection. What is missing, concretely, is exactly Lemma 1.15 and the approximation argument that avoids a point. The difference from S^1 is not technical but substantial: $\pi_1(S^1) = \mathbb{Z} \neq 0$, and it is this inequality that makes the circle the only sphere with a non-trivial fundamental group. Volume IV, which devotes a chapter to algebraic topology, proves van Kampen and deduces the statement.*

12.7. The degree of maps $S^1 \rightarrow S^1$

Definition 12.8: Degree of a map $S^1 \rightarrow S^1$. Let $f : S^1 \rightarrow S^1$ be continuous. The associated loop is $\gamma_f : I \rightarrow S^1$, $\gamma_f(s) = f(e^{2\pi is})$ (it is a loop because $\gamma_f(0) = f(1) = \gamma_f(1)$). The **degree** of f is

$$\deg f = w(\gamma_f) \in \mathbb{Z}.$$

Proposition 12.2: The lifted map and its functional equation. Let $f : S^1 \rightarrow S^1$ be continuous. Then there is a continuous $u : \mathbb{R} \rightarrow \mathbb{R}$ with

$$f(e^{it}) = e^{iu(t)} \quad \text{for every } t \in \mathbb{R}, \quad \text{and} \quad u(t + 2\pi) = u(t) + 2\pi \deg f \quad \text{for every } t.$$

The function u is unique up to an additive constant in $2\pi\mathbb{Z}$.

Proof. **Step 1 — existence of u .** The map $g : \mathbb{R} \rightarrow S^1$, $g(t) = f(e^{it})$, is continuous (composition of continuous maps). By Corollary 12.3 there is a continuous $u : \mathbb{R} \rightarrow \mathbb{R}$ with $E \circ u = g$, i.e. $f(e^{it}) = e^{iu(t)}$, and u is unique once $u(0)$ is fixed; two choices of $u(0)$ in the fibre differ by a multiple of 2π , whence uniqueness up to $2\pi\mathbb{Z}$ (Lemma 12.5).

Step 2 — the functional equation. Set $d(t) = u(t + 2\pi) - u(t)$, continuous. From $e^{iu(t+2\pi)} = f(e^{i(t+2\pi)}) = f(e^{it}) = e^{iu(t)}$ we get $e^{id(t)} = 1$, i.e. $d(t) \in 2\pi\mathbb{Z}$ for every t . Since $\mathbb{R}$ is connected and $2\pi\mathbb{Z}$ discrete, d is constant (same argument as in Lemma 12.5): $d \equiv 2\pi k$ for some $k \in \mathbb{Z}$.

Step 3 — $k = \deg f$. The path $s \mapsto u(2\pi s)$, $s \in I$, is continuous and lifts $s \mapsto f(e^{2\pi is}) = \gamma_f(s)$. Hence

$$\deg f = w(\gamma_f) = \frac{u(2\pi) - u(0)}{2\pi} = \frac{d(0)}{2\pi} = k.$$

□

Theorem 12.8: Classification of maps $S^1 \rightarrow S^1$ by degree (R15.7). Let $f, g : S^1 \rightarrow S^1$ be continuous. Then

$$f \simeq g \text{ (homotopic as maps, with no constraint on the base point)} \iff \deg f = \deg g.$$

Moreover, for every $n \in \mathbb{Z}$ the map $p_n(z) = z^n$ has $\deg p_n = n$. Hence

$$\deg : [S^1, S^1] \longrightarrow \mathbb{Z}$$

is a bijection between the set of free homotopy classes of maps $S^1 \rightarrow S^1$ and $\mathbb{Z}$.

Proof. **Step 1 — $\deg p_n = n$.** $\gamma_{p_n}(s) = (e^{2\pi is})^n = e^{2\pi ins} = \omega_n(s)$, hence $\deg p_n = w(\omega_n) = n$ by Theorem 12.5(v). In particular $\deg$ is surjective.

Step 2 — homotopic $\Rightarrow$ same degree. Let $H : S^1 \times I \rightarrow S^1$ be continuous with $H(\cdot, 0) = f$ and $H(\cdot, 1) = g$. Set $F(s, u) = H(e^{2\pi is}, u)$, continuous on $I \times I$, with $F(\cdot, 0) = \gamma_f$, $F(\cdot, 1) = \gamma_g$ and $F(0, u) = F(1, u)$ for every u (because $e^0 = e^{2\pi i} = 1$). Let $\tilde{F}$ be its lifting (Lemma 12.7). The function

$$u \mapsto \frac{\tilde{F}(1, u) - \tilde{F}(0, u)}{2\pi}$$

is continuous; it takes values in $\mathbb{Z}$ because $E(\tilde{F}(1, u)) = F(1, u) = F(0, u) = E(\tilde{F}(0, u))$; hence, I being connected, it is constant (same argument as in Lemma 12.5). For $u = 0$ it equals $w(\gamma_f) = \deg f$ and for $u = 1$ it equals $\deg g$: they are equal. *Note* that we did not require the homotopy to fix the base point: the degree is invariant under free homotopy too.

Step 3 — same degree $\Rightarrow$ homotopic. Let $\deg f = \deg g = n$ and let $u, v : \mathbb{R} \rightarrow \mathbb{R}$ be the lifted maps of Proposition 12.2, so that $f(e^{it}) = e^{iu(t)}$, $g(e^{it}) = e^{iv(t)}$ and

$$u(t + 2\pi) = u(t) + 2\pi n, \quad v(t + 2\pi) = v(t) + 2\pi n.$$

Set $L(t, \theta) = (1 - \theta)u(t) + \theta v(t)$, continuous on $\mathbb{R} \times I$. Then

$$L(t + 2\pi, \theta) = (1 - \theta)(u(t) + 2\pi n) + \theta(v(t) + 2\pi n) = L(t, \theta) + 2\pi n,$$

hence $e^{iL(t+2\pi, \theta)} = e^{iL(t, \theta)}$: the function $(t, \theta) \mapsto e^{iL(t, \theta)}$ is 2π -periodic in t . Define

$$H : S^1 \times I \rightarrow S^1, \quad H(e^{it}, \theta) = e^{iL(t, \theta)}.$$

It is well defined by the periodicity just proved. It is continuous: the map $q : \mathbb{R} \times I \rightarrow S^1 \times I$, $q(t, \theta) = (e^{it}, \theta)$, is continuous and surjective; its restriction to $[0, 2\pi] \times I$ is continuous and surjective from a compact space to a Hausdorff space, hence a quotient map by Lemma 12.1(iii); since $H \circ q = e^{iL}$ is continuous on $[0, 2\pi] \times I$, H is continuous. Finally $H(\cdot, 0) = f$ and $H(\cdot, 1) = g$. Hence $f \simeq g$.

Step 4 — conclusion. Step 2 says that $\deg$ is well defined on $[S^1, S^1]$ and Step 3 that it is injective; Step 1 that it is surjective. $\square$

Corollary 12.6: Extension to the disc and vanishing degree. For a continuous $f : S^1 \rightarrow S^1$ the following are equivalent: (a) $\deg f = 0$; (b) f is homotopic to a constant map; (c) f extends to a continuous map $F : D^2 \rightarrow S^1$.

Proof. (a) $\Rightarrow$ (b). The constant map $c(z) = 1$ has $\gamma_c \equiv 1$, so $\deg c = 0$; by Theorem 12.8, $f \simeq c$.

(b) $\Rightarrow$ (c). Let $H : S^1 \times I \rightarrow S^1$ with $H(\cdot, 0) = f$ and $H(z, 1) = z_1$ constant. Set

$$F(w) = \begin{cases} H\left(\frac{w}{|w|}, 1 - |w|\right), & w \neq 0, \\ z_1, & w = 0. \end{cases}$$

F is continuous on $D^2 \setminus \{0\}$ (composition of continuous maps); it is continuous at 0 because, as $w \rightarrow 0$, the second argument tends to 1 and $H(\cdot, 1) \equiv z_1$: precisely, given $\varepsilon > 0$, by uniform continuity of H on the compact set $S^1 \times I$ there is $\eta > 0$ such that $|H(z, \theta) - H(z, 1)| < \varepsilon$ if $|1 - \theta| < \eta$, hence $|F(w) - z_1| < \varepsilon$ if $|w| < \eta$. Finally for $|w| = 1$ we have $F(w) = H(w, 0) = f(w)$.

(c) $\Rightarrow$ (a). Let $F : D^2 \rightarrow S^1$ be continuous with $F|_{S^1} = f$. Then $H(z, \theta) = F((1 - \theta)z)$ is continuous on $S^1 \times I$, with $H(\cdot, 0) = f$ and $H(\cdot, 1) \equiv F(0)$ constant. Hence f is homotopic to a constant and, by Theorem 12.8, $\deg f = \deg(\text{constant}) = 0$. $\square$

Proposition 12.3: The degree is multiplicative. For continuous $f, g : S^1 \rightarrow S^1$ one has $\deg(f \circ g) = \deg f \cdot \deg g$.

Proof. Let $u, v : \mathbb{R} \rightarrow \mathbb{R}$ be the lifted maps of f and g (Proposition 12.2), with $u(t + 2\pi) = u(t) + 2\pi \deg f$ and $v(t + 2\pi) = v(t) + 2\pi \deg g$. Then

$$(f \circ g)(e^{it}) = f(e^{iv(t)}) = e^{iu(v(t))},$$

so $u \circ v$ is a lifted map of $f \circ g$ (it is continuous). Setting $m = \deg g$ and using the functional equation of v (for $m \geq 0$; for $m < 0$ use the same relation backwards),

$$v(t + 2\pi) = v(t) + 2\pi m \implies u(v(t + 2\pi)) = u(v(t) + 2\pi m) = u(v(t)) + 2\pi m \deg f,$$

where the last equality follows by applying $|m|$ times $u(s + 2\pi) = u(s) + 2\pi \deg f$. By the uniqueness of the integer in the functional equation (Proposition 12.2, Steps 2–3), $\deg(f \circ g) = m \deg f = \deg g \cdot \deg f$. $\square$

12.8. Panorama: hairy ball and Hopf fibration

The circle has two properties that higher-dimensional spheres lose or modify: it can be “combed” (S^1 has a nowhere-vanishing tangent field) and its maps are classified by a single integer. The next two subsections say what happens in higher dimension, and distinguish precisely what is proved here from what is merely reported.

Proposition 12.4: *S^1 can be combed.* The function $v : S^1 \rightarrow \mathbb{R}^2$, $v(x, y) = (-y, x)$, is continuous, tangent to S^1 at every point and never zero. Hence on S^1 there is a continuous tangent vector field that never vanishes.

Proof. v is linear, hence continuous. It is tangent: the tangent line to S^1 at $P = (x, y)$ is the line orthogonal to the radius OP , and $\langle (x, y), (-y, x) \rangle = -xy + yx = 0$. It never vanishes: $|v(x, y)|^2 = y^2 + x^2 = 1$, so $|v| = 1 \neq 0$ on all of S^1 . (In complex notation: $v(z) = iz$, the rotation of the radius by 90° .) $\square$

Remark 12.6: *What we import: the hairy ball theorem (panorama).* **Panorama.** On S^2 there is no continuous nowhere-vanishing tangent vector field; more generally S^n admits such a field if and only if n is odd (Hatcher, *Algebraic Topology*, Theorem 2.28, p. 135). The case $n = 1$ of the “if” part is exactly Proposition 12.4; the case $n = 2$ is the celebrated hairy ball theorem, whose meteorological reading is that at every instant there is at least one point of the globe where the horizontal wind vanishes.

The statement is here **imported**: it is not proved and it is not presented as a theorem of this treatise. The argument is short but uses a tool that this chapter does not build. Given a unit tangent field v on S^n , the homotopy $f_\theta(x) = (\cos \theta)x + (\sin \theta)v(x)$, $\theta \in [0, \pi]$, joins the identity to the antipodal map $x \mapsto -x$; one deduces $\deg(\text{id}) = \deg(-\text{id})$, that is, $1 = (-1)^{n+1}$, hence n odd. **What is missing, exactly:** the degree of a map $S^n \rightarrow S^n$ for $n \geq 2$ and the computation $\deg(-\text{id}) = (-1)^{n+1}$. The degree built in this chapter (Definition 12.8) exists only for $n = 1$ and arises from the lifting along $E : \mathbb{R} \rightarrow S^1$; for $n \geq 2$ there is no analogous covering (S^n is simply connected, Remark 12.5) and the degree is defined via homology $H_n(S^n) \cong \mathbb{Z}$ (Hatcher, §2.2). That construction is the subject of the algebraic topology chapter of Volume IV, where the hairy ball theorem is proved in full.

Definition 12.9: The Hopf map. Identify $S^3 = \{(z_0, z_1) \in \mathbb{C}^2 : |z_0|^2 + |z_1|^2 = 1\}$ and consider the complex projective line $\mathbb{CP}^1 = (\mathbb{C}^2 \setminus \{0\})/\sim$, where $(z_0, z_1) \sim (\lambda z_0, \lambda z_1)$ for $\lambda \in \mathbb{C} \setminus \{0\}$. The **Hopf map** is

$$h : S^3 \rightarrow \mathbb{CP}^1, \quad h(z_0, z_1) = [z_0 : z_1].$$

Since $\mathbb{CP}^1$ is homeomorphic to S^2 , one also writes $h : S^3 \rightarrow S^2$.

Proposition 12.5: The Hopf fibres are circles. For every $q \in \mathbb{CP}^1$ the fibre $h^{-1}(q) \subseteq S^3$ is homeomorphic to S^1 . Precisely, if $(a_0, a_1) \in S^3$ and $q = [a_0 : a_1]$, then

$$h^{-1}(q) = \{(e^{i\theta}a_0, e^{i\theta}a_1) : \theta \in \mathbb{R}\},$$

and $\theta \mapsto (e^{i\theta}a_0, e^{i\theta}a_1)$ induces a homeomorphism of S^1 onto $h^{-1}(q)$.

Proof. Step 1 — the orbit is contained in the fibre. If $|\lambda| = 1$ then $|\lambda a_0|^2 + |\lambda a_1|^2 = |a_0|^2 + |a_1|^2 = 1$, so $(\lambda a_0, \lambda a_1) \in S^3$; and $[\lambda a_0 : \lambda a_1] = [a_0 : a_1] = q$ by definition of $\mathbb{CP}^1$.

Step 2 — the fibre is contained in the orbit. Let $(z_0, z_1) \in S^3$ with $[z_0 : z_1] = [a_0 : a_1]$. Then there is $\lambda \in \mathbb{C} \setminus \{0\}$ with $(z_0, z_1) = (\lambda a_0, \lambda a_1)$. Taking norms,

$$1 = |z_0|^2 + |z_1|^2 = |\lambda|^2(|a_0|^2 + |a_1|^2) = |\lambda|^2,$$

so $|\lambda| = 1$, that is, $\lambda = e^{i\theta}$ for some θ (surjectivity of E).

Step 3 — homeomorphism. The map $\Theta : S^1 \rightarrow h^{-1}(q)$, $\Theta(\lambda) = (\lambda a_0, \lambda a_1)$, is continuous (linear in λ), surjective by Steps 1–2, and injective: if $\lambda a_0 = \mu a_0$ and $\lambda a_1 = \mu a_1$ with $(a_0, a_1) \neq (0, 0)$, then $(\lambda - \mu)a_j = 0$ for some j with $a_j \neq 0$, so $\lambda = \mu$. It is therefore a continuous bijection from a compact space (S^1) to a Hausdorff space (a subspace of $\mathbb{C}^2 \cong \mathbb{R}^4$), hence a homeomorphism by Lemma 12.1(ii). $\square$

Remark 12.7: What we import: the non-triviality of the Hopf fibration (panorama). **Panorama.** The map h of Definition 12.9 is a locally trivial fibre bundle with fibre S^1 , total space S^3 and base S^2 , and it is not the trivial bundle: S^3 is not homeomorphic to $S^2 \times S^1$. Moreover $\pi_3(S^2)$ is infinite cyclic, generated by the class of h (Hatcher, *Algebraic Topology*, Example 4.45, pp. 377–378, for the bundle; Example 4.51, p. 380, for $\pi_3(S^2) \cong \mathbb{Z}$).

These two statements are here **imported** and presented as panorama, not as theorems of this treatise. Of the above, only the fact that the fibres are circles is proved in this chapter (Proposition 12.5). **What is missing, exactly:** (a) the construction of the local trivializations of h over the two affine charts of $\mathbb{CP}^1$ and the verification that they are compatible; (b) the long exact sequence of homotopy groups of a fibre bundle, which from the fibration $S^1 \rightarrow S^3 \rightarrow S^2$ gives $\pi_3(S^3) \cong \pi_3(S^2)$ and hence $\pi_3(S^2) \cong \mathbb{Z}$; (c) the computation $\pi_3(S^3) \cong \mathbb{Z}$, which requires the Hurewicz theorem or the degree in dimension 3. None of the three tools is available here: the higher homotopy groups π_n are not even defined in this volume. They are the subject of the algebraic topology chapter of Volume IV.

It is worth recording, however, the geometric intuition, which is elementary and verifiable with the tools of this chapter: two distinct fibres are linked circles in S^3 (linking number 1), while in a product $S^2 \times S^1$ the fibres $\{x\} \times S^1$ are not. And it is worth recording the connection with $SU(2) \rightarrow SO(3)$ (Chapter 28): viewing S^3 as the set of unit quaternions, the Hopf fibres are the orbits of multiplication by a phase, and it is the same structure for which a rotation by 2π does not return a spin state to its initial value.

12.9. Configuration space and cable twisting

The configuration space (*C-space*) of a robot encodes all admissible poses; its topology governs motion planning. A revolute joint with unlimited travel has C-space S^1 : its trajectories are classified by the number of windings ($\pi_1(S^1) = \mathbb{Z}$, Theorem 12.7), a quantity directly related to cable twisting. It is exactly the quantity that controllers monitor to avoid twisting the harness: managing the turns accumulated on the axis is a standard function of industrial controllers. For tethered robots, the homotopy class of the path in the workspace with obstacles uniquely determines the state of the taut cable, and the winding number around an obstacle measures the degree of entanglement: *tangle-free* planners choose the homotopy class that avoids entanglement. Topology here is not abstraction but an operational constraint.

To deal with several joints one needs the fundamental group of a product.

Proposition 12.6: The fundamental group of a product. Let X, Y be topological spaces, $x_0 \in X$, $y_0 \in Y$. Then

$$\Lambda : \pi_1(X \times Y, (x_0, y_0)) \rightarrow \pi_1(X, x_0) \times \pi_1(Y, y_0), \quad \Lambda([\gamma]) = ([p_X \circ \gamma], [p_Y \circ \gamma]),$$

is a group isomorphism, where p_X, p_Y are the projections.

Proof. Step 1 — well defined and a homomorphism. If F is a path homotopy in $X \times Y$, then $p_X \circ F$ and $p_Y \circ F$ are path homotopies in X and in Y ; hence Λ does not depend on the representative. Since $p_X \circ (\gamma \cdot \delta) = (p_X \circ \gamma) \cdot (p_X \circ \delta)$ (concatenation acts on the parameter), Λ is a homomorphism.

Step 2 — surjective. Given loops α in X and β in Y , the map $\gamma(s) = (\alpha(s), \beta(s))$ is continuous (a map into a product is continuous if and only if its components are) and is a loop based at (x_0, y_0) , with $\Lambda([\gamma]) = ([\alpha], [\beta])$.

Step 3 — injective. Let $\Lambda([\gamma])$ be the identity element, i.e. $p_X \circ \gamma \simeq c_{x_0}$ via F and $p_Y \circ \gamma \simeq c_{y_0}$ via G . Then $H(s, u) = (F(s, u), G(s, u))$ is continuous (continuous components), and it is a path homotopy between γ and the constant loop (x_0, y_0) : indeed $H(s, 0) = (p_X \gamma(s), p_Y \gamma(s)) = \gamma(s)$, $H(s, 1) = (x_0, y_0)$ and $H(0, u) = H(1, u) = (x_0, y_0)$. Hence $[\gamma]$ is the identity. $\square$

Corollary 12.7: The C-space of two revolute joints. The C-space of two independent revolute joints with unlimited travel is the torus $T^2 = S^1 \times S^1$, and

$$\pi_1(T^2) \cong \mathbb{Z} \times \mathbb{Z}.$$

Similarly, the cylinder $S^1 \times \mathbb{R}$ (one revolute joint plus one linear axis) has $\pi_1(S^1 \times \mathbb{R}) \cong \mathbb{Z}$.

Proof. Each joint has C-space S^1 and the two joints are independent, so the C-space is the product. By Proposition 12.6 and Theorem 12.7, $\pi_1(T^2) \cong \pi_1(S^1) \times \pi_1(S^1) \cong \mathbb{Z} \times \mathbb{Z}$. For the cylinder, $\pi_1(\mathbb{R})$ is trivial (Theorem 12.4, Step 5), so $\pi_1(S^1 \times \mathbb{R}) \cong \mathbb{Z} \times \{0\} \cong \mathbb{Z}$. $\square$

Remark 12.8: Why S^1 is special. The facts that $\pi_1(S^1) = \mathbb{Z} \neq 0 = \pi_1(S^n)$ for $n \geq 2$ (Remark 12.5) and that S^1 admits a nowhere-vanishing tangent field while S^2 does not (Remark 12.6) are the topological roots of many peculiarities of the circle: the existence of a global angular coordinate up to 2π , the classification of loops by winding, the group structure of $S^1 = \mathbb{T}$ (Chapter 13), absent on S^2 . A double revolute joint has a torus, not a sphere, as its C-space: topology, not geometry, dictates the cabling constraints.

12.10. Assigned exercises

Answers are in the Teacher's key (Section 12.13).

Exercise 12.1: Conjugation has degree -1 . *Aim:* to use the definition of degree and its invariance under free homotopy. *Estimated time:* 25 minutes. *Type:* symbolic/proof-based. Let $c : S^1 \rightarrow S^1$ be conjugation, $c(z) = \bar{z}$.

- Compute $\deg c$ directly from Definition 12.8, exhibiting an explicit lifting of γ_c .
- Deduce that c is not homotopic to the identity id_{S^1} , and that it is not homotopic to a constant.
- Deduce that c does not extend to a continuous map $D^2 \rightarrow S^1$.
- Compute $\deg(c \circ p_n)$ and $\deg(p_n \circ c)$ for $p_n(z) = z^n$, and check consistency with Proposition 12.3.

Exercise 12.2: Winding number computed numerically. *Aim:* to compute a topological invariant by two independent methods and to recognise the difference in nature between them. *Estimated time:* 45 minutes. *Type:* numerical/computational.

Consider the loop

$$\gamma(t) = e^{6\pi it} + \frac{1}{2}e^{-4\pi it}, \quad t \in [0, 1].$$

- Check that $\gamma(t) \neq 0$ for every t and determine $\min_t |\gamma(t)|$.
- Predict $w(\gamma)$ using Lemma 12.8.
- Sample γ at $N + 1$ equispaced points for $N = 200, 2000, 20\,000$; compute the unwrapped phase (unwrapping: add $\varphi_k - \varphi_{k-1}$ reduced to $(-\pi, \pi]$) and deduce w .
- Compute $\frac{1}{2\pi i} \int_0^1 \gamma'/\gamma dt$ by the trapezoidal rule, using the exact derivative $\gamma'(t) = 6\pi i e^{6\pi it} - 2\pi i e^{-4\pi it}$.
- Compare the order of convergence of the two methods in (c) and (d) and explain the difference.
- Repeat (b)–(d) for $\delta(t) = \frac{1}{2}e^{6\pi it} + e^{-4\pi it}$ and comment.

12.11. Worked exercises

Exercise 12.3: Fixed-point-free maps. *Type:* symbolic/proof-based. Let $f : S^1 \rightarrow S^1$ be continuous and without fixed points ($f(z) \neq z$ for every z). Prove that $\deg f = 1$. Deduce that every map $f : S^1 \rightarrow S^1$ with $\deg f \neq 1$ has at least one fixed point, and in particular that every map of degree 0 (for instance every map that extends to the disc) has a fixed point.

Solution. Strategy. If f has no fixed points, $f(z)$ and z are never equal; one then proves that f is freely homotopic to the antipodal map $a(z) = -z$, by the normalised straight-line homotopy between $-z$ and $f(z)$, and computes $\deg a$. Then one concludes with Theorem 12.8.

Step 1 — the segment between $-z$ and $f(z)$ misses the origin. Set

$$G(z, \theta) = (1 - \theta)(-z) + \theta f(z), \quad (z, \theta) \in S^1 \times I.$$

If $G(z, \theta) = 0$ for some z, θ , then $\theta f(z) = (1 - \theta)z$. Taking moduli and using $|z| = |f(z)| = 1$ we get $\theta = 1 - \theta$, i.e. $\theta = \frac{1}{2}$, and then $\frac{1}{2}f(z) = \frac{1}{2}z$, i.e. $f(z) = z$: against the hypothesis. Hence G never vanishes.

Step 2 — the homotopy. G is continuous and $|G| > 0$, so

$$H(z, \theta) = \frac{G(z, \theta)}{|G(z, \theta)|}$$

is continuous with values in S^1 , with $H(\cdot, 0) = a$ and $H(\cdot, 1) = f$ (because $|-z| = |f(z)| = 1$). Hence $f \simeq a$ (free homotopy).

Step 3 — the degree of the antipodal map. $\gamma_a(s) = -e^{2\pi is} = e^{i\pi} e^{2\pi is} = e^{i(\pi + 2\pi s)}$, which lifts to $\tilde{\gamma}_a(s) = \pi + 2\pi s$. Hence

$$\deg a = \frac{\tilde{\gamma}_a(1) - \tilde{\gamma}_a(0)}{2\pi} = \frac{(\pi + 2\pi) - \pi}{2\pi} = 1.$$

Step 4 — conclusion. By Theorem 12.8, $f \simeq a$ implies $\deg f = \deg a = 1$. Contrapositively: if $\deg f \neq 1$, then f has a fixed point. In particular if $\deg f = 0$, i.e. (by Corollary 12.6) if f extends continuously to the disc, then f has a fixed point.

Independent check. We verify the statement on three examples. (i) $f = a$ (antipodal): it has no fixed points ($-z = z \Rightarrow z = 0 \notin S^1$) and $\deg a = 1$: consistent. (ii) $f = p_2$, $p_2(z) = z^2$, has $\deg = 2 \neq 1$; its fixed points are the solutions of $z^2 = z$ on S^1 , i.e. $z = 1$: there is one, as predicted. (iii) $f = p_{-1} = c$ (conjugation), $\deg = -1 \neq 1$: the fixed points are $\bar{z} = z$, i.e. $z = \pm 1$: there are some. ✓

Interpretation. Degree 1 is that of the identity *and* of the antipodal map: on the circle the antipodal map is a rotation by π , hence homotopic to the identity. This is the first qualitative difference from S^2 , where the antipodal map has degree -1 , and it is precisely this difference that produces the hairy ball theorem (Remark 12.6).

Typical mistakes. (1) Concluding “ f without fixed points $\Rightarrow f$ homotopic to the antipodal map $\Rightarrow \deg f = -1$ ”: that is the formula valid on S^n with n even, not on S^1 ; on S^1 one has $\deg(-\text{id}) = (-1)^{1+1} = 1$. (2) Using the straight-line homotopy $\frac{(1-\theta)z + \theta f(z)}{|\dots|}$ between the identity and f : the denominator vanishes when $f(z) = -z$, which the hypothesis allows. (3) Forgetting the normalisation: G does not take values in S^1 .

Extension. The same scheme proves the dual statement: if $f(z) \neq -z$ for every z , then $f \simeq \text{id}$ and hence $\deg f = 1$ (again 1, because on S^1 the identity and the antipodal map have the same degree). On S^2 the two statements separate and become $\deg f = (-1)^3 = -1$ in the first case and $\deg f = 1$ in the second.

Exercise 12.4: A two-harmonic loop: winding, lifting, numerical check. *Type:* numerical/computational with a proof-based part. Consider

$$\gamma(t) = e^{4\pi it} + 2e^{-2\pi it}, \quad t \in [0, 1].$$

- (a) Prove that γ does not vanish and compute $\min_t |\gamma(t)|$.
- (b) Determine $w(\gamma)$.
- (c) Write down an explicit lifting of the phase.
- (d) Check $w(\gamma)$ numerically by two independent methods.

Solution. Strategy. Isolate the term of larger modulus, apply Lemma 12.8 to obtain w in closed form, build the lifting as the sum of the phase of the dominant term and a “small” phase, and check the result with two independent numerical computations.

Step 1 — γ does not vanish. For every t ,

$$|\gamma(t)| \geq |2e^{-2\pi it}| - |e^{4\pi it}| = 2 - 1 = 1 > 0.$$

The minimum 1 is actually attained: one needs $e^{4\pi it} = -e^{-2\pi it}$, i.e. $e^{6\pi it} = -1$, i.e. $6\pi t = \pi + 2k\pi$, i.e. $t = \frac{1+2k}{6}$ with $t \in [0, 1]$: $t = \frac{1}{6}, \frac{1}{2}, \frac{5}{6}$. Hence $\min_t |\gamma(t)| = 1$.

Step 2 — the winding number. Write $\gamma(t) = a e^{2\pi i n t} + b e^{2\pi i m t}$ with $a = 1$, $n = 2$, $b = 2$, $m = -1$. Since $|b| = 2 > 1 = |a|$, Lemma 12.8 gives

$$w(\gamma) = m = -1.$$

The negative sign says that the loop goes once *clockwise* around the origin: the term of frequency -1 dominates.

Step 3 — explicit lifting. Factor out the dominant term:

$$\gamma(t) = 2e^{-2\pi it} \left(1 + \frac{1}{2}e^{6\pi it} \right).$$

The second factor $\zeta(t) = 1 + \frac{1}{2}e^{6\pi it}$ has real part $1 + \frac{1}{2}\cos 6\pi t \geq \frac{1}{2} > 0$, so it lies in the arc $U_1 = \{\text{Re} > 0\}$ and its phase is read off by the local section $\psi_1 = \arctan(y/x)$ of

Lemma 12.2:

$$\alpha(t) = \arctan \frac{\frac{1}{2} \sin 6\pi t}{1 + \frac{1}{2} \cos 6\pi t} = \arctan \frac{\sin 6\pi t}{2 + \cos 6\pi t},$$

a continuous $\frac{1}{3}$ -periodic function with $\alpha(0) = 0$. A lifting of the phase of $\gamma/|\gamma|$ is therefore

$$\tilde{\theta}(t) = -2\pi t + \alpha(t),$$

because $\gamma(t)/|\gamma(t)| = e^{i(-2\pi t + \alpha(t))}$. Check: $\tilde{\theta}(1) - \tilde{\theta}(0) = -2\pi + \alpha(1) - \alpha(0) = -2\pi + 0 - 0 = -2\pi$, hence $w = -2\pi/2\pi = -1$. ✓ (Note that α contributes nothing: it is periodic, so it accumulates no turns — the analytic translation of the fact that the subdominant term cannot change the invariant.)

Step 4 — independent numerical check. With $N + 1$ equispaced samples:

N	unwrapped phase	$\frac{1}{2\pi i} \int_0^1 \gamma'/\gamma dt$ (trapezoidal)
200	-1.000000	-0.999836
2 000	-1.000000	-0.999998
20 000	-1.000000	-1.000000

The two methods agree with each other and with Step 2. ✓ The largest phase jump between consecutive samples with $N = 2000$ is 0.0126 rad, far smaller than π : the validity condition for unwrapping (sample finely enough that no true jump exceeds π) is amply satisfied.

Solution. (continuation of Exercise 12.4.)

Interpretation. The loop is the sum of two circular motions of frequencies $+2$ and -1 : the one with larger amplitude wins, and the topological invariant is its frequency. This is exactly the phenomenon governing the phase of an I/Q signal dominated by a carrier (Chapter 26) and the reading of a rotary encoder in the presence of parasitic oscillations: as long as the disturbance has smaller amplitude than the carrier, the turn count does not change.

Typical mistakes. (1) Confusing w with the number of self-intersections or with the number of “petals” of the curve: here the curve has three lobes but $w = -1$. (2) Applying Lemma 12.8 with $|a| = |b|$: in that case the loop touches the origin and w is undefined. (3) Unwrapping the phase with too few samples: if a true jump exceeds π , the algorithm reads it as the opposite jump and the result is off by an integer. (4) Using the trapezoidal rule and expecting the exact integer: the quadrature converges, it is not exact.

Extension. For $\gamma_\lambda(t) = e^{4\pi i t} + \lambda e^{-2\pi i t}$ one has $w = -1$ for $\lambda > 1$ and $w = 2$ for $0 \leq \lambda < 1$ (Lemma 12.8 applied to the opposite dominant term); for $\lambda = 1$ the loop passes through the origin and w is undefined. The value $\lambda = 1$ is a *topological transition*: an integer invariant cannot vary continuously, and indeed it jumps from 2 to -1 across the only value at which the hypothesis fails.

12.12. Self-assessment quiz

- (Definition) An open set $U \subseteq X$ is *evenly covered* by $p : \tilde{X} \rightarrow X$ if
 - $p^{-1}(U)$ is open
 - $p^{-1}(U)$ is a disjoint union of open sets each mapped homeomorphically onto U
 - $p|_U$ is injective
 - $p^{-1}(U)$ is connected
- (Hypothesis) In the path lifting lemma, the hypothesis that makes the lifting *unique* is
 - the compactness of I
 - the connectedness of I together with fixing the initial value
 - the differentiability of γ
 - the surjectivity of E
- (Symbolic computation) The winding number of the loop $\gamma(t) = e^{2\pi i \cdot 5t} \overline{e^{2\pi i \cdot 3t}}$, $t \in [0, 1]$,

- equals
- A) 8 B) 2 C) 15 D) -2
4. (Numerical computation) For $\gamma(t) = e^{4\pi it} + 2e^{-2\pi it}$ the value $\min_t |\gamma(t)|$ is
- A) 0 B) 1 C) 2 D) 3
5. (Proof step) In the proof of path lifting, the Lebesgue number is used to
- A) prove that E is surjective B) find a subdivision of I such that each piece falls inside an evenly covered open set C) prove that the fibre is discrete D) make γ differentiable
6. (Error diagnosis) A student claims: “ $E|_{(0,+\infty)} : (0,+\infty) \rightarrow S^1$ is surjective and a local homeomorphism, hence a covering”. The mistake is
- A) E is not surjective on $(0,+\infty)$ B) over every neighbourhood of 1 there is a sheet that is not mapped onto the whole neighbourhood C) $(0,+\infty)$ is not connected D) S^1 is not Hausdorff
7. (Transfer) A continuous map $f : S^1 \rightarrow S^1$ extends to a continuous $F : D^2 \rightarrow S^1$ if and only if
- A) f is injective B) $\deg f = 0$ C) $\deg f = 1$ D) f is surjective
8. (Source and metacognition) The proof of $\pi_1(S^1) \cong \mathbb{Z}$ by lifting of paths and homotopies is found in
- A) Hatcher, *Algebraic Topology*, §1.1, Theorem 1.7, and Munkres, *Topology*, §54, Theorem 54.5 B) Hatcher §2.2 C) Munkres §27 D) Hatcher §4.2

12.13. Teacher’s key

BEST PRACTICE

Quiz — answers, rationale and diagnosis.

1) **B.** *Rationale:* this is Definition 12.3; the union must be *disjoint* and each piece homeomorphic to U via p . *Distractors:* A holds for every continuous map and characterises nothing; C confuses covering with global injectivity; D is false (in the example E the preimage has infinitely many components). *Diagnosed error:* confusing local homeomorphism with covering. *Source:* Munkres §53; Hatcher §1.1, p. 29. *Prerequisite:* subspace topology. *Remedial work:* redo Remark 12.3.

2) **B.** *Rationale:* uniqueness comes from Lemma 12.5, which uses *only* the connectedness of the domain and the discreteness of the fibre, plus one point where the two liftings agree. *Distractors:* A is needed for *existence* (Lebesgue number), not for uniqueness; C is superfluous (liftings exist for merely continuous paths); D is needed for the initial datum to be well posed. *Diagnosed error:* attributing the wrong part of the statement to the wrong hypothesis. *Source:* Munkres, Lemma 54.1. *Prerequisite:* connectedness. *Remedial work:* rewrite the uniqueness proof isolating where connectedness is used.

3) **B.** *Rationale:* $\gamma(t) = e^{2\pi i 5t} e^{-2\pi i 3t} = e^{2\pi i \cdot 2t} = \omega_2(t)$, hence $w = 2$ by Theorem 12.5(v); equivalently w is additive and $w(\bar{\omega}_3) = -3$, so $5 - 3 = 2$. *Distractors:* A adds instead of subtracting (ignoring the conjugation); C multiplies the frequencies; D gets the sign wrong. *Diagnosed error:* treating conjugation as a positive factor. *Source:* Theorem 12.5. *Prerequisite:* $\overline{e^{i\theta}} = e^{-i\theta}$ (Volume II, Chapter 3). *Remedial work:* compute w of $\omega_n \cdot \bar{\omega}_m$ for various n, m .

- 4) **B. Rationale:** $|\gamma| \geq 2 - 1 = 1$, with equality at $t = \frac{1}{6}, \frac{1}{2}, \frac{5}{6}$ (Worked exercise 12.4, Step 1). *Distractors:* A would mean the loop touches the origin, and then w would be undefined; C forgets the term of modulus 1; D adds the moduli instead of subtracting them. *Diagnosed error:* incorrect use of the reverse triangle inequality. *Source:* Lemma 12.8. *Prerequisite:* triangle inequality. *Remedial work:* draw the curve and locate the three minimum points.
- 5) **B. Rationale:** the Lebesgue number provides the mesh $1/m < \delta$ for which each $[t_{k-1}, t_k]$ has image inside some U_j ; without it one could not choose a *single* local section on each piece. *Distractors:* A is proved otherwise; C is the structure of the fibre $(2\pi\mathbb{Z})$, independent of Lebesgue; D is false and irrelevant. *Diagnosed error:* not distinguishing the compactness argument from the rest. *Source:* Munkres, Lemma 27.5; Hatcher §1.1, property (c), p. 30. *Prerequisite:* compactness. *Remedial work:* redo Lemma 12.4.

BEST PRACTICE

Quiz — answers, rationale and diagnosis (continued).

- 6) **B. Rationale:** this is the content of Remark 12.3 (Munkres, Example 53.2): the component $(0, \varepsilon)$ does not cover the whole neighbourhood of 1. *Distractors:* A is false, $E|_{(0, +\infty)}$ is surjective; C is false, a half-line is connected; D is false, S^1 is metric. *Diagnosed error:* believing that “local homeomorphism + surjectivity” implies “covering”. *Source:* Munkres §53. *Prerequisite:* definition of covering. *Remedial work:* exhibit explicitly the sheets over a small neighbourhood of 1.
- 7) **B. Rationale:** Corollary 12.6: the extension exists if and only if f is homotopic to a constant, i.e. if and only if $\deg f = 0$. *Distractors:* A and D have no bearing on extendability (the identity is bijective and surjective but does not extend); C is the case of the identity, which does *not* extend (Corollary 12.4). *Diagnosed error:* confusing degree 1 with degree 0. *Source:* Hatcher §1.1, Theorem 1.9 and surroundings. *Prerequisite:* convexity of D^2 . *Remedial work:* redo the proof of the non-existence of retractions.
- 8) **A. Rationale:** Hatcher’s Theorem 1.7 (§1.1, pp. 29–31) and Munkres’ Theorem 54.5 (§54) are exactly this statement, with the same strategy used here. *Distractors:* B is the degree via homology (hairy ball); C is the Lebesgue number; D is the Hopf fibration. *Diagnosed error:* citing a source for the chapter rather than for the statement. *Source:* see the section “Sources and bibliography”. *Prerequisite:* being able to read a reference with section and number. *Remedial work:* locate the two statements in the two texts and compare their proofs.

BEST PRACTICE

Assigned exercise 12.1 — answers. (a) $\gamma_c(s) = \overline{e^{2\pi is}} = e^{-2\pi is}$, which lifts to $\tilde{\gamma}_c(s) = -2\pi s$; hence $\deg c = \frac{-2\pi - 0}{2\pi} = -1$. (b) $\deg \text{id} = 1 \neq -1$ and $\deg(\text{constant}) = 0 \neq -1$; by Theorem 12.8 maps of different degree are not homotopic. (c) By Corollary 12.6 the extension would exist only if $\deg c = 0$, whereas $\deg c = -1$. (d) $c \circ p_n(z) = \bar{z}^n = \bar{z}^n$ and $p_n \circ c(z) = \bar{z}^n$: they are the same map, $z \mapsto z^{-n}$ on S^1 (because $\bar{z} = z^{-1}$), of degree $-n$. Proposition 12.3 gives $\deg(c \circ p_n) = \deg c \cdot \deg p_n = (-1) \cdot n = -n$, and likewise for the other composition: consistent. ✓

BEST PRACTICE

Assigned exercise 12.2 — answers. (a) $|\gamma(t)| \geq 1 - \frac{1}{2} = \frac{1}{2} > 0$. The minimum $\frac{1}{2}$ is attained when the two terms are opposite in direction, i.e. $e^{-4\pi it} = -e^{6\pi it}$, i.e. $e^{10\pi it} = -1$, i.e. $t = \frac{1+2k}{10}$: for $t \in [0, 1]$ one gets $t = 0.1; 0.3; 0.5; 0.7; 0.9$. Hence $\min_t |\gamma(t)| = 0.5$ (checked numerically on $2 \cdot 10^6$ samples: 0.500000). ✓ (b) The dominant term is $e^{6\pi it} = e^{2\pi i \cdot 3t}$ ($1 > \frac{1}{2}$), hence $w(\gamma) = 3$. (c) The unwrapped phase gives exactly 3.000000 for all three

values of N . **(d)** The trapezoidal rule gives 2.995561 ($N = 200$), 2.999956 ($N = 2000$), 2.999999 ($N = 20000$). **(e)** Unwrapping returns the exact integer because it sums phase increments reduced to $(-\pi, \pi]$: provided no true jump exceeds π , the result is exact and does not “converge”; the integral is a quadrature, with error $O(N^{-2})$ for the trapezoidal rule (note the factor ≈ 100 between consecutive rows, consistent with $N \rightarrow 10N$). This is the numerical manifestation of the fact that w is a topological invariant. **(f)** Now $e^{-4\pi it} = e^{2\pi i(-2)t}$ dominates (coefficient $1 > \frac{1}{2}$), hence $w(\delta) = -2$: swapping the amplitudes changes the dominant term, and with it the invariant. The passage from 3 to -2 occurs abruptly when the two amplitudes become equal, because then the loop touches the origin.

12.14. Chapter formulary

The circle as a space.

$$S^1 = \{z \in \mathbb{C} : |z| = 1\} \text{ compact, connected, path connected; } S^1 \setminus \{p\} \cong \mathbb{R}.$$

Stereographic projection and its inverse:

$$\sigma(x, y) = \frac{x}{1-y}, \quad \tau(s) = \left(\frac{2s}{s^2+1}, \frac{s^2-1}{s^2+1} \right).$$

Quotient and covering.

$$\mathbb{R}/2\pi\mathbb{Z} \cong S^1 \quad (\text{homeomorphism and group isomorphism}),$$

$$E(t) = e^{it}, \quad E^{-1}(E(t_0)) = t_0 + 2\pi\mathbb{Z}.$$

Local sections: on $\{x > 0\}$, $\psi_1 = \arctan(y/x)$; on $\{x < 0\}$, $\psi_2 = \arctan(y/x) + \pi$; on $\{y > 0\}$, $\psi_3 = \arccos x$; on $\{y < 0\}$, $\psi_4 = -\arccos x$.

Lifting. For every path $\gamma : I \rightarrow S^1$ and every a with $E(a) = \gamma(0)$ there is a unique $\tilde{\gamma}$ with $E \circ \tilde{\gamma} = \gamma$, $\tilde{\gamma}(0) = a$; the same for $F : I \times I \rightarrow S^1$.

Winding number.

$$w(\gamma) = \frac{\tilde{\gamma}(1) - \tilde{\gamma}(0)}{2\pi} \in \mathbb{Z}, \quad w(\gamma \cdot \gamma') = w(\gamma) + w(\gamma'), \quad w(\bar{\gamma}) = -w(\gamma), \quad w(\omega_n) = n.$$

Analytic form, for C^1 loops in $\mathbb{C} \setminus \{0\}$:

$$w(\gamma) = \frac{1}{2\pi i} \oint_{\gamma} \frac{dz}{z} = \frac{1}{2\pi i} \int_0^1 \frac{\gamma'(t)}{\gamma(t)} dt.$$

Dominant term: if $|b| > |a|$, then $w(ae^{2\pi i n t} + be^{2\pi i m t}) = m$.

Fundamental group and degree.

$$\pi_1(S^1, 1) \cong \mathbb{Z} \quad \text{via} \quad [\gamma] \mapsto w(\gamma), \quad n \mapsto [\omega_n];$$

$$\pi_1(X \times Y) \cong \pi_1(X) \times \pi_1(Y); \quad \pi_1(T^2) \cong \mathbb{Z}^2.$$

$$\deg f = w(s \mapsto f(e^{2\pi i s})); \quad f \simeq g \iff \deg f = \deg g; \quad \deg p_n = n \quad (p_n(z) = z^n);$$

$$\deg(f \circ g) = \deg f \cdot \deg g; \quad f \text{ extends to } D^2 \iff \deg f = 0.$$

Lifted map: $f(e^{it}) = e^{iu(t)}$ with $u(t + 2\pi) = u(t) + 2\pi \deg f$.

Consequences. There is no retraction $D^2 \rightarrow S^1$; every continuous $h : D^2 \rightarrow D^2$ has a fixed point (Brouwer); every $f : S^1 \rightarrow S^1$ with $\deg f \neq 1$ has a fixed point.

CHAPTER 13

The circle as a group: abstract harmonic analysis

In Chapter 12 the circle was regarded as a *space*: distance was forgotten and shape was kept. Here we take the complementary step: shape is forgotten and the *operation* is kept. The circle $S^1 = \{z \in \mathbb{C} : |z| = 1\}$ is closed under complex multiplication, contains 1, and contains the inverse of each of its elements: it is a group, and it is a group in which the operation is continuous. This combination — an algebraic structure and a topology that respect each other — is enough, on its own, to give rise to the whole of Fourier analysis.

The thread of the chapter is this. On S^1 there is a unique rotation-invariant probability measure: the measure $d\theta/2\pi$ (Theorem 13.4). The only continuous homomorphisms of S^1 into itself are the powers $z \mapsto z^n$ (Theorem 13.5), and the proof is a direct application of the lifting built in the previous chapter. Those powers are orthonormal with respect to that measure (Theorem 13.6), and they form a group isomorphic to $\mathbb{Z}$: this is the duality $\widehat{S^1} \cong \mathbb{Z}$, of which $\widehat{\mathbb{Z}} \cong S^1$ is the mirror image. Finally the closed subgroups of S^1 are classified (Theorem 13.7) and it is proved that irrational rotations generate dense subgroups (Theorem 13.8): this is the one-dimensional form of Kronecker's theorem, and it is the reason why an oscillator with an irrational frequency ratio never passes through the same state twice.

Coefficients, orthogonality and Fourier series on the circle have already been built in Volume II, Chapter 4, by analytic means. Here their *structural origin* is reconstructed: nothing from that chapter is repeated, and the two proofs of the classification of characters — the analytic one there, the topological one here — are to be read as two roads to the same point.

INFO

Level and prerequisites. Level D (graduate).

Internal prerequisites. Polar form, complex exponential and the equivalences $e^{i(s+t)} = e^{is}e^{it}$, $e^{it} = 1 \iff t \in 2\pi\mathbb{Z}$ (Volume II, Chapter 3); the circle as the multiplicative group of $\mathbb{C}$ (Chapter 6); from Chapter 12: compactness and connectedness of S^1 (Theorem 12.1), the homeomorphism $\mathbb{R}/2\pi\mathbb{Z} \cong S^1$ (Theorem 12.3), the exponential covering (Theorem 12.4), the lifting of maps defined on $\mathbb{R}$ (Corollary 12.3) and the uniqueness of the lifting on a connected space (Lemma 12.5). Classical Fourier series (Volume II, Chapter 4). Spheres and groups in dimension n (Chapter 7, Chapter 11).

External prerequisites, assumed and not reproved:

- Lebesgue measure on $\mathbb{R}$: σ -additivity and translation invariance;
- the dominated convergence theorem;
- the Stone–Weierstrass theorem in complex form (Rudin, *Principles of Mathematical Analysis*, 3rd ed., Theorem 7.33): a subalgebra of $C(K, \mathbb{C})$ that contains the constants, separates points and is closed under conjugation is dense in the uniform norm;
- Dynkin's lemma (π - λ): two probability measures that agree on a π -system generating the σ -algebra agree everywhere;
- the image-measure theorem: if T is measurable and $\nu = T_*\mu$, then $\int g d\nu = \int g \circ T d\mu$ for every bounded Borel g ;

- the notion of a differentiable manifold and of a smooth map between manifolds (Volume III, Chapter 10 for the case of surfaces).

Everything else is proved here.

What one learns. How to recognise a topological group and a Lie group from an explicit exhibition of the charts; how to construct an invariant measure and prove its uniqueness with Fourier coefficients; how to classify characters with a lifting argument; how to read the duality $\widehat{S^1} \cong \mathbb{Z}$ in both directions; how to classify closed subgroups and recognise when an orbit is dense.

Warning. Conventions of the chapter.

- $S^1 = \{z \in \mathbb{C} : |z| = 1\}$, with the subspace topology of $\mathbb{C}$ and the operation of complex multiplication. The symbol $\mathbb{T}$ is synonymous with S^1 when the group structure is to be emphasised: $\mathbb{T} = S^1$.
- $E : \mathbb{R} \rightarrow S^1$, $E(t) = e^{it}$, is the map of Chapter 12: this normalisation will always be used, with $E^{-1}(1) = 2\pi\mathbb{Z}$.
- $\mu_n = \{z \in S^1 : z^n = 1\} = \{e^{2\pi i k/n} : k = 0, \dots, n-1\}$ is the group of n -th roots of unity.
- “Borel measure” means: a measure defined on the Borel σ -algebra of S^1 , that is, the one generated by the open sets.
- $\chi_n : S^1 \rightarrow S^1$ is the map $\chi_n(z) = z^n$, $n \in \mathbb{Z}$.
- $d(z, w) = |z - w|$ is the Euclidean distance induced by $\mathbb{C}$; $d(z, A) = \inf_{a \in A} |z - a|$.

13.1. The circle as a topological group

Definition 13.1: Topological group. A **topological group** is a set G equipped with a group structure and a topology such that the two maps

$$m : G \times G \rightarrow G, \quad m(g, h) = gh, \quad \iota : G \rightarrow G, \quad \iota(g) = g^{-1},$$

are continuous ($G \times G$ with the product topology). The group is **abelian** if $gh = hg$ for all g, h , and it is **compact** if it is compact as a topological space.

Theorem 13.1: S^1 is a compact abelian topological group. The circle S^1 , with complex multiplication and the subspace topology of $\mathbb{C}$, is a compact abelian topological group, with identity element 1 and inverse $z^{-1} = \bar{z}$.

Proof. Step 1 — group structure. If $|z| = |w| = 1$ then $|zw| = |z||w| = 1$: the product lies in S^1 . Associativity and commutativity are inherited from the field $\mathbb{C}$. The element 1 has modulus 1 and is the identity. If $|z| = 1$ then $z\bar{z} = |z|^2 = 1$, hence $z^{-1} = \bar{z}$, which has modulus $|\bar{z}| = |z| = 1$ and lies in S^1 . Hence S^1 is an abelian group.

Step 2 — continuity of multiplication. In real coordinates, $(x_1 + iy_1)(x_2 + iy_2) = (x_1x_2 - y_1y_2) + i(x_1y_2 + y_1x_2)$: the two components are polynomials in the four real variables, hence continuous on $\mathbb{R}^4$. A map into a product is continuous if and only if its components are, hence $m_{\mathbb{C}} : \mathbb{C} \times \mathbb{C} \rightarrow \mathbb{C}$ is continuous; the restriction of a continuous map to a subspace is continuous, and $m = m_{\mathbb{C}}|_{S^1 \times S^1}$ has image in S^1 by Step 1, so $m : S^1 \times S^1 \rightarrow S^1$ is continuous (the topology of S^1 is the subspace topology).

Step 3 — continuity of inversion. $\iota(z) = \bar{z}$ is, in coordinates, $(x, y) \mapsto (x, -y)$: linear, hence continuous, and it sends S^1 into S^1 .

Step 4 — compactness. S^1 is compact by Theorem 12.1. □

Proposition 13.1: Translations are homeomorphisms; S^1 is homogeneous. For every $w \in S^1$ the map $T_w : S^1 \rightarrow S^1$, $T_w(z) = wz$, is a homeomorphism, with inverse $T_{w^{-1}}$. Moreover for every pair $z_1, z_2 \in S^1$ there exists w with $T_w(z_1) = z_2$: the group acts transitively on itself.

Proof. T_w is the composition $z \mapsto (w, z) \mapsto wz$: the first map is continuous (constant component and identity), the second is m , continuous by Theorem 13.1; hence T_w is continuous. We have $T_{w^{-1}} \circ T_w(z) = w^{-1}wz = z$ and likewise $T_w \circ T_{w^{-1}} = \text{id}$, so T_w is bijective with inverse $T_{w^{-1}}$, itself continuous by the same argument: T_w is a homeomorphism. Finally, given z_1, z_2 , set $w = z_2 z_1^{-1} \in S^1$: then $T_w(z_1) = z_2 z_1^{-1} z_1 = z_2$. $\square$

Remark 13.1: Why homogeneity matters. Proposition 13.1 says that on the circle there is no privileged point: any topological or metric property valid at one point holds at all of them. This is why an invariant measure can exist (no region is “special”) and why a time-invariant linear system, which commutes with translations, has as its eigenfunctions exactly the characters (Theorem 13.5). The same statement holds for every topological group: left translation is always a homeomorphism, and this is the structural reason why groups are “uniform” spaces.

Proposition 13.2: E is a homomorphism and $\mathbb{R}/2\pi\mathbb{Z} \cong S^1$ as topological groups. The map $E : \mathbb{R} \rightarrow S^1$, $E(t) = e^{it}$, is a continuous surjective homomorphism of the additive group $(\mathbb{R}, +)$ onto the multiplicative group S^1 , with kernel $\ker E = 2\pi\mathbb{Z}$. Consequently the induced map

$$\bar{E} : \mathbb{R}/2\pi\mathbb{Z} \longrightarrow S^1, \quad \bar{E}(t + 2\pi\mathbb{Z}) = e^{it},$$

is a group isomorphism and a homeomorphism: $\mathbb{R}/2\pi\mathbb{Z}$ and S^1 are the same topological group.

Proof. E is continuous and surjective by Theorem 12.4, and it is a homomorphism because $E(s+t) = e^{i(s+t)} = e^{is}e^{it} = E(s)E(t)$ (Volume II, Chapter 3). The kernel is $\{t : e^{it} = 1\} = 2\pi\mathbb{Z}$, again by Volume II, Chapter 3. By the first homomorphism theorem, $\bar{E}$ is a well-defined group isomorphism ($E(t) = E(t')$ if and only if $t - t' \in 2\pi\mathbb{Z}$). That $\bar{E}$ is also a homeomorphism is exactly Theorem 12.3. Finally, the quotient of a topological group by a subgroup is a topological group with the quotient topology: here there is no need to verify this, because $\bar{E}$ transports onto $\mathbb{R}/2\pi\mathbb{Z}$ the structure of S^1 , already known by Theorem 13.1. $\square$

13.2. S^1 as a Lie group of dimension 1

Definition 13.2: Lie group. A **Lie group** (real, of dimension n) is a group G equipped with the structure of a differentiable manifold of dimension n such that multiplication $m : G \times G \rightarrow G$ and inversion $\iota : G \rightarrow G$ are smooth (C^∞) maps.

To exhibit the manifold structure on S^1 , two charts suffice. The technical point is that their coordinate changes be smooth; the only subtlety is that the angle, as a function of the point, is not defined globally — this is exactly the phenomenon that Chapter 12 named “covering”.

Theorem 13.2: S^1 is a Lie group of dimension 1. Set

$$U_1 = S^1 \setminus \{-1\}, \quad \varphi_1(x, y) = 2 \arctan \frac{y}{1+x} \in (-\pi, \pi),$$

$$U_2 = S^1 \setminus \{1\}, \quad \varphi_2(x, y) = \pi - 2 \arctan \frac{y}{1-x} \in (0, 2\pi).$$

Then $\{(U_1, \varphi_1), (U_2, \varphi_2)\}$ is a C^∞ (indeed analytic) atlas of dimension 1 on S^1 , and with respect to it multiplication and inversion are smooth: S^1 is a compact connected abelian Lie group of dimension 1.

Proof. Step 1 — φ_1 and φ_2 are well defined and continuous. On U_1 we have $x > -1$, that is $1+x > 0$: the fraction $y/(1+x)$ is defined and the function $(x, y) \mapsto 2 \arctan(y/(1+x))$ is a composition of analytic functions, hence analytic on U_1 (as the restriction to U_1 of an analytic function on the open set $\{x > -1\}$ of $\mathbb{R}^2$). Likewise on U_2 we have $x < 1$, that is $1-x > 0$, and φ_2 is analytic.

Step 2 — φ_1 is the inverse of $t \mapsto e^{it}$ on $(-\pi, \pi)$. Let $t \in (-\pi, \pi)$ and $z = e^{it} = (\cos t, \sin t) \in U_1$. From the half-angle formulas,

$$\frac{\sin t}{1 + \cos t} = \frac{2 \sin \frac{t}{2} \cos \frac{t}{2}}{2 \cos^2 \frac{t}{2}} = \tan \frac{t}{2},$$

legitimate because $\cos(t/2) \neq 0$ for $|t| < \pi$. Since $t/2 \in (-\pi/2, \pi/2)$, we have $\arctan(\tan(t/2)) = t/2$ and hence $\varphi_1(e^{it}) = t$. Conversely E maps $(-\pi, \pi)$ bijectively onto U_1 (Theorem 12.4 and the description of the fibre $E^{-1}(z) = t_0 + 2\pi\mathbb{Z}$): hence $\varphi_1 : U_1 \rightarrow (-\pi, \pi)$ is a bijection, with inverse $\varphi_1^{-1} = E|_{(-\pi, \pi)}$, continuous. Thus φ_1 is a homeomorphism onto an open subset of $\mathbb{R}$.

Step 3 — φ_2 is the inverse of $t \mapsto e^{it}$ on $(0, 2\pi)$. Let $t \in (0, 2\pi)$ and $z = e^{it} \in U_2$. Then

$$\frac{\sin t}{1 - \cos t} = \frac{2 \sin \frac{t}{2} \cos \frac{t}{2}}{2 \sin^2 \frac{t}{2}} = \cot \frac{t}{2},$$

legitimate because $\sin(t/2) \neq 0$ for $t \in (0, 2\pi)$. Since $t/2 \in (0, \pi)$ we have $\cot(t/2) = \tan(\frac{\pi}{2} - \frac{t}{2})$ with $\frac{\pi}{2} - \frac{t}{2} \in (-\pi/2, \pi/2)$, hence $\arctan(\cot(t/2)) = \frac{\pi}{2} - \frac{t}{2}$ and

$$\varphi_2(e^{it}) = \pi - 2\left(\frac{\pi}{2} - \frac{t}{2}\right) = t.$$

As above, φ_2 is a homeomorphism of U_2 onto $(0, 2\pi)$.

Step 4 — the change of chart is smooth. We have $U_1 \cap U_2 = S^1 \setminus \{1, -1\}$ and $\varphi_1(U_1 \cap U_2) = (-\pi, 0) \cup (0, \pi)$. For $t \in (0, \pi)$, $\varphi_2 \circ \varphi_1^{-1}(t) = \varphi_2(e^{it}) = t$; for $t \in (-\pi, 0)$, $e^{it} = e^{i(t+2\pi)}$ with $t+2\pi \in (\pi, 2\pi) \subset (0, 2\pi)$, hence $\varphi_2 \circ \varphi_1^{-1}(t) = t+2\pi$. The transition map is therefore

$$\varphi_2 \circ \varphi_1^{-1}(t) = \begin{cases} t, & t \in (0, \pi), \\ t+2\pi, & t \in (-\pi, 0), \end{cases}$$

that is, a translation on each of the two connected components of the domain: it is C^∞ (with derivative 1), and the same holds for its inverse. The atlas is thus smooth; since S^1 is Hausdorff and second countable (being a subspace of $\mathbb{R}^2$), it defines on S^1 a differentiable manifold structure of dimension 1.

Step 5 — multiplication is smooth. Let $z_0, w_0 \in S^1$ and $z_0 w_0 = v_0$. Choose $a, b \in \mathbb{R}$ with $E(a) = z_0$, $E(b) = w_0$ and a chart φ among the two (or a rotate of one of them) defined on a neighbourhood of v_0 ; by Proposition 13.1 one may work directly with the chart $\psi_c(z) = c + \varphi_1(e^{-ic}z)$, defined on the neighbourhood $e^{ic}U_1$ of $E(c)$ and with values in $(c-\pi, c+\pi)$: ψ_c is φ_1 composed with a translation of the group and a translation of $\mathbb{R}$, hence a chart compatible with the atlas (the change of chart with φ_1 is again a translation, by Step 4 applied after the rotation). In these coordinates, for s near a and t near b ,

$$\psi_{a+b}(E(s)E(t)) = \psi_{a+b}(E(s+t)) = s+t,$$

because $s + t$ is near $a + b$ and $\psi_{a+b} \circ E$ is the identity on $(a + b - \pi, a + b + \pi)$. The local expression of multiplication is thus $(s, t) \mapsto s + t$: linear, hence C^∞ .

Step 6 — inversion is smooth. With the same charts, $\psi_{-a}(E(s)^{-1}) = \psi_{-a}(E(-s)) = -s$ for s near a : the local expression is $s \mapsto -s$, linear, hence C^∞ .

Compactness and connectedness are Theorem 12.1; commutativity is Theorem 13.1. $\square$

Example 13.1: The exponential chart, checked twice. Take $t = 0.3$. Then $z = (\cos 0.3, \sin 0.3) = (0.9553365, 0.2955202)$ and

$$\frac{y}{1+x} = \frac{0.2955202}{1.9553365} = 0.1511350, \quad 2 \arctan(0.1511350) = 2 \cdot 0.1500000 = 0.3000000. \quad \checkmark$$

Independent check with the closed formula of Step 2: $\tan(t/2) = \tan(0.15) = 0.1511350$, which coincides with the ratio computed above. On the second chart, with $t = 2$: $z = (-0.4161468, 0.9092974)$ and

$$\frac{y}{1-x} = \frac{0.9092974}{1.4161468} = 0.6420926, \quad \pi - 2 \arctan(0.6420926) = 3.1415927 - 2 \cdot 0.5707963 = 2.0000001. \quad \checkmark$$

(The discrepancy of 10^{-7} in the last computation is the effect of rounding to the seven reported digits: in double precision the two sides equal 2.0000000000000000 and 1.9999999999999998. Over 10^6 equispaced values of t in $[-3, 3]$ the maximum discrepancy $|\varphi_1(e^{it}) - t|$ is $8.9 \cdot 10^{-16}$; over 10^6 equispaced values in $[0.15, 2\pi - 0.15]$ the maximum discrepancy $|\varphi_2(e^{it}) - t|$ is $1.1 \cdot 10^{-15}$.) $\checkmark$

Proposition 13.3: The exponential as a one-parameter homomorphism. The map $E : \mathbb{R} \rightarrow S^1$ is smooth, is a group homomorphism, is a local diffeomorphism at every point and has kernel $2\pi\mathbb{Z}$; its restriction to $(-\pi, \pi)$ is a diffeomorphism onto U_1 . In particular S^1 is connected and is generated by every neighbourhood of 1.

Proof. That E is a surjective homomorphism with kernel $2\pi\mathbb{Z}$ is Proposition 13.2. In the chart φ_1 , for $t \in (-\pi, \pi)$, the local expression of E is $\varphi_1(E(t)) = t$ (Step 2 of Theorem 13.2): this is the identity, hence $E|_{(-\pi, \pi)}$ is a diffeomorphism onto U_1 . For an arbitrary t_0 one uses the chart ψ_{t_0} of Step 5, which again gives the identity: E is a local diffeomorphism everywhere. Finally, let V be a neighbourhood of 1 and H the subgroup generated by V : H contains $E((-\varepsilon, \varepsilon))$ for some $\varepsilon > 0$, and every $t \in \mathbb{R}$ is written as a sum of finitely many terms of modulus $< \varepsilon$; since E is a homomorphism, $E(t) \in H$. Hence $H = S^1$. $\square$

Remark 13.2: What we import: the general theory of Lie groups (panorama).

Theorem 13.2 is a special case of a theory that is not developed here and is declared **imported**. Three reference facts are recorded, without proof. (i) Every connected, compact, abelian Lie group is isomorphic to a torus $(S^1)^n$; in dimension 1 this gives: S^1 and $\mathbb{R}$ are, up to isomorphism, the only connected Lie groups of dimension 1. (ii) Cartan's closed subgroup theorem: a closed subgroup of a Lie group is an embedded Lie subgroup. Theorem 13.7 of this chapter is its direct, and complete, verification in the case $G = S^1$. (iii) Hilbert's fifth problem (Gleason, Montgomery–Zippin, 1952): a locally Euclidean topological group admits a unique analytic Lie group structure. What is missing here is the whole apparatus of Lie algebras, the exponential map and the subalgebra/subgroup correspondence: see Bröcker–tom Dieck, *Representations of Compact Lie Groups*, and Warner, *Foundations of Differentiable Manifolds and Lie Groups*, listed in the sources. Nothing proved in this chapter depends on (i)–(iii).

13.3. The invariant measure $d\theta/2\pi$

Definition 13.3: The normalised measure of S^1 . Let λ be Lebesgue measure on $\mathbb{R}$. For every Borel set $A \subseteq S^1$, set

$$m(A) = \frac{1}{2\pi} \lambda(E^{-1}(A) \cap [0, 2\pi)).$$

The definition makes sense: E is continuous, hence $E^{-1}(A)$ is Borel in $\mathbb{R}$, and so is its intersection with $[0, 2\pi)$. One also writes $dm = \frac{d\theta}{2\pi}$.

Proposition 13.4: m is a Borel probability measure. m is a σ -additive measure on the Borel sets of S^1 with $m(S^1) = 1$, and for every bounded Borel function $f : S^1 \rightarrow \mathbb{C}$,

$$\int_{S^1} f dm = \frac{1}{2\pi} \int_0^{2\pi} f(e^{i\theta}) d\theta.$$

Proof. Step 1 — m is an image of λ . The restriction $E_0 = E|_{[0, 2\pi)} : [0, 2\pi) \rightarrow S^1$ is a bijection: it is surjective because E is and every class modulo 2π meets $[0, 2\pi)$; it is injective because $E(s) = E(t)$ with $s, t \in [0, 2\pi)$ implies $s - t \in 2\pi\mathbb{Z} \cap (-2\pi, 2\pi) = \{0\}$. Moreover $E_0^{-1}(A) = E^{-1}(A) \cap [0, 2\pi)$. Hence $m = \frac{1}{2\pi}(E_0)_*(\lambda|_{[0, 2\pi)})$ is the normalised image measure of $\lambda|_{[0, 2\pi)}$.

Step 2 — σ -additivity. If (A_k) are disjoint Borel sets, their $E_0^{-1}(A_k)$ are disjoint (because E_0 is a function) and $E_0^{-1}(\bigcup A_k) = \bigcup E_0^{-1}(A_k)$; the σ -additivity of λ concludes. Moreover $m(\emptyset) = 0$ and $m(S^1) = \frac{1}{2\pi}\lambda([0, 2\pi)) = 1$.

Step 3 — integral formula. This is the image-measure theorem, recalled in the prerequisites, applied to $T = E_0$: $\int_{S^1} f dm = \frac{1}{2\pi} \int_{[0, 2\pi)} f(E_0(\theta)) d\theta$, which is the statement (the point 2π , of measure zero, does not change the integral). $\square$

Theorem 13.3: Rotation invariance. For every $w \in S^1$ and every Borel set $A \subseteq S^1$, $m(wA) = m(A)$, where $wA = \{wz : z \in A\}$. Equivalently, $\int f(wz) dm(z) = \int f dm$ for every bounded Borel f .

Proof. Step 1 — reduction to $\mathbb{R}$. Let $w = E(\alpha)$ with $\alpha \in [0, 2\pi)$. Since E is a homomorphism, for every t we have $E(t) \in wA \iff E(t - \alpha) \in A \iff t \in \alpha + E^{-1}(A)$. Hence

$$E^{-1}(wA) = \alpha + E^{-1}(A).$$

Step 2 — the computation on the interval. Set $B = E^{-1}(A)$; B is 2π -periodic ($B + 2\pi = B$, because E is 2π -periodic) and $m(A) = \frac{1}{2\pi}\lambda(B \cap [0, 2\pi))$. We must compute $\lambda((\alpha + B) \cap [0, 2\pi))$. We split:

$$(\alpha + B) \cap [0, 2\pi) = ((\alpha + B) \cap [\alpha, 2\pi)) \cup ((\alpha + B) \cap [0, \alpha)),$$

a disjoint union (recall $0 \leq \alpha < 2\pi$). For the first piece, the translation $t \mapsto t - \alpha$ maps $[\alpha, 2\pi)$ onto $[0, 2\pi - \alpha)$ and $\alpha + B$ onto B ; since λ is translation-invariant,

$$\lambda((\alpha + B) \cap [\alpha, 2\pi)) = \lambda(B \cap [0, 2\pi - \alpha)).$$

For the second piece, the translation $t \mapsto t - \alpha + 2\pi$ maps $[0, \alpha)$ onto $[2\pi - \alpha, 2\pi)$ and maps $\alpha + B$ onto $B + 2\pi = B$; hence

$$\lambda((\alpha + B) \cap [0, \alpha)) = \lambda(B \cap [2\pi - \alpha, 2\pi)).$$

Adding the two pieces, and noting that $[0, 2\pi - \alpha)$ and $[2\pi - \alpha, 2\pi)$ partition $[0, 2\pi)$:

$$\lambda((\alpha + B) \cap [0, 2\pi)) = \lambda(B \cap [0, 2\pi)),$$

that is, $m(wA) = m(A)$.

Step 3 — integral form. The equality just proved says $(T_{w^{-1}})_*m = m$, hence by the image-measure theorem $\int f \circ T_w dm = \int f dm$ for every bounded Borel f (first for indicator functions, where it is Step 2; then for simple functions, by linearity; then for bounded Borel functions, by dominated convergence along a sequence of simple functions converging uniformly). $\square$

Definition 13.4: Fourier coefficients of a measure. Let μ be a finite Borel measure on S^1 . Its **Fourier coefficients** are

$$c_n(\mu) = \int_{S^1} z^n d\mu(z), \quad n \in \mathbb{Z}.$$

They are well defined because $|z^n| = 1$ and μ is finite, and they satisfy $|c_n(\mu)| \leq \mu(S^1)$.

Lemma 13.1: A finite measure is determined by its coefficients. Let μ, ν be two Borel probability measures on S^1 with $c_n(\mu) = c_n(\nu)$ for every $n \in \mathbb{Z}$. Then $\mu = \nu$.

Proof. **Step 1 — trigonometric polynomials.** Let $\mathcal{P}$ be the set of finite linear combinations, with complex coefficients, of the functions $z \mapsto z^n$, $n \in \mathbb{Z}$ (the *trigonometric polynomials* on S^1). By hypothesis and by linearity of the integral, $\int P d\mu = \int P d\nu$ for every $P \in \mathcal{P}$.

Step 2 — density. $\mathcal{P}$ is a subalgebra of $C(S^1, \mathbb{C})$: the product of two monomials is a monomial, $z^n z^m = z^{n+m}$. It contains the constants ($n = 0$). It separates points: if $z \neq w$ then $\chi_1(z) = z \neq w = \chi_1(w)$. It is closed under conjugation, because $\overline{z^n} = z^{-n}$ on S^1 . Since S^1 is compact, the Stone–Weierstrass theorem (complex version) gives: $\mathcal{P}$ is dense in $C(S^1, \mathbb{C})$ for the uniform norm.

Step 3 — from the P 's to continuous f . Let $f \in C(S^1, \mathbb{C})$ and $(P_k) \subset \mathcal{P}$ with $\|P_k - f\|_\infty \rightarrow 0$. Then

$$\left| \int f d\mu - \int f d\nu \right| \leq \left| \int (f - P_k) d\mu \right| + \left| \int (P_k - f) d\nu \right| \leq 2\|f - P_k\|_\infty \xrightarrow[k \rightarrow \infty]{} 0,$$

having used Step 1 and $\mu(S^1) = \nu(S^1) = 1$. Hence $\int f d\mu = \int f d\nu$ for every continuous f .

Step 4 — from continuous functions to closed sets. Let $F \subseteq S^1$ be closed and set, for $k \in \mathbb{N}$,

$$f_k(z) = \max(0, 1 - k d(z, F)), \quad d(z, F) = \inf_{a \in F} |z - a|.$$

The function $z \mapsto d(z, F)$ is 1-Lipschitz, hence continuous, and f_k is continuous with $0 \leq f_k \leq 1$. If $z \in F$ then $d(z, F) = 0$ and $f_k(z) = 1$. If $z \notin F$, since F is closed we have $d(z, F) > 0$, and for $k > 1/d(z, F)$ we get $f_k(z) = 0$: hence $f_k \rightarrow \mathbf{1}_F$ pointwise, with $|f_k| \leq 1$ and $\mathbf{1}_F$ integrable with respect to probability measures. By dominated convergence and Step 3,

$$\mu(F) = \lim_k \int f_k d\mu = \lim_k \int f_k d\nu = \nu(F).$$

Step 5 — from closed sets to all Borel sets. The family of closed subsets of S^1 is a π -system (the intersection of two closed sets is closed) and generates the Borel σ -algebra (the complements of closed sets are the open sets). Two probability measures that agree on a generating π -system agree on the generated σ -algebra (Dynkin's lemma, recalled in the prerequisites). Hence $\mu = \nu$. $\square$

Theorem 13.4: Uniqueness of the invariant measure on S^1 . Let μ be a Borel probability measure on S^1 such that $\mu(wA) = \mu(A)$ for every $w \in S^1$ and every Borel set A . Then $\mu = m$, the measure of Definition 13.3. In other words $d\theta/2\pi$ is the unique Haar probability measure on S^1 .

Proof. Step 1 — the coefficients of m . By Proposition 13.4, for $n \neq 0$,

$$c_n(m) = \frac{1}{2\pi} \int_0^{2\pi} e^{in\theta} d\theta = \frac{1}{2\pi} \left[\frac{e^{in\theta}}{in} \right]_0^{2\pi} = \frac{e^{2\pi in} - 1}{2\pi in} = 0,$$

because $e^{2\pi in} = 1$ for integer n ; and $c_0(m) = \frac{1}{2\pi} \int_0^{2\pi} 1 d\theta = 1$.

Step 2 — the coefficients of μ . As in Step 3 of the proof of Theorem 13.3, the invariance hypothesis gives $\int f(wz) d\mu(z) = \int f d\mu$ for every bounded Borel f and every $w \in S^1$. Applying this to $f = \chi_n$, that is $f(z) = z^n$:

$$c_n(\mu) = \int z^n d\mu(z) = \int (wz)^n d\mu(z) = w^n \int z^n d\mu(z) = w^n c_n(\mu) \quad \text{for every } w \in S^1.$$

Let $n \neq 0$ and choose $w = e^{i\pi/n}$: then $w^n = e^{i\pi} = -1$, and the relation becomes $c_n(\mu) = -c_n(\mu)$, that is $c_n(\mu) = 0$. For $n = 0$, $c_0(\mu) = \mu(S^1) = 1$.

Step 3 — conclusion. The coefficients of μ and of m agree for every $n \in \mathbb{Z}$; by Lemma 13.1, $\mu = m$. $\square$

Remark 13.3: Both hypotheses are needed. (a) Invariance under a proper subgroup is not enough. Let $\omega = e^{2\pi i/3}$ and $\mu_* = \frac{1}{3}(\delta_1 + \delta_\omega + \delta_{\omega^2})$, where δ_z is the Dirac mass at z . Then μ_* is a probability measure invariant under all rotations of the subgroup μ_3 , but not under the others, and certainly $\mu_* \neq m$ (the first is concentrated on three points, the second does not charge points). Its coefficients are computed in Example 13.2: they equal 1 if $3 \mid n$ and 0 otherwise, and indeed they do not agree with those of m . (b) An arbitrary invariant measure is not enough either. The counting measure on S^1 is rotation-invariant, but it is not finite: without the normalisation to a probability, uniqueness trivially fails (every positive multiple of m is invariant). The correct formulation in general is: the Haar measure is unique up to a positive multiplicative constant, and it is made unique by the normalisation $\mu(S^1) = 1$.

Example 13.2: Coefficients of the equidistributed measure on μ_3 , computed twice. With $\omega = e^{2\pi i/3}$ and $\mu_* = \frac{1}{3}(\delta_1 + \delta_\omega + \delta_{\omega^2})$, by definition

$$c_n(\mu_*) = \frac{1}{3}(1 + \omega^n + \omega^{2n}).$$

Symbolic computation. If $3 \mid n$, then $\omega^n = \omega^{2n} = 1$ and $c_n = 1$. If $3 \nmid n$, then $\omega^n \neq 1$ and the geometric sum gives

$$1 + \omega^n + \omega^{2n} = \frac{\omega^{3n} - 1}{\omega^n - 1} = \frac{1 - 1}{\omega^n - 1} = 0,$$

because $\omega^{3n} = (\omega^3)^n = 1$. Hence $c_n = 0$. *Independent check in double precision* (arithmetic mean of the three powers, `numpy`), for $n = 0, \dots, 6$:

$$1, 0, 0, 1, 0, 0, 1$$

with imaginary part zero within 10^{-16} and real part exact to 12 decimal digits after rounding. $\checkmark$ Comparison with Step 1 of the proof of Theorem 13.4 makes visible what distinguishes μ_* from m : the nonzero coefficients of index $\neq 0$.

Remark 13.4: What we import: the general Haar measure (panorama). On every locally compact Hausdorff topological group G there exists a nonzero Radon measure invariant under left translations, and it is unique up to a positive factor: this is **Haar's theorem** (Haar 1933 for the second-countable case, Weil and Cartan for the general case). If G is compact it is normalised to a probability, as here; if G is abelian, left and right invariance coincide. This statement is **not** proved in this treatise: it is declared imported. What is missing is the general construction (by coverings and passage to the limit, or via the Riesz representation theorem applied to an invariant functional obtained by a fixed-point/compactness argument). Theorem 13.4 of this section is its specialisation to $G = S^1$, and it is proved in full: the proof uses nothing from the general theory, only characters and Stone–Weierstrass. Sources: Folland, *A Course in Abstract Harmonic Analysis*, Chapter 2, §2.2 “Haar Measure”; Rudin, *Fourier Analysis on Groups*, Chapter 1, §1.1.

13.4. The characters of S^1

Definition 13.5: Character of an abelian topological group. Let G be an abelian topological group. A **character** of G is a continuous homomorphism $\chi : G \rightarrow S^1$, that is, a continuous function with $\chi(gh) = \chi(g)\chi(h)$ for all $g, h \in G$. The set of characters, with the pointwise product $(\chi\chi')(g) = \chi(g)\chi'(g)$, is denoted $\hat{G}$ and is called the **dual group** of G .

Lemma 13.2: Continuous additive functions on $\mathbb{R}$ are linear. Let $\psi : \mathbb{R} \rightarrow \mathbb{R}$ be continuous with $\psi(s+t) = \psi(s) + \psi(t)$ for all s, t . Then $\psi(t) = at$ with $a = \psi(1)$.

Proof. **Step 1 — integers.** From $\psi(0+0) = 2\psi(0)$ it follows that $\psi(0) = 0$. By induction, $\psi(nt) = n\psi(t)$ for every $n \in \mathbb{N}$: true for $n = 0$, and $\psi((n+1)t) = \psi(nt) + \psi(t) = (n+1)\psi(t)$. From $0 = \psi(0) = \psi(t) + \psi(-t)$ it follows that $\psi(-t) = -\psi(t)$, hence $\psi(nt) = n\psi(t)$ holds for every $n \in \mathbb{Z}$.

Step 2 — rationals. Let $q \in \mathbb{N}$, $q \geq 1$. From $\psi(1) = \psi(q \cdot \frac{1}{q}) = q\psi(\frac{1}{q})$ it follows that $\psi(\frac{1}{q}) = \frac{a}{q}$ with $a = \psi(1)$. Hence for $p \in \mathbb{Z}$, $\psi(\frac{p}{q}) = p\psi(\frac{1}{q}) = a\frac{p}{q}$: we get $\psi(r) = ar$ for every $r \in \mathbb{Q}$.

Step 3 — continuity. Let $t \in \mathbb{R}$ and $(r_k) \subset \mathbb{Q}$ with $r_k \rightarrow t$ ($\mathbb{Q}$ is dense in $\mathbb{R}$). By continuity of ψ and of multiplication, $\psi(t) = \lim_k \psi(r_k) = \lim_k ar_k = at$. $\square$

Theorem 13.5: Classification of the characters of S^1 . The characters of S^1 are exactly the power maps

$$\chi_n : S^1 \rightarrow S^1, \quad \chi_n(z) = z^n, \quad n \in \mathbb{Z},$$

and they are pairwise distinct. In angular coordinates, $\chi_n(e^{i\theta}) = e^{in\theta}$.

Proof. **Step 1 — every χ_n is a character.** χ_n is continuous (for $n \geq 0$ it is a polynomial in z ; for $n < 0$ it is $z \mapsto \bar{z}^{|n|}$, continuous by Theorem 13.1), takes values in S^1 because $|z^n| = |z|^n = 1$, and is a homomorphism: $(zw)^n = z^n w^n$ by commutativity of $\mathbb{C}$.

Step 2 — they are distinct. If $\chi_n = \chi_m$ with $n \neq m$, then $z^{n-m} = 1$ for every $z \in S^1$; setting $k = n - m \neq 0$ and $z = e^{i\pi/k}$ gives $e^{i\pi} = -1 = 1$, a contradiction.

Step 3 — reduction to the line. Let χ be a character of S^1 and set

$$\phi = \chi \circ E : \mathbb{R} \rightarrow S^1, \quad \phi(t) = \chi(e^{it}).$$

ϕ is continuous (composition of continuous functions) and, since E and χ are homomorphisms,

$\phi(s+t) = \chi(E(s)E(t)) = \phi(s)\phi(t)$; in particular $\phi(0) = \chi(1) = 1$.

Step 4 — lifting. By Corollary 12.3 (lifting of continuous maps defined on $\mathbb{R}$, which is connected, simply connected and locally path-connected) there exists a unique continuous $\psi : \mathbb{R} \rightarrow \mathbb{R}$ with

$$E \circ \psi = \phi, \quad \psi(0) = 0.$$

Step 5 — the additivity defect is locally constant. Define

$$D : \mathbb{R}^2 \rightarrow \mathbb{R}, \quad D(s, t) = \psi(s+t) - \psi(s) - \psi(t).$$

D is continuous. Moreover, since E is a homomorphism,

$$E(D(s, t)) = \frac{E(\psi(s+t))}{E(\psi(s))E(\psi(t))} = \frac{\phi(s+t)}{\phi(s)\phi(t)} = 1,$$

by Step 3. Hence $D(s, t) \in E^{-1}(1) = 2\pi\mathbb{Z}$ for every (s, t) : D is a continuous function from $\mathbb{R}^2$, which is connected, into the discrete set $2\pi\mathbb{Z}$. Such a function is constant: if it took two distinct values $2\pi j \neq 2\pi l$, the sets $D^{-1}(\{2\pi j\})$ and $D^{-1}(\mathbb{R} \setminus \{2\pi j\})$ would be open (the second preimage is open because $\{2\pi j\}$ is closed and, since $2\pi\mathbb{Z}$ is discrete and closed in $\mathbb{R}$, $\{2\pi j\}$ is also open in $2\pi\mathbb{Z}$: its preimage is open in $\mathbb{R}^2$), nonempty and disjoint, with union $\mathbb{R}^2$, contradicting connectedness. Since $D(0, 0) = \psi(0) - 2\psi(0) = 0$, the constant is 0: ψ is additive.

Step 6 — ψ is linear. By Lemma 13.2, $\psi(t) = at$ with $a = \psi(1) \in \mathbb{R}$. Hence $\phi(t) = E(at) = e^{iat}$.

Step 7 — periodicity quantises a . Since $E(2\pi) = 1$,

$$1 = \chi(1) = \chi(E(2\pi)) = \phi(2\pi) = e^{2\pi ia},$$

hence $2\pi a \in E^{-1}(1) = 2\pi\mathbb{Z}$, that is $a = n$ with $n \in \mathbb{Z}$.

Step 8 — conclusion. For every $z \in S^1$ there exists θ with $z = e^{i\theta}$ (E is surjective), and then $\chi(z) = \phi(\theta) = e^{in\theta} = (e^{i\theta})^n = z^n = \chi_n(z)$. Hence $\chi = \chi_n$. $\square$

***Remark 13.5: Two proofs, two readings.** In Volume II, Chapter 4, the same theorem is proved by analytic means: one shows that every character is differentiable (by an integral-mean trick), solves the equation $\varphi' = a\varphi$ and concludes with periodicity. The proof given here is topological: it uses no regularity at all, only the existence and uniqueness of the lifting (Chapter 12) and the connectedness of $\mathbb{R}^2$. The two roads illuminate different things: the first says that a character is automatically smooth, the second says that the quantisation of the exponent n is the winding number of the character. Indeed $\deg \chi_n = n$ (Chapter 12, Theorem 12.8): the dual $\widehat{S^1} \cong \mathbb{Z}$ and the fundamental group $\pi_1(S^1) \cong \mathbb{Z}$ are the same $\mathbb{Z}$, read once algebraically and once topologically.*

Theorem 13.6: Orthogonality relations. For all $n, m \in \mathbb{Z}$,

$$\int_{S^1} \chi_n(z) \overline{\chi_m(z)} dm(z) = \frac{1}{2\pi} \int_0^{2\pi} e^{i(n-m)\theta} d\theta = \delta_{nm} = \begin{cases} 1, & n = m, \\ 0, & n \neq m. \end{cases}$$

In particular $\{\chi_n\}_{n \in \mathbb{Z}}$ is an orthonormal system in $L^2(S^1, m)$.

Proof. On S^1 we have $\overline{\chi_m(z)} = \overline{z^m} = z^{-m}$, hence $\chi_n \overline{\chi_m} = \chi_{n-m}$. By Proposition 13.4 the integral equals $c_{n-m}(m)$, which by Step 1 of the proof of Theorem 13.4 is 1 if $n - m = 0$ and 0 otherwise.

Alternatively, and without using anything from the previous section: if $n = m$ the integrand is 1 and the mean integral equals 1; if $k = n - m \neq 0$,

$$\frac{1}{2\pi} \int_0^{2\pi} e^{ik\theta} d\theta = \frac{1}{2\pi} \cdot \frac{e^{2\pi ik} - 1}{ik} = 0.$$

Orthonormality in $L^2(S^1, m)$ is the same equality written as $\langle \chi_n, \chi_m \rangle = \delta_{nm}$, with the inner product $\langle f, g \rangle = \int f \bar{g} dm$. $\square$

Example 13.3: Orthogonality checked with the periodic trapezoidal rule. We approximate $\int \chi_n \overline{\chi_m} dm$ by the average over the equispaced nodes $\theta_k = 2\pi k/N$, $k = 0, \dots, N-1$:

$$Q_N(n, m) = \frac{1}{N} \sum_{k=0}^{N-1} e^{i(n-m)2\pi k/N}.$$

Symbolic computation. Set $k_0 = n - m$ and $\zeta = e^{2\pi i k_0/N}$: if $N \mid k_0$ then $\zeta = 1$ and $Q_N = 1$; otherwise $\zeta \neq 1$ and the geometric sum gives $Q_N = \frac{1}{N} \cdot \frac{\zeta^N - 1}{\zeta - 1} = 0$ because $\zeta^N = e^{2\pi i k_0} = 1$. The periodic trapezoidal rule is thus *exact* on every character, provided $N > |n - m|$.
Numerical check (`numpy`, double precision), for $N \in \{8, 16, 64, 1024\}$:

$$Q_N(3, 3) = 1.0000000000000000, \quad Q_N(-2, -2) = 1.0000000000000000,$$

$$|Q_N(3, 5)| \leq 1.0 \cdot 10^{-15}, \quad |Q_N(0, 7)| \leq 1.0 \cdot 10^{-15}, \quad |Q_N(2, -2)| \leq 1.0 \cdot 10^{-15}.$$

The zero values are zero within rounding error, the unit values are exact to 15 digits. $\checkmark$

Corollary 13.1: $\widehat{S^1} \cong \mathbb{Z}$. $\widehat{S^1}$, with the pointwise product, is an abelian group, and

$$\Phi : \mathbb{Z} \rightarrow \widehat{S^1}, \quad \Phi(n) = \chi_n,$$

is a group isomorphism: $\widehat{S^1} \cong \mathbb{Z}$.

Proof. The pointwise product of two characters is a character ($\chi\chi'$ is continuous with values in S^1 and $(\chi\chi')(zw) = \chi(z)\chi(w)\chi'(z)\chi'(w) = (\chi\chi')(z)(\chi\chi')(w)$, using the commutativity of $\mathbb{C}$); the constant character $\chi_0 \equiv 1$ is the identity; the inverse of χ is $\bar{\chi}$, which is a character. Hence $\widehat{S^1}$ is an abelian group. Φ is a homomorphism: $\chi_n \chi_m(z) = z^n z^m = z^{n+m} = \chi_{n+m}(z)$, that is $\Phi(n)\Phi(m) = \Phi(n+m)$. It is injective by Step 2 of the proof of Theorem 13.5 (equivalently: $\Phi(n) = \chi_0$ forces $n = 0$). It is surjective by Theorem 13.5. $\square$

Proposition 13.5: The dual of S^1 is discrete. For $n \neq m$, $\|\chi_n - \chi_m\|_\infty = \sup_{z \in S^1} |z^n - z^m| = 2$. Consequently, with the topology of uniform convergence (which on a compact group coincides with the compact-open topology), $\widehat{S^1}$ is discrete: the isomorphism of Corollary 13.1 is an isomorphism of topological groups between the discrete group $\mathbb{Z}$ and $\widehat{S^1}$.

Proof. Let $k = n - m \neq 0$. Since $|z^m| = 1$, $|z^n - z^m| = |z^m| |z^k - 1| = |z^k - 1|$. The map $z \mapsto z^k$ is surjective on S^1 (given $w = e^{i\beta}$, take $z = e^{i\beta/k}$), so $\sup_z |z^k - 1| = \sup_{u \in S^1} |u - 1| = 2$, the maximum being attained at $u = -1$. Hence two distinct characters are exactly 2 apart in uniform norm: the ball of radius 1 around χ_n contains only χ_n , and every singleton is open.
Numerical check: on a grid of 2 000 001 points of $[0, 2\pi]$, $\max_z |z^n - z^m| = 2.0000000000$ for $(n, m) = (0, 1), (2, 5), (-3, 4)$. $\checkmark$ $\square$

Proposition 13.6: $\widehat{\mathbb{Z}} \cong S^1$. Consider $\mathbb{Z}$ with the discrete topology (a locally compact abelian topological group). Then

$$\Psi : \widehat{\mathbb{Z}} \rightarrow S^1, \quad \Psi(\chi) = \chi(1),$$

is a group isomorphism, with inverse $w \mapsto (k \mapsto w^k)$; and it is a homeomorphism for the topology of pointwise convergence on $\widehat{\mathbb{Z}}$. Hence $\widehat{\mathbb{Z}} \cong S^1$.

Proof. Step 1 — every homomorphism is determined by its value at 1. Let $\chi : \mathbb{Z} \rightarrow S^1$ be a homomorphism (continuity is automatic: on the discrete $\mathbb{Z}$ every function is continuous). Set $w = \chi(1) \in S^1$; by induction $\chi(k) = w^k$ for $k \geq 0$ (with $\chi(0) = 1$), and $\chi(-k) = \chi(k)^{-1} = w^{-k}$. Hence χ is determined by w .

Step 2 — every w gives a homomorphism. For fixed $w \in S^1$, $k \mapsto w^k$ is a homomorphism $\mathbb{Z} \rightarrow S^1$ (laws of exponents), continuous because $\mathbb{Z}$ is discrete. Hence Ψ is bijective.

Step 3 — Ψ is a homomorphism. $(\chi\chi')(1) = \chi(1)\chi'(1)$, that is $\Psi(\chi\chi') = \Psi(\chi)\Psi(\chi')$.

Step 4 — topology. On $\widehat{\mathbb{Z}}$ we use pointwise convergence (which here coincides with uniform convergence on compact subsets of $\mathbb{Z}$, that is, on finite subsets). If $\chi_j \rightarrow \chi$ pointwise, in particular $\chi_j(1) \rightarrow \chi(1)$, that is $\Psi(\chi_j) \rightarrow \Psi(\chi)$: Ψ is continuous. Conversely, if $w_j \rightarrow w$ in S^1 , then for every fixed k , $w_j^k \rightarrow w^k$ (continuity of $z \mapsto z^k$), that is, the corresponding characters converge pointwise: Ψ^{-1} is continuous. $\square$

Remark 13.6: What we import: Pontryagin duality (panorama). Corollary 13.1 and Proposition 13.6 are the two sides of a single general statement, here declared **imported**: for every locally compact abelian group G , the dual $\widehat{G}$ (with the compact-open topology) is itself locally compact abelian, and the canonical map $G \rightarrow \widehat{\widehat{G}}$, $g \mapsto (\chi \mapsto \chi(g))$, is an isomorphism of topological groups (**Pontryagin duality theorem**, Pontryagin 1934, van Kampen 1935). Under this duality: G compact $\iff \widehat{G}$ discrete, and this is precisely the pair $(S^1, \mathbb{Z})$ verified above; moreover $\widehat{\mathbb{R}} \cong \mathbb{R}$ and $\widehat{\mathbb{Z}/n\mathbb{Z}} \cong \mathbb{Z}/n\mathbb{Z}$. What is missing here is: the construction of the compact-open topology on $\widehat{G}$ with the proof that it makes $\widehat{G}$ locally compact, the abstract Plancherel theorem and the inversion theorem, which are the tools of the proof. By checking $\widehat{\widehat{S^1}} = \widehat{\mathbb{Z}} \cong S^1$ with the two results of this section, however, the duality has been verified in the case that matters for the treatise. Sources: Rudin, *Fourier Analysis on Groups*, Chapter 1, §1.2 and §1.7; Folland, *A Course in Abstract Harmonic Analysis*, Chapter 4.

Remark 13.7: Why Fourier series are “forced”. Putting together the three results of the section gives the structural explanation of Fourier analysis on the circle. (i) There is one and only one invariant notion of “average” on S^1 : the measure m (Theorem 13.4). (ii) The only functions that turn the group operation into a product are the χ_n (Theorem 13.5). (iii) With respect to that average, those functions are orthonormal (Theorem 13.6). The Fourier coefficients $\hat{f}(n) = \int f \overline{\chi_n} dm$ are thus not an ad hoc construction, but the only decomposition compatible with the group structure. That the system is also complete — that is, that $\hat{f}(n) = 0$ for every n implies $f = 0$ — does not follow from the orthogonality relations and requires an additional argument: this is the content of Chapter 17 (and, for measures, of Lemma 13.1 proved above, which is the “for measures” version of the same completeness, obtained from Stone–Weierstrass).

13.5. Closed subgroups and dense subgroups

Lemma 13.3: Closed subgroups of $\mathbb{R}$. Let $G \subseteq \mathbb{R}$ be a closed subgroup of the additive group $(\mathbb{R}, +)$. Then exactly one of the following three cases holds:

- (i) $G = \{0\}$;
- (ii) $G = a\mathbb{Z}$ for a unique $a > 0$, precisely $a = \inf (G \cap (0, +\infty))$;
- (iii) $G = \mathbb{R}$.

Proof. Suppose $G \neq \{0\}$. Then G contains an element $g \neq 0$ and, being a subgroup, also contains $-g$: hence $G \cap (0, +\infty) \neq \emptyset$ and $a := \inf (G \cap (0, +\infty)) \geq 0$ is well defined.

Case $a > 0$. We first show $a \in G$. By definition of infimum there is a sequence $g_k \in G \cap (0, +\infty)$ with $g_k \rightarrow a$; since G is closed, $a \in G$. Hence $a\mathbb{Z} \subseteq G$ (G is a subgroup). Conversely let $g \in G$ and set $n = \lfloor g/a \rfloor$, that is, the unique integer with $n \leq g/a < n+1$. Then $r = g - na \in G$ (a difference of elements of G) and $0 \leq r < a$. If $r > 0$ held, we would have $r \in G \cap (0, +\infty)$ with $r < a$, contradicting the definition of a as infimum. Hence $r = 0$ and $g = na \in a\mathbb{Z}$: $G = a\mathbb{Z}$. The uniqueness of a is clear, since $a = \min (a\mathbb{Z} \cap (0, +\infty))$.

Case $a = 0$. We show that G is dense, and hence, being closed, $G = \mathbb{R}$. Let $x \in \mathbb{R}$ and $\varepsilon > 0$. Since $\inf (G \cap (0, +\infty)) = 0$, there exists $g \in G$ with $0 < g < \varepsilon$. Let $n = \lfloor x/g \rfloor$: then $ng \in G$ and

$$0 \leq x - ng < g < \varepsilon.$$

Hence every x is approximable by elements of G up to ε : G is dense in $\mathbb{R}$, and $\overline{G} = G = \mathbb{R}$.

The three cases are mutually exclusive: in (i) G is finite, in (ii) G is infinite but discrete (two distinct elements of it are at least a apart), in (iii) G is not discrete. $\square$

Theorem 13.7: Closed subgroups of S^1 . Let $H \subseteq S^1$ be a closed subgroup. Then $H = S^1$ or there exists a unique $n \geq 1$ such that

$$H = \mu_n = \{z \in S^1 : z^n = 1\} = \{e^{2\pi i k/n} : k = 0, 1, \dots, n-1\}.$$

In particular every proper closed subgroup of S^1 is finite and cyclic, generated by $e^{2\pi i/n}$.

Proof. Step 1 — H is lifted to the line. Set $G = E^{-1}(H) \subseteq \mathbb{R}$. This is a subgroup: if $E(s), E(t) \in H$ then $E(s \pm t) = E(s)E(t)^{\pm 1} \in H$ because E is a homomorphism (Proposition 13.2) and H is a subgroup. It is closed, because E is continuous and H is closed. It contains $2\pi\mathbb{Z}$, because $E(2\pi k) = 1 \in H$. In particular $G \neq \{0\}$. Finally $E(G) = H$, because E is surjective and $G = E^{-1}(H)$.

Step 2 — Lemma 13.3 is applied. Since $G \neq \{0\}$, either $G = \mathbb{R}$ or $G = a\mathbb{Z}$ with $a > 0$.

If $G = \mathbb{R}$: $H = E(\mathbb{R}) = S^1$.

If $G = a\mathbb{Z}$: from $2\pi \in G$ it follows that $2\pi = an$ for some integer n , necessarily $n \geq 1$ because $a > 0$ and $2\pi > 0$. Hence $a = 2\pi/n$ and

$$H = E(a\mathbb{Z}) = \{e^{2\pi i k/n} : k \in \mathbb{Z}\} = \{e^{2\pi i k/n} : k = 0, \dots, n-1\},$$

because $e^{2\pi i(k+n)/n} = e^{2\pi i k/n} e^{2\pi i} = e^{2\pi i k/n}$. This set has exactly n elements (if $e^{2\pi i k/n} = e^{2\pi i j/n}$ with $0 \leq j < k < n$, then $2\pi(k-j)/n \in 2\pi\mathbb{Z}$, that is $n \mid k-j$, that is $k=j$) and it is exactly $\{z : z^n = 1\} = \mu_n$: indeed $(e^{2\pi i k/n})^n = e^{2\pi i k} = 1$, and conversely $z^n = 1$ with $z = e^{i\theta}$ gives $n\theta \in 2\pi\mathbb{Z}$, that is $\theta = 2\pi k/n$. It is cyclic, generated by $e^{2\pi i/n}$.

Step 3 — uniqueness of n and exclusivity of the cases. μ_n has n elements, hence n is determined by H . And $\mu_n \neq S^1$ because S^1 is infinite (E is injective on $[0, 2\pi)$). $\square$

Corollary 13.2: An infinite closed subgroup is all of S^1 . If $H \subseteq S^1$ is a closed subgroup with infinitely many elements, then $H = S^1$. Equivalently: if H is an arbitrary subgroup with infinitely many elements, then $\overline{H} = S^1$, that is, H is dense.

Proof. The first part follows immediately from Theorem 13.7, because every proper closed subgroup is finite. For the second: the closure of a subgroup of a topological group is a subgroup. Indeed, if $z, w \in \overline{H}$, take sequences $z_k, w_k \in H$ with $z_k \rightarrow z$, $w_k \rightarrow w$ (in the metric space S^1 , the closure is the sequential closure); by continuity of multiplication and inversion (Theorem 13.1) we get $z_k w_k^{-1} \rightarrow zw^{-1}$, and $z_k w_k^{-1} \in H$, hence $zw^{-1} \in \overline{H}$. If H is infinite, $\overline{H}$ is too, and it is closed: hence $\overline{H} = S^1$. $\square$

Lemma 13.4: Dirichlet: how soon one returns near 1. Let $\alpha \in \mathbb{R}$ and $w = e^{2\pi i \alpha}$. Let $\|x\| = \min_{k \in \mathbb{Z}} |x - k|$ be the distance of x from the nearest integer. For every integer $N \geq 1$ there exists an integer n with $1 \leq n \leq N$ such that

$$\|n\alpha\| < \frac{1}{N}, \quad \text{and consequently} \quad |w^n - 1| < \frac{2\pi}{N}.$$

Proof. Step 1 — pigeonhole principle. Consider the $N + 1$ numbers $\{j\alpha\}$ (fractional part), $j = 0, 1, \dots, N$: they all lie in $[0, 1)$. Divide $[0, 1)$ into the N intervals $I_l = [\frac{l}{N}, \frac{l+1}{N})$, $l = 0, \dots, N - 1$, pairwise disjoint and with union $[0, 1)$. Since there are $N + 1$ numbers and N pigeonholes, there exist $0 \leq j < j' \leq N$ with $\{j\alpha\}$ and $\{j'\alpha\}$ in the same I_l , hence

$$|\{j'\alpha\} - \{j\alpha\}| < \frac{1}{N}.$$

Step 2 — from here to $\|n\alpha\|$. Set $n = j' - j$, so that $1 \leq n \leq N$. Since $\{x\} = x - [x]$, we have

$$\{j'\alpha\} - \{j\alpha\} = n\alpha - ([j'\alpha] - [j\alpha]) = n\alpha - k, \quad k \in \mathbb{Z},$$

hence $\|n\alpha\| \leq |n\alpha - k| < \frac{1}{N}$.

Step 3 — from the fractional part to the chord. If $\|n\alpha\| = \eta$, there is $k \in \mathbb{Z}$ with $n\alpha = k + \varepsilon$ and $|\varepsilon| = \eta$; then, since $e^{2\pi i k} = 1$,

$$|w^n - 1| = |e^{2\pi i n\alpha} - 1| = |e^{2\pi i \varepsilon} - 1| = 2|\sin(\pi \varepsilon)| \leq 2\pi|\varepsilon| = 2\pi\eta < \frac{2\pi}{N},$$

having used $|e^{i\vartheta} - 1| = 2|\sin(\vartheta/2)|$ and $|\sin x| \leq |x|$. $\square$

Theorem 13.8: Irrational rotations: density of the orbit. Let $\alpha \in \mathbb{R}$ and $w = e^{2\pi i \alpha}$. Let $\langle w \rangle = \{w^n : n \in \mathbb{Z}\}$ be the generated subgroup.

- (i) If $\alpha = p/q \in \mathbb{Q}$ (reduced fraction, $q \geq 1$), then $\langle w \rangle = \mu_q$: it is finite, closed, and not dense.
- (ii) If $\alpha \notin \mathbb{Q}$, then $\langle w \rangle$ is infinite and dense in S^1 : $\overline{\langle w \rangle} = S^1$. The same holds for the half-orbit $\{w^n : n \geq 1\}$.

Proof. (i) If $\alpha = p/q$ with $\gcd(p, q) = 1$, then $w^q = e^{2\pi i p} = 1$, hence $w \in \mu_q$ and $\langle w \rangle \subseteq \mu_q$. Conversely the order of w is exactly q : if $w^k = 1$ then $kp/q \in \mathbb{Z}$, that is $q \mid kp$, and since $\gcd(p, q) = 1$ it follows that $q \mid k$. Hence $\langle w \rangle$ is cyclic of order q and, having q elements in μ_q , which has q elements, coincides with μ_q . A finite subset of S^1 is closed (a finite union of points in a Hausdorff space) and is not dense because S^1 is infinite.

(ii) Step 1 — $\langle w \rangle$ is infinite. If it were finite, there would be $n \geq 1$ with $w^n = 1$, that is $e^{2\pi i n\alpha} = 1$, that is $n\alpha \in \mathbb{Z}$, that is $\alpha \in \mathbb{Q}$: against the hypothesis. In particular the powers

w^n , $n \in \mathbb{Z}$, are all distinct (if $w^n = w^{n'}$ with $n \neq n'$ then $w^{n-n'} = 1$).

Step 2 — density. $\langle w \rangle$ is an infinite subgroup; by Corollary 13.2, $\overline{\langle w \rangle} = S^1$.

Step 3 — the positive half-orbit suffices. Let $z \in S^1$ and $\varepsilon > 0$. Choose N with $2\pi/N < \varepsilon$ and, by Lemma 13.4, an $M \in \{1, \dots, N\}$ with $|w^M - 1| < 2\pi/N < \varepsilon$. Let δ be the principal argument of w^M , that is the unique $\delta \in (-\pi, \pi]$ with $w^M = e^{i\delta}$. We have $\delta \neq 0$, because $w^M \neq 1$ by Step 1, and

$$|\delta| \leq \frac{\pi}{2} |e^{i\delta} - 1| = \frac{\pi}{2} |w^M - 1| < \frac{\pi}{2} \varepsilon,$$

having used $|e^{i\delta} - 1| = 2|\sin(\delta/2)| \geq \frac{2}{\pi}|\delta|$, valid because $|\sin x| \geq \frac{2}{\pi}|x|$ for $|x| \leq \pi/2$. The points $w^{kM} = e^{ik\delta}$, for $k = 1, 2, \dots, K$ with $K = \lceil 2\pi/|\delta| \rceil$, have arguments advancing in constant steps of size $|\delta|$ in the same direction and covering a full turn: hence every point of S^1 is within $|\delta|$ of one of them in arc length, and a fortiori in Euclidean distance (the chord does not exceed the arc). In particular there exists $k \in \{1, \dots, K\}$ with $|w^{kM} - z| < |\delta| < \frac{\pi}{2}\varepsilon$, and the exponent kM is positive. Since $\varepsilon > 0$ is arbitrary, the half-orbit $\{w^n : n \geq 1\}$ is dense. $\square$

Example 13.4: $\alpha = \sqrt{2}$: returns near 1 and equidistribution. Take $\alpha = \sqrt{2}$, irrational, and $w = e^{2\pi i \sqrt{2}}$.

(a) *Returns.* Looking for the n that improve the record of $|w^n - 1|$ gives the sequence

$$n = 1, 2, 5, 12, 29, 70, 169, 408, 985, 2378, 5741, 13860, 33461,$$

with

$$\begin{aligned} |w^1 - 1| &= 1.9278051, & |w^5 - 1| &= 0.4428317, & |w^{29} - 1| &= 0.0765941, \\ |w^{169} - 1| &= 0.0131446, & |w^{985} - 1| &= 0.0022553, & |w^{33461} - 1| &= 0.0000664. \end{aligned}$$

These n are the Pell numbers P_k ($P_{k+1} = 2P_k + P_{k-1}$, with $1, 2, 5, 12, 29, \dots$), that is, the denominators of the convergents of $\sqrt{2}$: Lemma 13.4 guarantees that $|w^n - 1| < 2\pi/N$ for some $n \leq N$, and indeed $|w^{169} - 1| = 0.01314 < 2\pi/169 = 0.03718$. $\checkmark$

(b) *Exponential sums.* Set $S_N = \sum_{n=1}^N w^n$. By the geometric sum ($w \neq 1$),

$$S_N = w \frac{w^N - 1}{w - 1}, \quad |S_N| = \frac{|w^N - 1|}{|w - 1|} = \frac{|\sin(\pi N \alpha)|}{|\sin(\pi \alpha)|} \leq \frac{1}{|\sin(\pi \alpha)|}.$$

Closed formula versus direct computation (numpy, double precision):

N	$ S_N /N$ (direct sum)	$ S_N /N$ (closed formula)
10^2	0.0100594608	0.0100594608
10^4	0.0000428777	0.0000428777
10^6	0.0000010176	0.0000010176

The two computations agree to 10 digits. $\checkmark$ The mean $\frac{1}{N}S_N \rightarrow 0$ is the numerical check of the fact, proved in Proposition 13.7, that the means of the character χ_1 along the orbit tend to its integral with respect to m , which is 0.

Proposition 13.7: The means of characters along an irrational orbit tend to zero. Let $\alpha \notin \mathbb{Q}$, $w = e^{2\pi i \alpha}$ and $k \in \mathbb{Z}$, $k \neq 0$. Then

$$\left| \frac{1}{N} \sum_{n=1}^N \chi_k(w^n) \right| = \left| \frac{1}{N} \sum_{n=1}^N e^{2\pi i k n \alpha} \right| \leq \frac{1}{N |\sin(\pi k \alpha)|} \xrightarrow{N \rightarrow \infty} 0 = \int_{S^1} \chi_k dm.$$

Proof. Set $v = e^{2\pi i k \alpha}$. Since $\alpha \notin \mathbb{Q}$ and $k \neq 0$, we have $k\alpha \notin \mathbb{Z}$ and hence $v \neq 1$. The geometric sum gives

$$\sum_{n=1}^N v^n = v \frac{v^N - 1}{v - 1}, \quad \left| \sum_{n=1}^N v^n \right| = \frac{|v^N - 1|}{|v - 1|} \leq \frac{2}{|v - 1|} = \frac{2}{2|\sin(\pi k \alpha)|} = \frac{1}{|\sin(\pi k \alpha)|},$$

using $|v - 1| = |e^{2\pi i k \alpha} - 1| = 2|\sin(\pi k \alpha)|$ and $|v^N - 1| \leq 2$. Dividing by N and letting $N \rightarrow \infty$ gives the claim; the value $\int \chi_k dm = 0$ is Theorem 13.6 with $m = 0$. $\square$

Remark 13.8: What we import: Weyl and Kronecker in dimension n (panorama). Proposition 13.7 is the hypothesis of Weyl's criterion; the conclusion — that the sequence (w^n) is not only dense but **equidistributed**, that is $\frac{1}{N} \#\{n \leq N : w^n \in A\} \rightarrow m(A)$ for every arc A — requires **Weyl's equidistribution criterion** (Weyl, *Über die Gleichverteilung von Zahlen mod. Eins*, Math. Ann. 77 (1916), 313–352), which is here declared **imported**: what is missing is the passage from the means of characters to the means of the indicator functions of arcs, obtained by uniformly approximating the indicators with trigonometric polynomials and controlling the error at the endpoints. Likewise **Kronecker's theorem** in dimension n is declared imported: if $1, \alpha_1, \dots, \alpha_n$ are linearly independent over $\mathbb{Q}$, then $\{(e^{2\pi i k \alpha_1}, \dots, e^{2\pi i k \alpha_n}) : k \in \mathbb{Z}\}$ is dense in the torus $(S^1)^n$. The case $n = 1$ — which is exactly Theorem 13.8 — is proved here, and its proof (via the classification of closed subgroups) is the same one that, with Cartan's theorem in place of Lemma 13.3, generalises to the torus. Sources: Stein–Shakarchi, *Fourier Analysis*, Chapter 4; Katznelson, *An Introduction to Harmonic Analysis*, Chapter VI.

Figure 13.1: The two types of subgroup. In green the closed subgroup μ_6 : six points, vertices of a regular hexagon, with coordinates $(\pm 1, 0)$, $(\pm 0.5, \pm 0.86603)$. In red the first twelve points of the orbit $w^n = e^{2\pi i n \sqrt{2}}$, $n = 1, \dots, 12$: the subgroup they generate is infinite, hence dense (Theorem 13.8), and no point repeats. The coordinates are $(\cos 2\pi n \sqrt{2}, \sin 2\pi n \sqrt{2})$; for example $w^1 = (-0.85822, 0.51329)$ and $w^{10} = (0.62703, 0.77900)$.

13.6. Assigned exercises

Answers are in the Teacher's key (Section 13.9).

Exercise 13.1: Closed subgroups: recognition and counting. *Aim:* to apply Theorem 13.7 in both directions. *Estimated time:* 30 minutes. *Type:* symbolic/proof-based.

- (a) Prove that $\mu_n \cap \mu_k = \mu_{\gcd(n,k)}$ and that the subgroup generated by $\mu_n \cup \mu_k$ is $\mu_{\text{lcm}(n,k)}$.
- (b) Let $H = \{z \in S^1 : z^{12} = 1\} \cup \{e^{2\pi i \sqrt{3}}\}$. Is H a subgroup? Is it closed? Justify.
- (c) Let H be the subgroup generated by $e^{2\pi i/6}$ and $e^{2\pi i/10}$. Determine it, say whether it is closed and how many elements it has.
- (d) Prove that S^1 has no proper closed subgroups of infinite cardinality, but has (non-closed) countable dense subgroups: exhibit one different from that of Theorem 13.8.

Exercise 13.2: An invariant measure “halfway”. *Aim:* to understand exactly where the uniqueness proof breaks down if the hypothesis is weakened. *Estimated time:* 35 minutes. *Type:* symbolic with numerical check.

Let $q \geq 2$ and $\mu_*^{(q)} = \frac{1}{q} \sum_{k=0}^{q-1} \delta_{e^{2\pi i k/q}}$.

- (a) Compute $c_n(\mu_*^{(q)})$ for every $n \in \mathbb{Z}$ and prove the formula.
- (b) Check that $\mu_*^{(q)}$ is invariant under the rotations of μ_q and determine exactly for which $w \in S^1$ one has $\mu_*^{(q)}(wA) = \mu_*^{(q)}(A)$ for every Borel set A .
- (c) Identify the step of the proof of Theorem 13.4 that fails for $\mu_*^{(q)}$, and explain why.
- (d) Check (a) numerically for $q = 5$ and $n = 0, \dots, 12$, and compare with the formula.

Exercise 13.3: The character as a degree- n map. *Aim:* to connect the dual $\widehat{S^1}$ to the degree of Chapter 12. *Estimated time:* 25 minutes. *Type:* proof-based.

- (a) Prove that the isomorphism $\Phi : \mathbb{Z} \rightarrow \widehat{S^1}$ of Corollary 13.1 satisfies $\deg \Phi(n) = n$, where $\deg$ is the degree of Definition 12.8.
- (b) Deduce that two characters are homotopic (as continuous maps $S^1 \rightarrow S^1$) if and only if they are equal.
- (c) Prove that the only character that extends continuously to the disc D^2 is χ_0 .
- (d) Can a character have fixed points? Determine the fixed points of χ_n and compare with the worked exercise on fixed points of Chapter 12.

13.7. Worked exercises

Exercise 13.4: Continuous homomorphisms $\mathbb{R} \rightarrow S^1$. *Type:* symbolic/proof-based. Prove that the continuous homomorphisms $\phi : (\mathbb{R}, +) \rightarrow S^1$ are exactly those of the form $\phi(t) = e^{i\xi t}$ with $\xi \in \mathbb{R}$, and hence that $\widehat{\mathbb{R}} \cong \mathbb{R}$. Explain where the proof departs from that of Theorem 13.5 and why the exponent is quantised there but not here.

Solution. Strategy. We repeat the proof of Theorem 13.5 up to Step 6 (lifting and linearity) and observe that Step 7 — periodicity — has no analogue here.

Step 1 — every $e^{i\xi t}$ is a continuous homomorphism. $|e^{i\xi t}| = 1$ and $e^{i\xi(s+t)} = e^{i\xi s} e^{i\xi t}$; continuity is that of E composed with $t \mapsto \xi t$.

Step 2 — lifting. Let $\phi : \mathbb{R} \rightarrow S^1$ be a continuous homomorphism. By Corollary 12.3 there exists a continuous $\psi : \mathbb{R} \rightarrow \mathbb{R}$ with $E \circ \psi = \phi$ and $\psi(0) = 0$.

Step 3 — additivity. As in Step 5 of Theorem 13.5: $D(s, t) = \psi(s+t) - \psi(s) - \psi(t)$ is continuous, with values in $2\pi\mathbb{Z}$ because $E(D) = \phi(s+t)/(\phi(s)\phi(t)) = 1$, and $\mathbb{R}^2$ is connected, hence $D \equiv D(0, 0) = 0$.

Step 4 — linearity. By Lemma 13.2, $\psi(t) = \xi t$ with $\xi = \psi(1) \in \mathbb{R}$, hence $\phi(t) = e^{i\xi t}$.

Step 5 — injectivity of the parametrisation. If $e^{i\xi t} = e^{i\xi' t}$ for every t , then $(\xi - \xi')t \in 2\pi\mathbb{Z}$ for every $t \in \mathbb{R}$; but $t \mapsto (\xi - \xi')t$ is continuous on the connected $\mathbb{R}$ with values in the

discrete set $2\pi\mathbb{Z}$, hence constant, and equals 0 at $t = 0$: so $(\xi - \xi')t = 0$ for every t , that is $\xi = \xi'$. The map $\xi \mapsto (t \mapsto e^{i\xi t})$ is thus a bijection of $\mathbb{R}$ onto $\widehat{\mathbb{R}}$, and it is a homomorphism because $e^{i\xi t} e^{i\xi' t} = e^{i(\xi+\xi')t}$: $\widehat{\mathbb{R}} \cong \mathbb{R}$.

Where it departs from the theorem. In Theorem 13.5 the domain is $S^1 = \mathbb{R}/2\pi\mathbb{Z}$: the character is defined *on the quotient*, hence $\phi = \chi \circ E$ inherits 2π -periodicity and the condition $\phi(2\pi) = \chi(1) = 1$ forces $2\pi\xi \in 2\pi\mathbb{Z}$, that is $\xi = n \in \mathbb{Z}$. Here the domain is $\mathbb{R}$, which has no periods: no condition, and ξ remains free in $\mathbb{R}$.

Independent check. We verify this on a case: $\xi = 3$ gives $\phi(t) = e^{3it}$, which restricted to $2\pi\mathbb{Z}$ equals $e^{6\pi ik} = 1$: consistent with the fact that for an *integer* ξ the homomorphism descends to the quotient and defines a character of S^1 (precisely χ_3). For $\xi = 3.5$, $\phi(2\pi) = e^{7\pi i} = -1 \neq 1$: it does not descend to the quotient. ✓

Interpretation. $\widehat{\mathbb{R}} \cong \mathbb{R}$ (continuous frequencies: the Fourier transform, Chapter 19) and $\widehat{S^1} \cong \mathbb{Z}$ (discrete frequencies: Fourier series). Compactness of the domain $\leftrightarrow$ discreteness of the spectrum: this is the general statement recalled in Remark 13.6, here verified in the two cases the treatise actually uses.

Typical errors. (1) Deducing the differentiability of ϕ “because it is a homomorphism”: an argument is needed (the analytic one of Volume II, Chapter 4, or the lifting used here). (2) Concluding $\xi \in \mathbb{Z}$ even for the domain $\mathbb{R}$, wrongly importing periodicity. (3) Forgetting $\psi(0) = 0$ in Step 2: without normalisation the lifting is not unique and $D(0, 0)$ is not zero.

Extension. The same scheme classifies the continuous homomorphisms $S^1 \rightarrow \mathbb{R}$: they are all zero. Indeed the image is a compact connected subgroup of $\mathbb{R}$ (continuous image of a compact connected set), hence a closed bounded interval that is a subgroup: only $\{0\}$.

Exercise 13.5: Uniqueness of the invariant measure: check on a family of candidates. *Type:* numerical/symbolic. For $\rho \in [0, 1)$ consider the probability measure P_ρ on S^1 with density with respect to m

$$p_\rho(e^{i\theta}) = \frac{1 - \rho^2}{1 - 2\rho \cos \theta + \rho^2},$$

that is $dP_\rho = p_\rho dm$ (the Poisson kernel, Chapter 16).

- Check that P_ρ is a probability measure.
- Compute $c_n(P_\rho)$ for every $n \in \mathbb{Z}$.
- Deduce for which ρ the measure P_ρ is rotation-invariant, and thus recover Theorem 13.4 within this family.
- Check (b) numerically for $\rho = 0.5$ and $n = 0, 1, 2, 3$.

Solution. Strategy. We compute the coefficients with the geometric expansion of the Poisson kernel and apply Lemma 13.1.

Step 1 — the expansion. For $|\rho| < 1$ and $z = e^{i\theta}$,

$$\frac{1 - \rho^2}{|1 - \rho z|^2} = \frac{1 - \rho^2}{(1 - \rho z)(1 - \rho \bar{z})} = \frac{1}{1 - \rho z} + \frac{1}{1 - \rho \bar{z}} - 1,$$

verifiable by putting everything over a common denominator: $(1 - \rho \bar{z}) + (1 - \rho z) - (1 - \rho z)(1 - \rho \bar{z}) = 1 - \rho^2$ (using $z\bar{z} = 1$). Since $|1 - \rho z|^2 = 1 - 2\rho \cos \theta + \rho^2$, the left-hand side is p_ρ . Expanding in geometric series, uniformly convergent because $|\rho z| = \rho < 1$,

$$p_\rho(e^{i\theta}) = \sum_{k \geq 0} \rho^k z^k + \sum_{k \geq 0} \rho^k \bar{z}^k - 1 = \sum_{k \in \mathbb{Z}} \rho^{|k|} z^k.$$

Step 2 — (a) and (b). Integrating term by term (legitimate by uniform convergence) and using orthogonality (Theorem 13.6):

$$c_n(P_\rho) = \int z^n p_\rho dm = \sum_{k \in \mathbb{Z}} \rho^{|k|} \int z^{n+k} dm = \rho^{|n|}.$$

In particular $c_0(P_\rho) = 1$, that is $P_\rho(S^1) = 1$; since moreover $p_\rho > 0$ (the denominator is $|1 - \rho z|^2 > 0$ and the numerator is $1 - \rho^2 > 0$), P_ρ is a probability measure: (a) is proved.

Step 3 — (c). If P_ρ were invariant, by Step 2 of the proof of Theorem 13.4 we would have $c_n(P_\rho) = 0$ for every $n \neq 0$, that is $\rho^{|n|} = 0$: impossible for $\rho > 0$. Hence the only invariant one in the family is P_0 , which has density $p_0 \equiv 1$, that is $P_0 = m$: consistent with Theorem 13.4, which says that m is the unique invariant measure absolutely.

Step 4 — (d), numerical check. For $\rho = 0.5$ the formula gives

$$c_0 = 1, \quad c_1 = 0.5, \quad c_2 = 0.25, \quad c_3 = 0.125.$$

Quadrature with the periodic trapezoidal rule on $N = 4096$ nodes of $\frac{1}{2\pi} \int_0^{2\pi} e^{in\theta} p_{0.5}(e^{i\theta}) d\theta$:

$$1.000000000000, \quad 0.500000000000, \quad 0.250000000000, \quad 0.125000000000,$$

with imaginary parts $< 10^{-16}$. ✓ (The periodic quadrature is spectrally accurate on analytic periodic functions: here the agreement is at machine precision.)

Interpretation. The family (P_ρ) interpolates between the invariant measure ($\rho = 0$) and the Dirac mass at 1 ($\rho \rightarrow 1^-$): the coefficients go from δ_{n0} to 1 for every n . The “distance from invariance” is measured precisely by the nonzero coefficients of index $\neq 0$, as in Example 13.2.

Typical errors. (1) Confusing $\int p_\rho dm = 1$ with “ p_ρ is invariant”: the first is the normalisation, the second a much stronger property. (2) Integrating term by term without justifying uniform convergence (here legitimate because $\rho < 1$ is fixed). (3) Using $|1 - \rho z|^2 = 1 - 2\rho \cos \theta + \rho^2$ without noting that $|z| = 1$ is needed.

Extension. The same computation shows that $P_\rho \rightarrow \delta_1$ weakly as $\rho \rightarrow 1^-$ (the coefficients tend to $1 = c_n(\delta_1)$ for every n , and one concludes with Lemma 13.1 in its “for sequences” version): this is the *approximate identity* used in Chapter 16.

Exercise 13.6: The subgroup generated by two rotations. *Type:* symbolic/proof-based. Let $\alpha, \beta \in \mathbb{R}$ and let H be the subgroup of S^1 generated by $e^{2\pi i\alpha}$ and $e^{2\pi i\beta}$. Prove that $\overline{H} = S^1$ if and only if at least one among α, β and their integer combinations $j\alpha + k\beta$ is irrational; and that otherwise $H = \mu_q$ for an explicit q .

Solution. Strategy. We lift H to a subgroup of $\mathbb{R}$ and use Lemma 13.3 via Theorem 13.7.

Step 1 — structure of H . By definition $H = \{e^{2\pi i(j\alpha + k\beta)} : j, k \in \mathbb{Z}\}$: indeed the set on the right is a subgroup (it contains 1 for $j = k = 0$, is closed under product and inverse) and contains the two generators, and every subgroup that contains them contains it.

Step 2 — the “all rational” case. Suppose $\alpha = p_1/q_1$ and $\beta = p_2/q_2$ are both rational, written as reduced fractions. By Theorem 13.8(i), $\langle e^{2\pi i\alpha} \rangle = \mu_{q_1}$ and $\langle e^{2\pi i\beta} \rangle = \mu_{q_2}$, hence H is the subgroup generated by $\mu_{q_1} \cup \mu_{q_2}$, which by Assigned exercise 13.1(a) is μ_q with $q = \text{lcm}(q_1, q_2)$. In this case H is finite (it has q elements), closed and not dense.

Step 3 — the “some irrational combination” case. Suppose there exist $j, k \in \mathbb{Z}$ with $\gamma = j\alpha + k\beta \notin \mathbb{Q}$. Then $e^{2\pi i\gamma} \in H$ generates, by Theorem 13.8(ii), a dense subgroup; a fortiori $\overline{H} = S^1$.

Step 4 — the equivalence. If all combinations $j\alpha + k\beta$ are rational, in particular α ($j = 1, k = 0$) and β ($j = 0, k = 1$) are, and we fall back into Step 2: $H = \mu_q$, not dense. If some is irrational, Step 3: H is dense. The two alternatives are exhaustive and mutually exclusive.

Independent check. (i) $\alpha = 1/6, \beta = 1/10$: $q = \text{lcm}(6, 10) = 30$ and indeed $\frac{1}{6} - \frac{1}{10} = \frac{1}{15}$, $\frac{1}{6} - 2 \cdot \frac{1}{10} = -\frac{1}{30}$: $e^{2\pi i/30} \in H$, hence $H = \mu_{30}$, which has 30 elements. (ii) $\alpha = 1/3, \beta = \sqrt{2}/2$: β is irrational and H is dense. (iii) $\alpha = \sqrt{2}, \beta = 1 - \sqrt{2}$: both irrational, but $\alpha + \beta = 1$ is an integer; this does not prevent density, because α alone is irrational. This is why the condition must be stated on *all* combinations and not on the sum alone. ✓

Interpretation. The “finite or dense” alternative admits no middle ground: it is Theorem 13.7 read as a dichotomy. On the torus $(S^1)^2$ the situation is richer (there exist proper closed subgroups of dimension 1: wound-up lines), and that is where Kronecker’s theorem in dimension 2 is needed (Remark 13.8).

Typical errors. (1) Concluding “ α irrational and β irrational $\Rightarrow$...” by reasoning on the sum: see check (iii). (2) Forgetting that H is dense but *not* closed: $\overline{H} = S^1 \neq H$ (because H is countable and S^1 is not). (3) Using $q = q_1 q_2$ instead of the least common multiple.

Extension. The same statement holds for any finite number of generators: H is finite if and only if all the α_i are rational, and then $H = \mu_q$ with q the least common multiple of the denominators.

13.8. Self-assessment quiz

- (Definition) A *character* of the abelian topological group G is
 - a continuous function $G \rightarrow \mathbb{C}$
 - a continuous homomorphism $G \rightarrow S^1$
 - an arbitrary homomorphism $G \rightarrow \mathbb{C}^*$
 - a function with $|\chi| = 1$
- (Hypothesis) In the uniqueness theorem for the invariant measure on S^1 , the hypothesis that makes the statement false if removed is
 - σ -additivity
 - invariance with respect to *all* rotations
 - continuity of E
 - compactness of S^1
- (Symbolic computation) The coefficient c_4 of the measure $\frac{1}{4}(\delta_1 + \delta_i + \delta_{-1} + \delta_{-i})$ equals
 - 0
 - 1
 - $\frac{1}{4}$
 - i
- (Numerical computation) For $\alpha = \sqrt{2}$ and $w = e^{2\pi i \alpha}$, the first $n \geq 1$ for which $|w^n - 1| < 0.02$ is
 - 29
 - 70
 - 169
 - 408
- (Proof step) In the classification of characters, the connectedness of $\mathbb{R}^2$ is used to
 - lift ϕ
 - prove that the additivity defect $D(s, t) \in 2\pi\mathbb{Z}$ is constant
 - prove that E is surjective
 - prove that ψ is differentiable
- (Error diagnosis) A student claims: “ $\mathbb{Q} \cap [0, 2\pi)$ gives, via E , a closed and dense subgroup of S^1 ”. The error is
 - it is not a subgroup
 - it is dense but not closed: a closed dense subgroup would be all of S^1 , which is uncountable
 - it is not dense
 - E is not surjective onto the rationals
- (Transfer) If G is a locally compact abelian group and $\widehat{G}$ is discrete, then
 - G is discrete
 - G is compact
 - G is finite
 - G is connected

8. (Source and metacognition) The general statement “the invariant measure on a locally compact group exists and is unique up to a constant” is found in

A) Folland, *A Course in Abstract Harmonic Analysis*, Ch. 2, §2.2 B) Hatcher, *Algebraic Topology*, §1.1 C) Rudin, *Principles*, Ch. 7 D) Munkres, *Topology*, §53

13.9. Teacher’s key

BEST PRACTICE

Quiz — answers, rationale and diagnosis.

1) **B.** *Rationale:* this is Definition 13.5: all *three* conditions are needed (homomorphism, continuous, valued in the circle). *Distractors:* A forgets homomorphism and codomain; C forgets continuity and allows values of modulus $\neq 1$ (for $G = \mathbb{R}$ it would give $t \mapsto e^{at}$ with a a real and not purely imaginary); D forgets the homomorphism. *Diagnosed error:* confusing “function of modulus 1” with “character”. *Source:* Rudin, *Fourier Analysis on Groups*, Ch. 1, §1.2. *Prerequisite:* definition of homomorphism. *Remediation:* reread Step 1 of the proof of Theorem 13.5.

2) **B.** *Rationale:* Remark 13.3(a) exhibits $\mu_* = \frac{1}{3}(\delta_1 + \delta_\omega + \delta_{\omega^2})$, invariant under the subgroup μ_3 and different from m . *Distractors:* A and C are technical hypotheses needed to give the statement meaning, not to make it true (without σ -additivity one cannot speak of a measure); D is true but is not what is removed (on $\mathbb{R}$, non-compact, uniqueness still holds up to a constant). *Diagnosed error:* settling for invariance under a subgroup. *Source:* Theorem 13.4 and Remark 13.3. *Prerequisite:* subgroups of S^1 . *Remediation:* redo Example 13.2 with $q = 5$.

3) **B.** *Rationale:* $c_4 = \frac{1}{4}(1^4 + i^4 + (-1)^4 + (-i)^4) = \frac{1}{4}(1 + 1 + 1 + 1) = 1$: this is the case $q \mid n$ of the formula of Assigned exercise 13.2(a) with $q = 4$, $n = 4$. *Distractors:* A is the value for n not a multiple of 4 (for example $c_1 = 0$); C confuses the coefficient with the weight of each mass; D confuses c_4 with c_1 of a single mass. *Diagnosed error:* not recognising the divisibility condition. *Source:* Example 13.2. *Prerequisite:* roots of unity. *Remediation:* compute c_n for $n = 0, \dots, 8$ and observe the period 4.

4) **C.** *Rationale:* the record table in Example 13.4 gives $|w^{70} - 1| = 0.0317327$ and $|w^{169} - 1| = 0.0131446$: the first value below 0.02 is reached at $n = 169$. *Distractors:* A gives 0.0766; B gives 0.0317, still above threshold; D is the next record (0.0054), correct but not the *first*. *Diagnosed error:* reading the table without comparing it to the threshold. *Source:* Example 13.4 and Lemma 13.4. *Prerequisite:* $|e^{i\vartheta} - 1| = 2|\sin(\vartheta/2)|$. *Remediation:* redo the computation with α the golden ratio and compare the denominators.

5) **B.** *Rationale:* this is Step 5 of Theorem 13.5: a continuous function from a connected space with values in a discrete set is constant. *Distractors:* A is Step 4 and uses the *simple* connectedness of $\mathbb{R}$, not that of $\mathbb{R}^2$; C is unrelated and belongs to Chapter 12; D is the analytic route of Volume II, not this one. *Diagnosed error:* attributing the wrong role to a topological hypothesis. *Source:* Theorem 13.5, Step 5. *Prerequisite:* connectedness. *Remediation:* rewrite Step 5 exhibiting the two disjoint open sets.

BEST PRACTICE

Quiz — answers, rationale and diagnosis (continued).

6) **B.** *Rationale:* the set $\{e^{2\pi i r} : r \in \mathbb{Q}\}$ is a countable and dense subgroup (it contains every μ_n), but it is not closed: by Theorem 13.7 an infinite closed subgroup is all of S^1 , which has the cardinality of the continuum. *Distractors:* A is false ($\mathbb{Q}$ is a subgroup of $\mathbb{R}$ and E is a homomorphism); C is false (it contains μ_n for every n , hence points arbitrarily close to every z); D makes no sense, E is defined on all of $\mathbb{R}$. *Diagnosed error:* confusing

“dense” with “closed”. *Source*: Theorem 13.7 and Corollary 13.2. *Prerequisite*: closure and density. *Remediation*: check that $\{e^{2\pi ir} : r \in \mathbb{Q}\} = S^1$.

7) **B.** *Rationale*: under Pontryagin duality (Remark 13.6), G compact $\iff \widehat{G}$ discrete; applying duality to $\widehat{G}$ and using $\widehat{\widehat{G}} \cong G$ gives the required implication. The pair verified in this chapter is $\widehat{S^1} = \mathbb{Z}$ (Corollary 13.1) with $\widehat{\mathbb{Z}} = S^1$ (Proposition 13.6). *Distractors*: A reverses the implication (it is G discrete $\Rightarrow \widehat{G}$ compact); C is too strong ($\mathbb{Z}$ is not finite and $\widehat{\mathbb{Z}} = S^1$ is not discrete, but S^1 is compact with discrete infinite dual $\mathbb{Z}$); D is unrelated (finite groups are compact and disconnected). *Diagnosed error*: using duality in only one direction. *Source*: Folland, Ch. 4; Rudin, *Fourier Analysis on Groups*, Ch. 1. *Prerequisite*: notion of the compact-open topology. *Remediation*: check the two pairs $(\mathbb{R}, \mathbb{R})$ and $(\mathbb{Z}/n\mathbb{Z}, \mathbb{Z}/n\mathbb{Z})$.

8) **A.** *Rationale*: Haar’s theorem (existence and uniqueness up to a constant) is in Chapter 2 of Folland, §2.2, as recalled in Remark 13.4. *Distractors*: B is the fundamental group of the circle; C is Stone–Weierstrass, which in this chapter is used for Lemma 13.1 but is not Haar’s theorem; D is the definition of a covering. *Diagnosed error*: citing a source used in the chapter in place of the source of the statement. *Source*: see the “Sources” section. *Prerequisite*: knowing how to read a reference with chapter and section. *Remediation*: locate Haar’s statement in the two texts (Folland and Rudin) and compare the two formulations.

BEST PRACTICE

Assigned exercise 13.1 — answers. (a) $z \in \mu_n \cap \mu_k$ means $z^n = z^k = 1$, that is, the order of z divides both n and k , that is, divides $d = \gcd(n, k)$: hence $z^d = 1$ and $\mu_n \cap \mu_k \subseteq \mu_d$; the opposite inclusion is clear because $d \mid n$ and $d \mid k$. For the second point set $L = \text{lcm}(n, k)$. Since $n \mid L$ and $k \mid L$, $\mu_n \cup \mu_k \subseteq \mu_L$, and μ_L is a subgroup: hence the generated subgroup is contained in μ_L . Conversely, setting $n' = L/n$ and $k' = L/k$, $\gcd(n', k') = 1$: if a prime p divided both, L/p would still be a common multiple of n and k (because $n \mid L/p$ follows from $p \mid L/n$, and likewise for k), against the minimality of L . By Bézout’s identity there exist $u, v \in \mathbb{Z}$ with $un' + vk' = 1$, and then

$$\frac{u}{n} + \frac{v}{k} = \frac{un' + vk'}{L} = \frac{1}{L}, \quad \text{hence} \quad e^{2\pi i/L} = (e^{2\pi i/n})^u (e^{2\pi i/k})^v$$

belongs to the generated subgroup, which therefore contains μ_L . In conclusion it is exactly $\mu_{\text{lcm}(n,k)}$. (b) *No*. H is not a subgroup: it contains $\zeta = e^{2\pi i\sqrt{3}}$ but not ζ^2 , because $\zeta^2 = e^{2\pi i \cdot 2\sqrt{3}}$ is neither a twelfth root of unity ($2\sqrt{3} \notin \mathbb{Q}$) nor equal to ζ . It is not even closed in a useful sense: it is closed as a set (it is finite, 13 points, a finite union of points in a Hausdorff space), but this does not make it a closed subgroup: the classification applies only to subgroups. (c) $H = \mu_{30}$, closed, with 30 elements: this is case (i) of Worked exercise 13.6, with $\text{lcm}(6, 10) = 30$ and $\frac{1}{6} - 2 \cdot \frac{1}{10} = -\frac{1}{30}$. (d) The first part is Corollary 13.2. A countable dense subgroup different from the one generated by a single irrational rotation is $\{e^{2\pi ir} : r \in \mathbb{Q}\} = \bigcup_{n \geq 1} \mu_n$: it is a subgroup (an increasing union of subgroups, and $\mu_n \cup \mu_k \subseteq \mu_{\text{lcm}(n,k)}$), it is countable, and it is infinite, hence dense by Corollary 13.2. ✓

BEST PRACTICE

Assigned exercise 13.2 — answers. (a) $c_n = \frac{1}{q} \sum_{k=0}^{q-1} e^{2\pi i kn/q}$. If $q \mid n$ every term equals 1 and $c_n = 1$; otherwise $\zeta = e^{2\pi in/q} \neq 1$ and the geometric sum gives $\frac{1}{q} \cdot \frac{\zeta^q - 1}{\zeta - 1} = 0$ because $\zeta^q = e^{2\pi in} = 1$. Hence $c_n = \mathbf{1}_{\{q \mid n\}}$. (b) $\mu_*^{(q)}$ is invariant exactly for $w \in \mu_q$: if $w \in \mu_q$, multiplication by w permutes the q points of μ_q and leaves the weights equal; if $w \notin \mu_q$, then $w \cdot 1 = w \notin \mu_q$ and, taking $A = \{w\}$, $\mu_*^{(q)}(A) = 0$ while $\mu_*^{(q)}(w^{-1}A) = \mu_*^{(q)}(\{1\}) = \frac{1}{q} \neq 0$. (c)

Step 2 of the proof of Theorem 13.4 fails: the relation $c_n = w^n c_n$ is available only for $w \in \mu_q$, and for such w one has $w^n = 1$ whenever $q \mid n$; hence there is no admissible w with $w^n \neq 1$ when $q \nmid n$, and from that one cannot conclude $c_n = 0$. Consistently, the coefficients of index a multiple of q equal 1. **(d)** For $q = 5$, $n = 0, \dots, 12$: 1, 0, 0, 0, 0, 1, 0, 0, 0, 0, 1, 0, 0, that is 1 exactly for $n = 0, 5, 10$. Check in double precision (**numpy**): real parts 1.000000000000 and 0.000000000000, imaginary parts in modulus $\leq 10^{-15}$. ✓

BEST PRACTICE

Assigned exercise 13.3 — answers. **(a)** By Definition 12.8, $\deg f$ is the winding number of the loop $s \mapsto f(e^{2\pi i s})$. For $f = \chi_n$ we have $\chi_n(e^{2\pi i s}) = e^{2\pi i n s}$, which lifts to $\tilde{\gamma}(s) = 2\pi n s$; hence $\deg \chi_n = \frac{2\pi n - 0}{2\pi} = n$. **(b)** By Theorem 12.8, two maps $S^1 \rightarrow S^1$ are homotopic if and only if they have the same degree; by (a) this is equivalent to $n = m$, that is $\chi_n = \chi_m$ (Step 2 of Theorem 13.5). Hence distinct characters lie in distinct homotopy classes: the dual $\widehat{S^1}$ injects into $[S^1, S^1] \cong \mathbb{Z}$, and indeed exhausts it. **(c)** By Corollary 12.6 the extension to the disc exists if and only if the degree is zero, that is $n = 0$, that is $\chi = \chi_0 \equiv 1$ (which extends to the constant 1). **(d)** The fixed points of χ_n are the solutions of $z^n = z$ in S^1 , that is $z^{n-1} = 1$: they are μ_{n-1} for $n \neq 1$ (hence $|n-1|$ points), and all of S^1 for $n = 1$. In particular χ_n always has at least the fixed point $z = 1$: consistent with the worked exercise of Chapter 12, according to which a map of degree $\neq 1$ has fixed points — here for $n \neq 1$ there are exactly $|n-1|$ of them. ✓

13.10. Chapter formulary

Structure.

$$S^1 = \{z \in \mathbb{C} : |z| = 1\}, \quad z^{-1} = \bar{z}, \quad S^1 \text{ compact abelian topological group};$$

$$E : \mathbb{R} \rightarrow S^1, \quad E(t) = e^{it} \text{ homomorphism, } \ker E = 2\pi\mathbb{Z}, \quad \mathbb{R}/2\pi\mathbb{Z} \cong S^1.$$

Smooth charts (S^1 Lie group of dimension 1):

$$\varphi_1(x, y) = 2 \arctan \frac{y}{1+x} \quad \text{on } S^1 \setminus \{-1\}, \quad \varphi_2(x, y) = \pi - 2 \arctan \frac{y}{1-x} \quad \text{on } S^1 \setminus \{1\}.$$

Invariant measure.

$$m(A) = \frac{\lambda(E^{-1}(A) \cap [0, 2\pi))}{2\pi}, \quad \int_{S^1} f \, dm = \frac{1}{2\pi} \int_0^{2\pi} f(e^{i\theta}) \, d\theta,$$

$$m(wA) = m(A) \quad \forall w \in S^1; \quad m \text{ is the unique invariant Borel probability.}$$

Coefficients of a finite measure: $c_n(\mu) = \int z^n \, d\mu$; $c_n(m) = \delta_{n0}$; $\mu = \nu \iff c_n(\mu) = c_n(\nu) \, \forall n$.

Characters and duality.

$$\widehat{S^1} = \{\chi_n : z \mapsto z^n, \, n \in \mathbb{Z}\}, \quad \int_{S^1} \chi_n \overline{\chi_m} \, dm = \delta_{nm};$$

$$\widehat{S^1} \cong \mathbb{Z} \text{ (discrete)}, \quad \widehat{\mathbb{Z}} \cong S^1, \quad \widehat{\mathbb{R}} \cong \mathbb{R}; \quad \deg \chi_n = n.$$

Uniform distance between distinct characters: $\|\chi_n - \chi_m\|_\infty = 2$.

Subgroups.

$$G \leq \mathbb{R} \text{ closed} \implies G \in \{\{0\}, a\mathbb{Z} \ (a > 0), \mathbb{R}\};$$

$$H \leq S^1 \text{ closed} \implies H = \mu_n = \{z : z^n = 1\} \text{ or } H = S^1;$$

$$\alpha \notin \mathbb{Q} \implies \overline{\{e^{2\pi i n \alpha} : n \in \mathbb{Z}\}} = S^1; \quad \alpha = \frac{p}{q} \implies \{e^{2\pi i n \alpha}\} = \mu_q.$$

Dirichlet: $\forall N \exists 1 \leq n \leq N$ with $\|n\alpha\| < 1/N$, hence $|e^{2\pi i n \alpha} - 1| < 2\pi/N$. Exponential sums: $|\sum_{n=1}^N e^{2\pi i k n \alpha}| \leq 1/|\sin(\pi k \alpha)|$.

Tangencies and packings: Ford circles, Farey and optimality

Two circles touch, or they do not. It is the poorest relation one can imagine between two figures, and for that very reason it is the most fruitful: from it are born the arithmetic of fractions (Ford circles), the combinatorics of contact (the kissing number), and the optimality problems that govern how pipes, cables and rods arrange themselves spontaneously when bundled together.

The chapter is organized around three results proved in full. The first is the tangency formula for Ford circles (Theorem 14.2): two Ford circles never cross, and they touch exactly when the two fractions are Farey neighbours. The second is that in the plane the kissing number is exactly six (Theorem 14.3): six equal circles can touch one, seven cannot, and the proof of the hard part fits in three lines of trigonometry. The third is that the triangular packing has density $\pi/\sqrt{12}$ (Theorem 14.4), computed and checked numerically. That *no* packing does better — the Thue–Fejes Tóth theorem — is not proved here: its central geometric lemma is proved (Lemma 14.3) and exactly what remains imported is stated (Remark 14.4). In the same way the Kepler conjecture and the Koebe–Andreiev–Thurston circle packing theorem appear only as panorama.

INFO

Level and prerequisites. Level **C** (undergraduate), with two sections at level **D** (the hexagon lemma and the definition of density).

Internal prerequisites. Tangency of circles, power of a point and inversion (Volume I, Chapter 5); Descartes’ theorem on four mutually tangent circles and the notion of signed curvature (Volume I, Chapter 5, section «Descartes’ circle theorem»): *recalled and not reproved*; circles of Apollonius (Volume I, Chapter 2). From Volume III: geometry of plane curves (Chapter 2), isometries of the plane (Chapter 5), lattices and spheres in dimension n (Chapter 11).

External prerequisites, assumed and not reproved:

- elementary arithmetic: Euclidean division, Bézout’s identity, greatest common divisor;
- the pigeonhole principle;
- Lebesgue measure in the plane: σ -additivity, invariance under isometries, area of the disc πr^2 ;
- convexity: a function with second derivative ≥ 0 on an interval is convex, and the discrete Jensen inequality holds.

Everything else is proved here.

What one learns. How to translate an arithmetic condition ($|ps - rq| = 1$) into a geometric one (tangency) and back; how to construct the Farey sequence and prove its characteristic property; how to derive a combinatorial upper bound from an angular inequality; how to compute a density as a limit and verify it; and how to recognize where a proof’s reach ends and what is imported begins.

Warning. Conventions of this chapter.

- “Circle” denotes the closed disc $D(C, r) = \{P : |P - C| \leq r\}$; “circumference” its

boundary. The *interior* of $D(C, r)$ is $\{P : |P - C| < r\}$.

- Two circles $D(C_1, r_1)$ and $D(C_2, r_2)$ are **externally tangent** if $|C_1C_2| = r_1 + r_2$; they have **disjoint interiors** if $|C_1C_2| \geq r_1 + r_2$.
- Fractions p/q are always understood *reduced*: $q \geq 1$ and $\gcd(p, q) = 1$.
- $\lfloor x \rfloor$ is the floor function.
- Lengths in millimetres in the applications are exact by construction; the results of the counts are integers.

14.1. Tangency and curvature: what is recalled

Definition 14.1: External tangency and signed curvature. Two circles $D(C_1, r_1)$, $D(C_2, r_2)$ with $C_1 \neq C_2$ are **externally tangent** if $|C_1C_2| = r_1 + r_2$; in that case they have exactly one point in common, the point of the segment C_1C_2 at distance r_1 from C_1 , and their interiors are disjoint. The **signed curvature** of a circle of radius r is $k = 1/r$ if the circle is externally tangent to the others in the configuration, $k = -1/r$ if it contains them; a line has curvature $k = 0$.

Remark 14.1: Recalled from Volume I: Descartes' theorem. *Descartes' theorem (1643) is proved in full in the Volume I, Chapter 5, section «Descartes' circle theorem»: if four circles are mutually tangent in pairs and have signed curvatures k_1, k_2, k_3, k_4 , then*

$$(k_1 + k_2 + k_3 + k_4)^2 = 2(k_1^2 + k_2^2 + k_3^2 + k_4^2),$$

and equivalently, given k_1, k_2, k_3 ,

$$k_4 = k_1 + k_2 + k_3 \pm 2\sqrt{k_1k_2 + k_2k_3 + k_3k_1}.$$

Here the theorem is used and not reproved: we refer to Volume I for the proof, which proceeds by coordinates and squared distances. It is used in two places: in Example 14.3, where three Ford circles and the real line are checked to form a Descartes configuration, and in Worked exercise 14.8.

Remark 14.2: Recalled from Volume I: circles of Apollonius and gaskets. The **circle of Apollonius** as the locus of points P with $PA/PB = k$ constant is proved in Volume I, Chapter 2; the **problem of Apollonius** (constructing the circles tangent to three given objects) and the case of three mutually tangent circles are treated in Volume I, Chapter 5, with the technique of inversion. Iterating Descartes' theorem starting from three mutually tangent circles yields the **Apollonian gasket**, whose connection with Ford circles is illustrated in Remark 14.3. Here too: it is recalled, not reproved.

14.2. Farey fractions

Definition 14.2: Farey sequence and Farey neighbours. For $n \geq 1$, the **Farey sequence** F_n is the set of reduced fractions p/q with $0 \leq p \leq q \leq n$, listed in increasing order. Two reduced fractions $\frac{p}{q} < \frac{r}{s}$ are called **Farey neighbours** if

$$rq - ps = 1.$$

The **mediant** of $\frac{p}{q}$ and $\frac{r}{s}$ is the fraction $\frac{p+r}{q+s}$.

Lemma 14.1: Property of the mediant. Let $\frac{p}{q} < \frac{r}{s}$ be fractions with $q, s \geq 1$. Then:

- (i) $\frac{p}{q} < \frac{p+r}{q+s} < \frac{r}{s}$;
(ii) if moreover $rq - ps = 1$, then $\frac{p+r}{q+s}$ is reduced, and is a Farey neighbour of both $\frac{p}{q}$ and $\frac{r}{s}$:

$$(p+r)q - p(q+s) = 1, \quad r(q+s) - (p+r)s = 1.$$

Proof. (i) We have

$$\frac{p+r}{q+s} - \frac{p}{q} = \frac{q(p+r) - p(q+s)}{q(q+s)} = \frac{qr - ps}{q(q+s)}, \quad \frac{r}{s} - \frac{p+r}{q+s} = \frac{r(q+s) - s(p+r)}{s(q+s)} = \frac{qr - ps}{s(q+s)}.$$

Since $\frac{p}{q} < \frac{r}{s}$ and $q, s > 0$, multiplying by $qs > 0$ gives $ps < rq$, i.e. $qr - ps > 0$; and $q+s > 0$. Hence both differences are positive.

(ii) With $rq - ps = 1$ the two computations of point (i) give exactly $(p+r)q - p(q+s) = qr - ps = 1$ and $r(q+s) - (p+r)s = qr - ps = 1$. Let now $d = \gcd(p+r, q+s)$: from $(p+r)q - p(q+s) = 1$ it follows that d divides 1, hence $d = 1$ and the mediant is reduced. $\square$

Lemma 14.2: The minimum denominator between two neighbours. Let $\frac{p}{q} < \frac{r}{s}$ be Farey neighbours ($rq - ps = 1$) and let $\frac{x}{y}$ be a fraction with $y \geq 1$ and

$$\frac{p}{q} < \frac{x}{y} < \frac{r}{s}.$$

Then $y \geq q+s$, and $y = q+s$ holds if and only if $\frac{x}{y} = \frac{p+r}{q+s}$.

Proof. Since $\frac{x}{y} - \frac{p}{q} = \frac{xq - yp}{qy} > 0$ and $xq - yp$ is an integer, we have $xq - yp \geq 1$, hence

$$\frac{x}{y} - \frac{p}{q} \geq \frac{1}{qy}.$$

Similarly $\frac{r}{s} - \frac{x}{y} = \frac{ry - sx}{sy} > 0$ with $ry - sx$ an integer, hence

$$\frac{r}{s} - \frac{x}{y} \geq \frac{1}{sy}.$$

Adding and using $\frac{r}{s} - \frac{p}{q} = \frac{rq - ps}{qs} = \frac{1}{qs}$:

$$\frac{1}{qs} \geq \frac{1}{qy} + \frac{1}{sy} = \frac{s+q}{qsy},$$

whence, multiplying by $qsy > 0$, one obtains $y \geq q+s$.

If $y = q+s$, the two inequalities used must be equalities (otherwise the sum would be strictly greater): hence $xq - yp = 1$, i.e. $xq = 1 + (q+s)p$. Using $1 = rq - ps$,

$$xq = rq - ps + qp + sp = q(r+p),$$

and dividing by $q > 0$ one gets $x = p+r$: hence $\frac{x}{y} = \frac{p+r}{q+s}$. The converse is Lemma 14.1(i)–(ii), which places the mediant strictly in between and assigns it denominator $q+s$. $\square$

Theorem 14.1: Consecutive Farey fractions. For every $n \geq 1$, if $\frac{p}{q} < \frac{r}{s}$ are consecutive in F_n , then

$$rq - ps = 1.$$

Moreover F_{n+1} is obtained from F_n by inserting, between every pair of consecutive terms $\frac{p}{q} < \frac{r}{s}$ with $q + s = n + 1$, their mediant $\frac{p+r}{q+s}$, and nothing else.

Proof. By induction on n .

Base case $n = 1$. $F_1 = (\frac{0}{1}, \frac{1}{1})$ and $1 \cdot 1 - 0 \cdot 1 = 1$. ✓

Inductive step. Suppose every pair of consecutive terms of F_n satisfies $rq - ps = 1$. Let $\frac{x}{y} \in F_{n+1} \setminus F_n$: then $y = n + 1$ (fractions with denominator $\leq n$ are already in F_n) and $\frac{x}{y}$ falls strictly between two consecutive terms $\frac{p}{q} < \frac{r}{s}$ of F_n (strictly, because $\frac{x}{y} \notin F_n$). By Lemma 14.2 we have $n + 1 = y \geq q + s$; on the other hand the mediant $\frac{p+r}{q+s}$ also lies strictly between $\frac{p}{q}$ and $\frac{r}{s}$ and is reduced (Lemma 14.1), hence it belongs to $F_{q+s} \subseteq F_{n+1}$ if $q + s \leq n + 1$; but if $q + s \leq n$ held the mediant would lie in F_n strictly between two consecutive terms of F_n , absurd. So $q + s \geq n + 1$, and with the opposite inequality $q + s = n + 1 = y$. By the second part of Lemma 14.2, then $\frac{x}{y} = \frac{p+r}{q+s}$: the only new fraction between $\frac{p}{q}$ and $\frac{r}{s}$ is the mediant, and it appears exactly when $q + s = n + 1$.

The consecutive pairs of F_{n+1} are therefore: the consecutive pairs of F_n with $q + s > n + 1$ (unchanged, and the relation holds by the induction hypothesis), and the pairs $(\frac{p}{q}, \frac{p+r}{q+s})$, $(\frac{p+r}{q+s}, \frac{r}{s})$ obtained by splitting those with $q + s = n + 1$: by Lemma 14.1(ii) both satisfy the relation with value 1. The induction is complete. □

Example 14.1: F_5 and the verification of the relation.

$$F_5 = \left(\frac{0}{1}, \frac{1}{5}, \frac{1}{4}, \frac{1}{3}, \frac{2}{5}, \frac{1}{2}, \frac{3}{5}, \frac{2}{3}, \frac{3}{4}, \frac{4}{5}, \frac{1}{1} \right).$$

Symbolic check of $rq - ps = 1$ on all ten consecutive pairs:

$$\begin{aligned} \left(\frac{0}{1}, \frac{1}{5} \right) : 1 \cdot 1 - 0 \cdot 5 = 1 & \quad \left(\frac{1}{5}, \frac{1}{4} \right) : 1 \cdot 5 - 1 \cdot 4 = 1 & \quad \left(\frac{1}{4}, \frac{1}{3} \right) : 1 \cdot 4 - 1 \cdot 3 = 1 & \quad \left(\frac{1}{3}, \frac{2}{5} \right) : 2 \cdot 3 - 1 \cdot 5 = 1 \\ \left(\frac{2}{5}, \frac{1}{2} \right) : 1 \cdot 5 - 2 \cdot 2 = 1 & \quad \left(\frac{1}{2}, \frac{3}{5} \right) : 3 \cdot 2 - 1 \cdot 5 = 1 & \quad \left(\frac{3}{5}, \frac{2}{3} \right) : 2 \cdot 5 - 3 \cdot 3 = 1 & \quad \left(\frac{2}{3}, \frac{3}{4} \right) : 3 \cdot 3 - 2 \cdot 4 = 1 \\ \left(\frac{3}{4}, \frac{4}{5} \right) : 4 \cdot 4 - 3 \cdot 5 = 1 & \quad \left(\frac{4}{5}, \frac{1}{1} \right) : 1 \cdot 5 - 4 \cdot 1 = 1 \end{aligned}$$

Independent check (brute-force generation of F_n in Python, for $n = 1, \dots, 60$: one lists all fractions p/q with $\gcd(p, q) = 1$, $0 \leq p \leq q \leq n$, sorts them and checks $rq - ps = 1$ on every consecutive pair): no counterexample. The number of terms grows as $|F_n| = 1 + \sum_{k=1}^n \varphi(k)$ — for $n = 1, \dots, 10$: 2, 3, 5, 7, 11, 13, 19, 23, 29, 33 — and is computed in Assigned exercise 14.3(b). ✓

14.3. Ford circles

Definition 14.3: Ford circle. Let $\frac{p}{q}$ be a reduced fraction. The **Ford circle** $\mathcal{C}(p/q)$ is the circle in the upper half-plane

$$\mathcal{C}\left(\frac{p}{q}\right) = D\left(\left(\frac{p}{q}, \frac{1}{2q^2}\right), \frac{1}{2q^2}\right),$$

that is, the circle of centre $(p/q, 1/(2q^2))$ and radius $1/(2q^2)$. It is tangent to the real axis at the point $(p/q, 0)$.

Theorem 14.2: Tangency and disjointness of Ford circles. Let $\frac{p}{q} \neq \frac{r}{s}$ be two distinct reduced fractions, with centres $Z_1 = (\frac{p}{q}, \frac{1}{2q^2})$, $Z_2 = (\frac{r}{s}, \frac{1}{2s^2})$ and radii $\rho_1 = \frac{1}{2q^2}$, $\rho_2 = \frac{1}{2s^2}$. Then

$$|Z_1 Z_2|^2 - (\rho_1 + \rho_2)^2 = \frac{(ps - rq)^2 - 1}{q^2 s^2}.$$

Consequently:

- (i) $\mathcal{C}(p/q)$ and $\mathcal{C}(r/s)$ always have disjoint interiors;
- (ii) they are (externally) tangent if and only if $|ps - rq| = 1$, that is, if and only if the two fractions are Farey neighbours;
- (iii) if $|ps - rq| \geq 2$ the two circles are disjoint, with a positive distance between their boundaries.

Proof. **Step 1 — the computation.** By definition

$$|Z_1 Z_2|^2 = \left(\frac{p}{q} - \frac{r}{s}\right)^2 + \left(\frac{1}{2q^2} - \frac{1}{2s^2}\right)^2, \quad (\rho_1 + \rho_2)^2 = \left(\frac{1}{2q^2} + \frac{1}{2s^2}\right)^2.$$

Subtracting, the squares of the individual terms cancel and the cross terms remain, with opposite signs:

$$\left(\frac{1}{2q^2} - \frac{1}{2s^2}\right)^2 - \left(\frac{1}{2q^2} + \frac{1}{2s^2}\right)^2 = -4 \cdot \frac{1}{2q^2} \cdot \frac{1}{2s^2} = -\frac{1}{q^2 s^2}.$$

Moreover

$$\left(\frac{p}{q} - \frac{r}{s}\right)^2 = \left(\frac{ps - rq}{qs}\right)^2 = \frac{(ps - rq)^2}{q^2 s^2}.$$

Adding:

$$|Z_1 Z_2|^2 - (\rho_1 + \rho_2)^2 = \frac{(ps - rq)^2}{q^2 s^2} - \frac{1}{q^2 s^2} = \frac{(ps - rq)^2 - 1}{q^2 s^2}.$$

Step 2 — (i). Since $\frac{p}{q} \neq \frac{r}{s}$ and the fractions are reduced, $ps - rq \neq 0$: indeed $ps = rq$ implies $\frac{p}{q} = \frac{r}{s}$. Since $ps - rq$ is a nonzero integer, $(ps - rq)^2 \geq 1$ and hence $|Z_1 Z_2|^2 \geq (\rho_1 + \rho_2)^2$, i.e. $|Z_1 Z_2| \geq \rho_1 + \rho_2$: the interiors are disjoint (if a point were interior to both, the triangle inequality would give $|Z_1 Z_2| < \rho_1 + \rho_2$).

Step 3 — (ii) and (iii). The equality $|Z_1 Z_2| = \rho_1 + \rho_2$, i.e. external tangency, is equivalent to $(ps - rq)^2 = 1$, i.e. $|ps - rq| = 1$: which is exactly the Farey neighbour condition of Definition 14.2 (up to the order of the two fractions, which only changes the sign). If instead $|ps - rq| \geq 2$, then $(ps - rq)^2 - 1 \geq 3 > 0$ and $|Z_1 Z_2| > \rho_1 + \rho_2$: the two circles are disjoint and the distance between the boundaries is $|Z_1 Z_2| - \rho_1 - \rho_2 > 0$. $\square$

Corollary 14.1: The circles of consecutive Farey fractions touch. If $\frac{p}{q} < \frac{r}{s}$ are consecutive in F_n , then $\mathcal{C}(p/q)$ and $\mathcal{C}(r/s)$ are externally tangent. In particular the Ford circles of the fractions of F_n , taken in order, form a chain of consecutively tangent circles, all tangent to the real axis and with pairwise disjoint interiors.

Proof. By Theorem 14.1 we have $rq - ps = 1$, hence $|ps - rq| = 1$, and Theorem 14.2(ii) applies. The disjointness of the interiors for every pair is point (i) of the same theorem; tangency to the real axis is immediate from Definition 14.3, because the centre has ordinate equal to the radius. $\square$

Example 14.2: Tangencies and distances, computed twice. Four pairs are compared.

pair	$ps - rq$	$\frac{(ps - rq)^2 - 1}{q^2 s^2}$	outcome
$(\frac{1}{3}, \frac{1}{2})$	$1 \cdot 2 - 1 \cdot 3 = -1$	0	tangent
$(\frac{1}{4}, \frac{1}{3})$	$1 \cdot 3 - 1 \cdot 4 = -1$	0	tangent
$(\frac{2}{5}, \frac{1}{2})$	$2 \cdot 2 - 1 \cdot 5 = -1$	0	tangent
$(\frac{1}{3}, \frac{2}{3})$	$1 \cdot 3 - 2 \cdot 3 = -3$	$\frac{8}{81} = 0.0987654$	disjoint
$(\frac{1}{3}, \frac{3}{4})$	$1 \cdot 4 - 3 \cdot 3 = -5$	$\frac{81}{144} = 0.1666667$	disjoint

Independent check in double precision, computing separately $|Z_1 Z_2|^2$ and $(\rho_1 + \rho_2)^2$ from the coordinates of the centres and the radii, and taking the difference:

$$(\frac{1}{3}, \frac{1}{2}) : 6.9 \cdot 10^{-18}, \quad (\frac{1}{4}, \frac{1}{3}) : -2.6 \cdot 10^{-18}, \quad (\frac{2}{5}, \frac{1}{2}) : -3.5 \cdot 10^{-18},$$

that is, zero within machine error, and

$$(\frac{1}{3}, \frac{2}{3}) : 0.0987654321, \quad (\frac{1}{3}, \frac{3}{4}) : 0.1666666667,$$

coinciding with the symbolic values $8/81$ and $1/6$. ✓

Figure 14.1: The Ford circles of the fractions of F_5 in the interval $[0, 1]$. The circle of p/q has centre $(p/q, 1/(2q^2))$ and radius $1/(2q^2)$: radius 0.5 for $q = 1$, 0.125 for $q = 2$, $1/18 = 0.05556$ for $q = 3$, $1/32 = 0.03125$ for $q = 4$, 0.02 for $q = 5$. Two circles touch exactly when the fractions are Farey neighbours (Theorem 14.2); for example $\frac{1}{3}$ and $\frac{1}{2}$ ($|ps - rq| = 1$) touch, while $\frac{1}{3}$ and $\frac{2}{3}$ ($|ps - rq| = 3$) stay apart. No pair ever overlaps.

Example 14.3: Three Ford circles and the line: a Descartes configuration. Let $\frac{p}{q} < \frac{r}{s}$ be Farey neighbours and $\frac{p+r}{q+s}$ their median. By Corollary 14.1 and Lemma 14.1(ii) the three corresponding Ford circles are mutually tangent, and each is tangent to the real axis: one thus has a quadruple of mutually tangent objects, with curvatures

$$k_1 = 0 \text{ (the line)}, \quad k_2 = 2q^2, \quad k_3 = 2s^2, \quad k_4 = 2(q + s)^2.$$

Symbolic check of Descartes' theorem (Remark 14.1): setting $u = q^2$, $v = s^2$, $w = (q + s)^2$,

$$(k_1 + k_2 + k_3 + k_4)^2 = 4(u + v + w)^2, \quad 2(k_1^2 + k_2^2 + k_3^2 + k_4^2) = 8(u^2 + v^2 + w^2).$$

The equality is equivalent to $(u + v + w)^2 = 2(u^2 + v^2 + w^2)$, i.e. to $2(uv + vw + wu) = u^2 + v^2 + w^2$. With $w = (q + s)^2 = u + v + 2qs$ and $qs = \sqrt{uv}$ this is verified directly: setting $t = qs$, one has $u^2 + v^2 + w^2 - 2uv - 2vw - 2wu = (w - u - v)^2 - 4uv = (2t)^2 - 4uv = 4q^2s^2 - 4q^2s^2 = 0$.
✓ Numerical check. For $\frac{p}{q} = \frac{0}{1}$, $\frac{r}{s} = \frac{1}{1}$ (neighbours: $1 \cdot 1 - 0 \cdot 1 = 1$), mediant $\frac{1}{2}$: curvatures $(0, 2, 2, 8)$, and $(0 + 2 + 2 + 8)^2 = 144$, $2(0 + 4 + 4 + 64) = 144$.
✓ For $\frac{p}{q} = \frac{0}{1}$, $\frac{r}{s} = \frac{1}{2}$, mediant $\frac{1}{3}$: curvatures $(0, 2, 8, 18)$, and $(0 + 2 + 8 + 18)^2 = 784$, $2(0 + 4 + 64 + 324) = 784$. **✓**

Remark 14.3: Ford, Farey and the Apollonian gasket. Example 14.3 shows that the set of Ford circles, together with the real axis, is an **Apollonian gasket**: starting from the line and the two circles $\mathcal{C}(0/1)$, $\mathcal{C}(1/1)$, every new circle is the fourth Descartes circle of three already present, and the sequence of curvatures $2q^2$ reproduces exactly the construction of Farey mediants. Historically the connection was made explicit by L. R. Ford in 1938 (*Fractions, American Mathematical Monthly* 45, 586–601), who introduced these circles precisely to “see” the properties of fractions: Theorem 14.2 translates the arithmetic $|ps - rq| = 1$ into geometry, and the best rational approximation of an irrational α can be read off as the chain of Ford circles that the point $(\alpha, 0)$ “crosses” rising upward. It is the same irrational α that in Chapter 13 generates a dense subgroup of S^1 : the denominators of the convergents that there measured the returns near 1 are here the radii of the tangent circles.

14.4. The kissing number in the plane

Definition 14.4: Kissing number. The **kissing number** of the plane, τ_2 , is the maximum number of circles of radius r with pairwise disjoint interiors that can all be externally tangent to a fixed circle of the same radius r .

Theorem 14.3: The kissing number of the plane is 6. $\tau_2 = 6$.

Proof. It is no loss of generality to take $r = 1$ and the central circle $D(O, 1)$ with O the origin. A circle $D(C_j, 1)$ externally tangent to $D(O, 1)$ has $|C_j| = 2$.

Step 1 — lower bound: six is possible. Take

$$C_j = (2 \cos(j\pi/3), 2 \sin(j\pi/3)), \quad j = 0, 1, \dots, 5,$$

that is

$$(2, 0), (1, \sqrt{3}), (-1, \sqrt{3}), (-2, 0), (-1, -\sqrt{3}), (1, -\sqrt{3}),$$

with $\sqrt{3} = 1.7320508$. Each has $|C_j| = 2$, hence $D(C_j, 1)$ is tangent to $D(O, 1)$. For $j \neq l$ the angle between C_j and C_l is a nonzero multiple of $\pi/3$, hence it is $\geq \pi/3$, and by the cosine theorem

$$|C_j - C_l|^2 = 4 + 4 - 8 \cos \theta_{jl} = 8(1 - \cos \theta_{jl}) \geq 8\left(1 - \frac{1}{2}\right) = 4,$$

that is, $|C_j - C_l| \geq 2$: the interiors are pairwise disjoint. *Explicit check* on the closest pair: $|(2, 0) - (1, \sqrt{3})|^2 = 1 + 3 = 4$, that is a distance of exactly 2 (the two circles touch). **✓** Hence $\tau_2 \geq 6$.

Step 2 — upper bound: seven is not possible. Let $D(C_1, 1), \dots, D(C_k, 1)$ be tangent to $D(O, 1)$ with pairwise disjoint interiors. Then $|C_j| = 2$ for every j and $|C_j - C_l| \geq 2$ for $j \neq l$.

Writing $\theta_{jl} \in [0, \pi]$ for the angle $\widehat{C_j O C_l}$, the cosine theorem gives

$$4 \leq |C_j - C_l|^2 = 8(1 - \cos \theta_{jl}) \implies \cos \theta_{jl} \leq \frac{1}{2} \implies \theta_{jl} \geq \frac{\pi}{3},$$

using that $\cos$ is decreasing on $[0, \pi]$ and $\cos(\pi/3) = \frac{1}{2}$.

Write the centres now in polar coordinates, $C_j = 2(\cos \alpha_j, \sin \alpha_j)$, with $\alpha_1 < \alpha_2 < \dots < \alpha_k$ in $[0, 2\pi)$ (the α_j are distinct because $\theta_{jl} > 0$). Set the k gaps

$$\Delta_j = \alpha_{j+1} - \alpha_j \quad (j = 1, \dots, k-1), \quad \Delta_k = 2\pi - \alpha_k + \alpha_1,$$

which are positive and whose sum is 2π . For every j , the angle $\widehat{C_j O C_{j+1}}$ equals $\min(\Delta_j, 2\pi - \Delta_j)$; since that angle is $\geq \pi/3$ and since $\Delta_j \leq 2\pi$, in every case $\Delta_j \geq \pi/3$ (if $\Delta_j < \pi/3$ held then $\min(\Delta_j, 2\pi - \Delta_j) = \Delta_j < \pi/3$, a contradiction). Hence

$$2\pi = \sum_{j=1}^k \Delta_j \geq k \cdot \frac{\pi}{3} \implies k \leq 6.$$

(For $k = 1$ and $k = 2$ the statement is trivially true and the count of gaps remains valid.)

Combining the two steps, $\tau_2 = 6$. □

Figure 14.2: The kissing number of the plane is 6. The six centres lie at the vertices of a regular hexagon of side 2 inscribed in the circle of radius 2: coordinates $(\pm 2, 0)$ and $(\pm 1, \pm 1.73205)$. The red triangle has all three sides of length 2 ($|(2, 0) - (1, \sqrt{3})|^2 = 1 + 3 = 4$), hence it is equilateral and the central angle is exactly 60° : six angles of 60° fill the full turn with no room to spare, and a seventh circle would require another angle $\geq 60^\circ$ (Theorem 14.3, Step 2).

Exercise 14.1: Seven cables in a conduit. *Aim:* to translate the kissing number into a sizing problem. *Estimated time:* 15 minutes. *Type:* numerical/applied. Seven equal cables of radius r must be bundled. What is the minimum radius of the circular conduit that contains them, in the “one central and six around” arrangement? Prove that in that arrangement the value found is optimal, and discuss whether a different arrangement of the seven circles could do better.

Solution. Strategy. The radius needed for the hexagonal configuration is computed and one observes that the constraint is given by the six outer circles.

Step 1 — the computation. In the “one central and six around” arrangement the central cable has its centre at the origin; the six outer ones are tangent to it, hence their centres are at distance $2r$ from the origin (Theorem 14.3, Step 1). The point farthest from the origin belonging to one of the seven circles is then at distance $2r + r = 3r$. Hence every circular conduit centred at the origin that contains them has radius $R \geq 3r$, and $R = 3r$ suffices:

the bundle has diameter $6r$, that is, three times the diameter of a single cable.

Step 2 — optimality within the configuration. In that configuration the value $3r$ is exactly the maximum of the distances from the origin of the points of the seven discs, hence it is the radius of the smallest circle centred at the origin that contains them. If one allows the centre of the conduit to move, the configuration is invariant under rotations of $\pi/3$ and symmetric, and every displacement of the centre moves at least one of the six outer circles farther away: the radius needed grows. Precisely, for a centre P the radius needed is $\max_j (|P - C_j| + r)$ with C_j the six outer centres, and by the triangle inequality $\max_j |P - C_j| \geq \frac{1}{2}(|P - C_j| + |P - C_{j+3}|) \geq \frac{1}{2}|C_j - C_{j+3}| = 2r$ for every pair of opposite centres: hence $R \geq 3r$ always.

Independent check. For $r = 6$ mm (a cable of 12 mm diameter) one gets $R = 18$ mm, a conduit of diameter 36 mm. Area check: the seven cables occupy $7\pi r^2 = 7\pi \cdot 36 = 791.68 \text{ mm}^2$; the conduit has area $\pi R^2 = \pi \cdot 324 = 1017.88 \text{ mm}^2$; the ratio is $7/9 = 0.7778$, that is 77.78%. ✓ (The value $7/9$ is exact: $7\pi r^2 / (\pi(3r)^2) = 7/9$.)

Interpretation. The 77.78% is lower than the density of the infinite packing $\pi/\sqrt{12} = 0.9069$ (Theorem 14.4): it is the boundary effect, which on only seven circles weighs very heavily. With 19 cables (two rings) the ratio rises to $19/25 = 0.76$... actually $19\pi r^2 / (\pi(5r)^2) = 19/25 = 0.76$: it does not improve, because the outer ring is still almost all boundary.

Typical errors. (1) Computing $R = 7r$ by adding radii in a row. (2) Forgetting the radius of the outer cable and concluding $R = 2r$. (3) Confusing the ratio of areas with the asymptotic density.

Extension. For n cables the problem (“pack n equal circles in the smallest possible circle”) has a known solution only for a few values of n ; for $n = 7$ the value $R = 3r$ is optimal and is one of the classical cases. See Remark 14.5 for the state of the art.

14.5. Packing density

Definition 14.5: Packing and density. A **packing** of circles of radius $r > 0$ in the plane is a family $\mathcal{P} = \{D(C_i, r)\}_{i \in I}$ of circles with pairwise disjoint interiors, that is with $|C_i - C_j| \geq 2r$ for $i \neq j$. Writing $B_R = D(O, R)$, the **density** of $\mathcal{P}$ is

$$\delta(\mathcal{P}) = \lim_{R \rightarrow +\infty} \frac{\text{area}\left(B_R \cap \bigcup_i D(C_i, r)\right)}{\pi R^2},$$

when the limit exists.

Theorem 14.4: The triangular packing has density $\pi/\sqrt{12}$. Let $r > 0$ and let

$$\Lambda = \{m(2r, 0) + n(r, r\sqrt{3}) : m, n \in \mathbb{Z}\}$$

be the triangular lattice. Then $\mathcal{P}_\Lambda = \{D(\lambda, r)\}_{\lambda \in \Lambda}$ is a packing, the limit of Definition 14.5 exists and

$$\delta(\mathcal{P}_\Lambda) = \frac{\pi r^2}{2\sqrt{3}r^2} = \frac{\pi}{2\sqrt{3}} = \frac{\pi}{\sqrt{12}} = 0.9068997.$$

Proof. **Step 1 — it is a packing.** A generic element of Λ is

$$\lambda_{m,n} = r(2m + n, n\sqrt{3}), \quad |\lambda_{m,n}|^2 = r^2((2m + n)^2 + 3n^2).$$

For $(m, n) \neq (0, 0)$ three cases are distinguished. If $n = 0$ then $m \neq 0$ and $|\lambda|^2 = 4m^2r^2 \geq 4r^2$.

If $|n| = 1$ then $(2m + n)^2 \geq 0$ and $|\lambda|^2 \geq 3r^2 + (2m \pm 1)^2 r^2 \geq 3r^2 + r^2 = 4r^2$, because $2m \pm 1$ is odd, hence nonzero, and its square is ≥ 1 . If $|n| \geq 2$ then $|\lambda|^2 \geq 12r^2 > 4r^2$. Hence the minimum of $|\lambda|$ over $\Lambda \setminus \{0\}$ is $2r$, attained (for example) at $(m, n) = (1, 0)$ and at $(m, n) = (0, 1)$. Since Λ is a group, $|\lambda - \lambda'| \geq 2r$ for $\lambda \neq \lambda'$: the interiors of the discs are disjoint.

Step 2 — area of the cell. The fundamental parallelogram $P = \{a(2r, 0) + b(r, r\sqrt{3}) : a, b \in [0, 1)\}$ has area

$$A = \left| \det \begin{pmatrix} 2r & 0 \\ r & r\sqrt{3} \end{pmatrix} \right| = 2r \cdot r\sqrt{3} = 2\sqrt{3} r^2 = 3.4641016 r^2,$$

and the translates $P + \lambda$, $\lambda \in \Lambda$, form a partition of the plane (this is the definition of a fundamental domain of a lattice). The diameter of P does not exceed $|(2r, 0)| + |(r, r\sqrt{3})| = 2r + 2r = 4r$; set $d_0 = 4r$.

Step 3 — counting lattice points. Let $\rho > d_0$ and $N(\rho) = \#\{\lambda \in \Lambda : |\lambda| \leq \rho\}$. The cells $P + \lambda$ with $|\lambda| \leq \rho$ are pairwise disjoint and contained in $B_{\rho+d_0}$ (every point of $P + \lambda$ is at distance at most d_0 from λ), hence, by additivity and monotonicity of area,

$$N(\rho) A \leq \pi(\rho + d_0)^2.$$

Conversely, every point $x \in B_{\rho-d_0}$ belongs to some cell $P + \lambda$, and for it $|\lambda| \leq |x| + d_0 \leq \rho$: hence $B_{\rho-d_0}$ is covered by the cells with $|\lambda| \leq \rho$ and

$$N(\rho) A \geq \pi(\rho - d_0)^2.$$

Step 4 — estimate of the covered area. Let $S = \bigcup_{\lambda \in \Lambda} D(\lambda, r)$. The discs have disjoint interiors, hence the area of their union is the sum of the areas. Every disc $D(\lambda, r)$ with $|\lambda| \leq R - r$ is contained in B_R , and every disc that meets B_R has $|\lambda| \leq R + r$; hence

$$\pi r^2 N(R - r) \leq \text{area}(B_R \cap S) \leq \pi r^2 N(R + r).$$

Combining with Step 3 (for large R):

$$\frac{\pi r^2}{A} \cdot \frac{(R - r - d_0)^2}{R^2} \leq \frac{\text{area}(B_R \cap S)}{\pi R^2} \leq \frac{\pi r^2}{A} \cdot \frac{(R + r + d_0)^2}{R^2}.$$

Both outer terms tend to $\pi r^2/A$ as $R \rightarrow +\infty$; by the squeeze theorem the limit exists and equals

$$\delta(\mathcal{P}_\Lambda) = \frac{\pi r^2}{A} = \frac{\pi r^2}{2\sqrt{3} r^2} = \frac{\pi}{2\sqrt{3}}.$$

Step 5 — the numerical value, computed twice. From the closed form, $\pi/(2\sqrt{3}) = 3.14159265/3.46410162 = 0.90689968$. In equivalent form, $\pi/\sqrt{12}$ with $\sqrt{12} = 3.46410162$: same value. *Independent check* in double precision (`numpy`): $\pi/\sqrt{12} = 0.9068996821171089$. ✓

□

Proposition 14.1: Density of the square packing. Let $\Lambda' = \{(2rm, 2rn) : m, n \in \mathbb{Z}\}$ be the square lattice. Then $\{D(\lambda, r)\}_{\lambda \in \Lambda'}$ is a packing of density

$$\delta' = \frac{\pi r^2}{4r^2} = \frac{\pi}{4} = 0.7853982,$$

that is $\delta'/\delta = \frac{\pi/4}{\pi/\sqrt{12}} = \frac{\sqrt{12}}{4} = \frac{\sqrt{3}}{2} = 0.8660254$: the square packing covers 13.40% less than the triangular one.

Proof. The minimum distance between distinct points of Λ' is $2r$ (it suffices to note $|(2rm, 2rn)|^2 = 4r^2(m^2 + n^2) \geq 4r^2$ for $(m, n) \neq (0, 0)$), hence it is a packing. The fundamental cell is the square of side $2r$, of area $A' = 4r^2$, and Steps 2–4 of the proof of Theorem 14.4 repeat identically (with $d_0 = |(2r, 0)| + |(0, 2r)| = 4r$), giving $\delta' = \pi r^2/A' = \pi/4$. The ratio is $\frac{\pi/4}{\pi/(2\sqrt{3})} = \frac{2\sqrt{3}}{4} = \frac{\sqrt{3}}{2}$, and $1 - \frac{\sqrt{3}}{2} = 1 - 0.8660254 = 0.1339746$. *Numerical check:* $\pi/4 = 0.7853981634$, and $0.7853981634/0.9068996821 = 0.8660254038 = \sqrt{3}/2$. $\checkmark$ $\square$

Figure 14.3: Triangular packing (also called hexagonal) of equal circles of radius 1: the centres lie in the lattice generated by $(2, 0)$ and $(1, \sqrt{3}) = (1, 1.73205)$, each circle touches six others (kissing number 6, Theorem 14.3) and the density is $\pi/\sqrt{12} = 0.9069$, that is 90.69% (Theorem 14.4). It is the spontaneous arrangement of rods, cables and pipes bundled together, and the basis of the *nesting* of circular parts.

Lemma 14.3: Hexagon lemma: polygons with at most six sides. Let $H \subset \mathbb{R}^2$ be a convex polygon with n sides, $3 \leq n \leq 6$, that contains the disc $D(O, r)$ with O in its interior. Then

$$\text{area}(H) \geq n r^2 \tan \frac{\pi}{n} \geq 6 r^2 \tan \frac{\pi}{6} = 2\sqrt{3} r^2,$$

with equality in the first inequality if and only if H is the regular n -gon circumscribed about $D(O, r)$.

Proof. Step 1 — decomposition. Let $A_1, \dots, A_n$ be the vertices of H in cyclic order. Since H is convex and O is interior, the triangles $T_i = OA_iA_{i+1}$ (indices modulo n) have disjoint interiors and union H , hence $\text{area}(H) = \sum_i \text{area}(T_i)$.

Step 2 — estimate of a triangle. Let ℓ_i be the line containing the side A_iA_{i+1} and F_i the foot of the perpendicular from O to ℓ_i ; set $h_i = |OF_i|$. Since $D(O, r) \subseteq H$ and H lies entirely on one side of ℓ_i (convexity), the line ℓ_i does not meet the interior of the disc, hence $h_i \geq r > 0$; in particular $O \notin \ell_i$.

Measure the positions of A_i and A_{i+1} on ℓ_i by the signed angles $\beta', \beta'' \in (-\pi/2, \pi/2)$ formed with OF_i , oriented so that $\beta' < \beta''$; then, by definition of tangent,

$$|A_iA_{i+1}| = h_i(\tan \beta'' - \tan \beta'), \quad \text{area}(T_i) = \frac{1}{2}h_i|A_iA_{i+1}| = \frac{1}{2}h_i^2(\tan \beta'' - \tan \beta').$$

Let $2\gamma_i = \beta'' - \beta' \in (0, \pi)$ be the angle $\widehat{A_iOA_{i+1}}$, so that $\gamma_i \in (0, \pi/2)$. We claim that

$$\tan \beta'' - \tan \beta' \geq 2 \tan \gamma_i. \quad (*)$$

Case $0 \leq \beta' < \beta''$: the tangent is superadditive on $[0, \pi/2)$, because $\tan(x+y) = \frac{\tan x + \tan y}{1 - \tan x \tan y} \geq \tan x + \tan y$ when $0 < 1 - \tan x \tan y \leq 1$; applying it to $x = \beta'$, $y = \beta'' - \beta' = 2\gamma_i$ gives $\tan \beta'' \geq \tan \beta' + \tan(2\gamma_i)$, that is $\tan \beta'' - \tan \beta' \geq \tan(2\gamma_i) \geq 2 \tan \gamma_i$, the last inequality by the same superadditivity with $x = y = \gamma_i$. *Case $\beta' < 0 \leq \beta''$:* set $a = \beta'' \geq 0$ and $b = -\beta' > 0$, so $a + b = 2\gamma_i$ and $\tan \beta'' - \tan \beta' = \tan a + \tan b \geq 2 \tan \frac{a+b}{2} = 2 \tan \gamma_i$ by convexity of $\tan$ on

$[0, \pi/2)$ (where $\tan'' = 2\sec^2 \tan \geq 0$). *Case $\beta' < \beta'' \leq 0$:* it is symmetric to the first by the oddness of $\tan$. In every case (*) holds.

Hence, using $h_i \geq r$,

$$\text{area}(T_i) \geq \frac{1}{2} h_i^2 \cdot 2 \tan \gamma_i = h_i^2 \tan \gamma_i \geq r^2 \tan \gamma_i.$$

Step 3 — sum and Jensen. The angles $2\gamma_i$ are the central angles of the triangles T_i , hence $\sum_i 2\gamma_i = 2\pi$, that is $\sum_i \gamma_i = \pi$ with $\gamma_i \in (0, \pi/2)$. Since $\tan$ is convex on $[0, \pi/2)$ and $\pi/n < \pi/2$ for $n \geq 3$, Jensen's inequality gives

$$\frac{1}{n} \sum_{i=1}^n \tan \gamma_i \geq \tan \left(\frac{1}{n} \sum_{i=1}^n \gamma_i \right) = \tan \frac{\pi}{n}.$$

Hence $\text{area}(H) \geq r^2 \sum_i \tan \gamma_i \geq n r^2 \tan \frac{\pi}{n}$. Equality requires $h_i = r$ for every i (circumscribed polygon), $\beta'' = -\beta'$ for every i (the foot F_i is the midpoint of the side) and all the γ_i equal to π/n (the case of equality in Jensen for a strictly convex function): that is, exactly the circumscribed regular polygon.

Step 4 — monotonicity in n . Set $g(n) = n \tan \frac{\pi}{n}$. With $x = \pi/n \in (0, \pi/2]$ one has $g = \pi \frac{\tan x}{x}$, and $\frac{\tan x}{x}$ is increasing on $(0, \pi/2)$: its derivative has numerator $x \sec^2 x - \tan x = \frac{2x - \sin 2x}{2 \cos^2 x} > 0$ because $\sin u < u$ for $u > 0$. Since x decreases as n increases, g is decreasing in n ; hence for $n \leq 6$

$$g(n) \geq g(6) = 6 \tan \frac{\pi}{6} = \frac{6}{\sqrt{3}} = 2\sqrt{3}.$$

Numerical check of the values of g : $g(3) = 5.1961524$, $g(4) = 4.0000000$, $g(5) = 3.6327126$, $g(6) = 3.4641016 = 2\sqrt{3}$, $g(7) = 3.3710223$, $g(8) = 3.3137085$: decreasing, and $g(6) = 2\sqrt{3} = 3.4641016$. $\checkmark$ □

Remark 14.4: What we import: the Thue–Fejes Tóth theorem (panorama). The **Thue–Fejes Tóth theorem** states that for every packing $\mathcal{P}$ of equal circles in the plane, every upper limit density satisfies

$$\limsup_{R \rightarrow +\infty} \frac{\text{area}(B_R \cap \bigcup \mathcal{P})}{\pi R^2} \leq \frac{\pi}{\sqrt{12}},$$

with equality for the triangular packing of Theorem 14.4. This statement is **not** proved here and is declared **imported**.

What is proved. Theorem 14.4 (the density $\pi/\sqrt{12}$ is attained) and Lemma 14.3 (a convex polygon with at most six sides containing a disc of radius r has area $\geq 2\sqrt{3}r^2$), which is the geometric heart of the classical proof.

What exactly is missing. The classical proof associates to each circle its Voronoi cell and would like to apply to it Lemma 14.3. Two points remain uncovered, and these are the ones that here are not closed with certainty:

(a) The number of sides. The Voronoi cells of a packing do not in general have at most six sides; the average number of sides is ≤ 6 by Euler's formula, and to conclude from an average one needs a convexity argument for the function $n \mapsto n \tan(\pi/n)$ (which is decreasing and convex) combined with Jensen's inequality in the opposite direction to that of Step 3 of the lemma. The step is correct but requires a version of Euler's formula valid for an infinite configuration.

(b) Unbounded cells and the boundary. Voronoi cells can be unbounded, and passing to the limit on B_R requires controlling separately the cells that meet the boundary of B_R . An attempt at a proof, with a pointwise analysis of (a) and (b), is deposited in `docs/dimostrazioni_originali/thue_fejes_toth_tentativo.md`.

Fejes Tóth, *Lagerungen in der Ebene, auf der Kugel und im Raum*, Springer, 1953 (2nd ed. 1972), where the first complete proof appears (1940); H.-C. Chang, L.-C. Wang, *A Simple Proof of Thue's Theorem on Circle Packing*, arXiv:1009.4322 (2010), which gives a self-contained elementary proof; J. H. Conway, N. J. A. Sloane, *Sphere Packings, Lattices and Groups*, 3rd ed., Springer, 1999, Chapter 1.

Remark 14.5: What we import: Kepler, Hales and dimensions 8 and 24 (panorama). In space, the densest arrangement of equal spheres is the face-centred cubic (FCC), equivalent to hexagonal close packing, with density

$$\delta_3 = \frac{\pi}{3\sqrt{2}} = 0.7404805.$$

This statement — the **Kepler conjecture**, formulated in 1611 by observing the stacking of oranges — is **not** a theorem of this treatise and is declared **imported**: it was proved by Thomas Hales in 1998, with a proof assisted by computer (published as *A proof of the Kepler conjecture*, *Annals of Mathematics* 162 (2005), 1065–1185) and formally verified in 2017 by the Flyspeck project (*A formal proof of the Kepler conjecture*, *Forum of Mathematics Pi* 5 (2017), e2). What is missing here is, literally, everything: the reduction to a finite number of local configurations and their certified numerical verification.

The kissing number goes from 6 in the plane (Theorem 14.3, proved) to 12 in space: it is the Newton–Gregory problem (1694), solved only in 1953 by Schütte and van der Waerden — also imported. In higher dimension the optimal packing is known only in special cases: dimension 8 with the E_8 lattice (M. Viazovska, *The sphere packing problem in dimension 8*, *Annals of Mathematics* 185 (2017), 991–1015) and dimension 24 with the Leech lattice (H. Cohn, A. Kumar, S. D. Miller, D. Radchenko, M. Viazovska, *The sphere packing problem in dimension 24*, *ibid.*, 1017–1033). It is another manifestation of the richness of n -dimensional geometry (Chapter 11).

Remark 14.6: What we import: the circle packing theorem (panorama). A statement of a different nature, but in the same area, is the **circle packing theorem** (Koebe 1936; Andreev 1970; Thurston 1978): for every finite simple planar graph there exists a packing of circles in the plane whose tangency graph is that graph, and if the graph is a triangulation of the sphere the packing is unique up to Möbius transformations. It is the bridge between the combinatorics of planar graphs and conformal geometry, and the basis of the theory of discrete analytic functions. This too is declared **imported**: it does not appear in any **teorema** environment of this treatise, because its proof requires either a topological degree argument or a variational method, both outside the scope of Volume III. Source: K. Stephenson, *Introduction to Circle Packing: The Theory of Discrete Analytic Functions*, Cambridge University Press, 2005, Chapters 4 and 6.

14.6. Applications to automation: nesting, cabling, pallets

Nesting, cabling and component arrangement. Optimal circle packing is a daily problem in production: the *nesting* of circular parts to be blanked from sheet metal (minimizing scrap), the bundling of cables in a cable tray or conduit (where the hexagonal arrangement determines the minimum bundle diameter), the arrangement of round nozzles, sensors or actuators on a plate, the filling of pallets with cylindrical objects. Nesting algorithms in CAM software seek approximations of the optimal packing on finite domains (an NP-hard problem in general), often

starting from the theoretical hexagonal grid and adapting it to the boundaries. The mathematics of circle optimality — isoperimetry (Chapter 4) and packing (this chapter) — thus translates directly into savings of material and space.

Remark 14.7: Setting up the pallet problem. An everyday technical application is the optimal arrangement of tubes (or bars) with circular cross-section on a pallet, to maximize the number transported for a given footprint while respecting the height and weight limits. Consider the **Euro pallet** (EPAL/EUR), with footprint 1200×800 mm, with usable stacking height H . A tube of length L is arranged with its axis along the 1200 mm side; with a total safety margin of 100 mm (so as not to touch the right and left edges) the allowed length is $L \leq 1100$ mm. The count is then done on the cross-section to be filled: the rectangle of usable width $W = 800$ mm and height H , in which circles of diameter d (the tubes seen end-on) are packed.

Theorem 14.5: Counting tubes on a pallet. Pack circles of diameter $d > 0$ in a rectangle of width $W \geq d$ and height $H \geq d$, with the centres arranged in horizontal rows. Then:

- (i) a row contains at most $n_c = \lfloor W/d \rfloor$ circles, and this number is attained;
- (ii) with aligned rows (grid arrangement, vertical pitch d) the number of rows is $n_r^{\text{gr}} = \lfloor H/d \rfloor$;
- (iii) with rows staggered by $d/2$ (honeycomb arrangement) the vertical pitch is $d\sqrt{3}/2$ and the number of rows is

$$n_r^{\text{na}} = 1 + \left\lfloor \frac{H-d}{d\sqrt{3}/2} \right\rfloor;$$

the staggered rows contain n_c circles if $W \geq n_c d + d/2$, otherwise $n_c - 1$.

Proof. (i) The centres of a row have the same ordinate and are pairwise at least d apart (disjoint interiors); moreover every centre is at least $d/2$ from each vertical boundary. If the row has k circles, with abscissas $x_1 < \dots < x_k$, then $x_k - x_1 \geq (k-1)d$ and $x_1 \geq d/2$, $x_k \leq W - d/2$, hence $(k-1)d \leq W - d$, that is $k \leq W/d$ and $k \leq \lfloor W/d \rfloor$ because k is an integer. The value is attained by setting $x_j = d/2 + (j-1)d$ for $j = 1, \dots, \lfloor W/d \rfloor$: the last abscissa is $d/2 + (\lfloor W/d \rfloor - 1)d \leq W - d/2$.

(ii) With aligned rows and vertical pitch d (the minimum possible between aligned rows, because two circles with the same abscissa must have centres at distance $\geq d$), the same count on the height gives $n_r^{\text{gr}} = \lfloor H/d \rfloor$.

(iii) With rows staggered by $d/2$ horizontally, let C and C' be two centres of consecutive rows with abscissas differing by $d/2$ and ordinates differing by Δ . The condition $|CC'| \geq d$ gives

$$\frac{d^2}{4} + \Delta^2 \geq d^2 \implies \Delta \geq d\frac{\sqrt{3}}{2},$$

and the minimum value $\Delta = d\sqrt{3}/2$ is admissible (the three centres form an equilateral triangle of side d). The first row has centres at ordinate $d/2$ and the last at ordinate $d/2 + (n_r - 1)\Delta$, which must be $\leq H - d/2$: hence $(n_r - 1)d\sqrt{3}/2 \leq H - d$, that is $n_r \leq 1 + \frac{H-d}{d\sqrt{3}/2}$ and, being an integer, $n_r^{\text{na}} = 1 + \lfloor \frac{H-d}{d\sqrt{3}/2} \rfloor$. For the last claim: in a staggered row the first abscissa is d (that is $d/2 + d/2$) and the last is $d + (k-1)d$; the condition $d + (k-1)d \leq W - d/2$ with $k = n_c$ gives $W \geq n_c d + d/2$. $\square$

Logistics best practices. Honeycomb (hexagonal) packing is the spontaneous and densest arrangement of bundled tubes: for the same number of layers it uses less height (pitch $0.866d$ against d), so more fit under the same limit. In practice wedges or base stops are added to

Figure 14.4: Cross-section of the load on a pallet (usable width 800 mm): tubes packed in honeycomb. The staggered rows nest with vertical pitch $d\sqrt{3}/2 = 0.866d$ against the pitch d of the grid (Theorem 14.5(iii)): for the same height more layers fit. The tubes have their axis along the 1200 mm side of the pallet. In the drawing the diameter is the unit, the width is 8 diameters and the vertical pitch is 0.866.

prevent the first row from rolling, straps or stretch film to stabilize the bundle, and the pallet's *weight limit* (typically 1000–1500 kg for an EPAL) is always checked in addition to the geometric one. The calculation gives the theoretical maximum; the practical number takes into account tolerances, deformations and handling constraints.

The count is automated in a few lines of Python:

Listing 14.1: Tube count on a pallet in Python

```
import math

def tubi_bancalc(W, H, d, nido_ape=True):
    nc = int(W // d)                    # tubes per row (usable width
    W)
    if nido_ape:
        dy = d*math.sqrt(3)/2          # vertical pitch for
        honeycomb
        nr = 1 + int((H - d)//dy)
    else:
        nr = int(H // d)                # grid rows
    return nc*nr, nc, nr

print(tubi_bancalc(800, 650, 120, True))    # -> (36, 6, 6)
print(tubi_bancalc(800, 650, 120, False))   # -> (30, 6, 5)
```

Exercise 14.2: Tubes on a Euro pallet: counting. *Aim:* to apply Theorem 14.5 to a real case and to quantify the gain from honeycomb packing. *Estimated time:* 20 minutes. *Type:* numerical/applied. Tubes of diameter $d = 120$ mm and length $L = 1100$ mm on a Euro pallet (1200×800), usable height $H = 650$ mm. How many tubes fit in grid and how many in honeycomb? By how much does the number grow, and by how much the occupied height?

Solution. Step 1 — length check. $L + 100 = 1200 \leq 1200$: the tubes fit along the 1200 mm side.

Step 2 — tubes per row. $n_c = \lfloor 800/120 \rfloor = \lfloor 6.6667 \rfloor = 6$ (Theorem 14.5(i)).

Step 3 — grid. $n_r^{\text{gr}} = \lfloor 650/120 \rfloor = \lfloor 5.4167 \rfloor = 5$, total $N_{\text{gr}} = 6 \times 5 = 30$ tubes; occupied height $5 \times 120 = 600$ mm.

Step 4 — honeycomb. Vertical pitch $d\sqrt{3}/2 = 120 \times 0.8660254 = 103.9231$ mm; hence

$$n_r^{\text{na}} = 1 + \left\lfloor \frac{650 - 120}{103.9231} \right\rfloor = 1 + \lfloor 5.0999 \rfloor = 1 + 5 = 6.$$

The staggered rows still contain 6 tubes, because $W = 800 \geq n_c d + d/2 = 6 \cdot 120 + 60 = 780$ (Theorem 14.5(iii)). Total $N_{\text{na}} = 6 \times 6 = 36$ tubes; occupied height $60 + 5 \times 103.9231 + 60 = 639.6154$ mm ≤ 650 . ✓

Step 5 — the gain. $36 - 30 = 6$ more tubes, that is +20%, with $639.6 - 600 = 39.6$ mm more height (still within the 650 available).

Independent check. The chapter's Python script returns (36, 6, 6) for honeycomb and (30, 6, 5) for grid. ✓

Interpretation. The 20% gain is not the asymptotic density difference (90.69% against 78.54%, that is +15.5% relative): on a small domain the quantization of the rows (the floor functions) dominates, and can give gains larger or smaller than the asymptotic value. That is why nesting on finite domains is a problem distinct from packing the plane.

Typical errors. (1) Using $n_r = \lfloor H/(d\sqrt{3}/2) \rfloor$ forgetting that the first row occupies d and not $d\sqrt{3}/2$. (2) Forgetting to check that the staggered row still contains n_c tubes. (3) Applying the density $\pi/\sqrt{12}$ to estimate the number: on 650×800 it would give $0.9069 \cdot 650 \cdot 800/(\pi \cdot 60^2) = 41.7$, that is 41 tubes, an unattainable value because it ignores the boundary.

Extension. With $H = 700$ mm one gets $n_r^{\text{na}} = 1 + \lfloor 580/103.9231 \rfloor = 1 + 5 = 6$ (unchanged) and $n_r^{\text{gr}} = \lfloor 700/120 \rfloor = 5$: the gain remains 6 tubes. With $H = 760$ mm one has $n_r^{\text{na}} = 1 + \lfloor 640/103.9231 \rfloor = 1 + 6 = 7$ and $n_r^{\text{gr}} = 6$: 42 against 36.

14.7. Assigned exercises

The answers are in the Teacher's key (Section 14.10).

Exercise 14.3: Farey: counting, mediants and Ford circles. *Aim:* to master the construction of F_n and its geometric translation. *Estimated time:* 40 minutes. *Type:* symbolic/numerical.

- Write F_6 and F_7 and check $rq - ps = 1$ on all consecutive pairs.
- Prove that $|F_n| = 1 + \sum_{k=1}^n \varphi(k)$, where φ is Euler's function, and compute $|F_n|$ for $n = 1, \dots, 10$.
- Prove that, if $\frac{p}{q} < \frac{r}{s}$ are consecutive in F_n , then $q + s > n$.
- For every consecutive pair of F_4 compute $|Z_1 Z_2|^2 - (\rho_1 + \rho_2)^2$ for the Ford circles and check that it is zero.

Exercise 14.4: The kissing number with different radii. *Aim:* to see that the 6 depends on the equality of the radii. *Estimated time:* 35 minutes. *Type:* proof-based/numerical.

- Let $D(O, 1)$ be the central circle and $D(C_j, \varrho)$ the tangent circles, all of radius $\varrho > 0$ and with disjoint interiors. Prove that the minimum angle between two centres satisfies
$$\cos \theta \leq 1 - \frac{2\varrho^2}{(1 + \varrho)^2}.$$
- Deduce an upper bound for the number of circles as a function of ϱ and compute it for $\varrho = 1$, $\varrho = \frac{1}{2}$, $\varrho = 2$.
- Check that for $\varrho = 1$ one recovers exactly 6.
- What happens as $\varrho \rightarrow 0^+$? Interpret the result.

Exercise 14.5: Density and scrap in nesting. *Aim:* to connect the asymptotic density to the computation of scrap on a finite piece. *Estimated time:* 30 minutes. *Type:* numerical/applied. From a sheet of 2000×1000 mm discs of diameter $d = 100$ mm must be blanked.

- (a) How many discs are obtained in grid and how many in honeycomb? (Use Theorem 14.5 with $W = 1000$, $H = 2000$.)
- (b) Compute in both cases the percentage of material used and the scrap.
- (c) Compare with the asymptotic densities $\pi/4$ and $\pi/\sqrt{12}$ and explain the discrepancy.
- (d) By how much does the result change if the diameter becomes $d = 99$ mm?

14.8. Worked exercises

Exercise 14.6: Density of the square packing, and why 13% is lost. *Type:* numerical/proof-based. What is the density of the square packing, how much less efficient is it than the triangular one, and exactly where does the difference come from?

Solution. Strategy. The two fundamental cells are compared at equal disc area.

Step 1 — the two densities. By Proposition 14.1, in the square lattice each circle of radius r has a cell $2r \times 2r$ of area $4r^2$ and the density is $\pi r^2/(4r^2) = \pi/4$. By Theorem 14.4, in the triangular lattice the cell has area $2\sqrt{3}r^2$ and the density is $\pi/(2\sqrt{3})$.

Step 2 — the ratio.

$$\frac{\pi/4}{\pi/(2\sqrt{3})} = \frac{2\sqrt{3}}{4} = \frac{\sqrt{3}}{2} = 0.8660254,$$

hence the square covers 86.60% of what the triangular covers: it loses 13.40% *relative*. In absolute terms, $0.9068997 - 0.7853982 = 0.1215015$, that is 12.15 percentage points.

Step 3 — where the difference comes from. The two cells each contain one circle and differ only in area: $4r^2$ against $2\sqrt{3}r^2 = 3.4641r^2$. The triangular cell is smaller by the factor $\sqrt{3}/2$ because the rows nest into the “valleys” of the previous one, gaining in height the factor $\sqrt{3}/2$ for the same width (Theorem 14.5(iii)): it is exactly the same $\sqrt{3}/2$ as the vertical pitch. The density difference *is* the nesting gain, nothing more.

Independent check. Direct computation in double precision: $\pi/4 = 0.7853981634$, $\pi/\sqrt{12} = 0.9068996821$, ratio 0.8660254038 ; and $\sqrt{3}/2 = 0.8660254038$. ✓ Alternative geometric check: in a regular hexagon circumscribed about the circle of radius r the area is $6 \cdot \frac{r^2}{\sqrt{3}} = 2\sqrt{3}r^2$ (six triangles of base $2r/\sqrt{3}$ and height r), which coincides with the area of the cell. ✓

Interpretation. The 13% is the reason why tubes and rods spontaneously arrange “in a honeycomb” and not on a grid: the triangular configuration is also a minimum of potential energy under lateral compression.

Typical errors. (1) Saying that the square “loses 12%”: 12.15 is the difference in percentage points, 13.40 is the relative loss; they are two different numbers and must be distinguished. (2) Using $\sqrt{3}$ instead of $\sqrt{3}/2$ for the vertical pitch. (3) Confusing the area of the circumscribed hexagon ($2\sqrt{3}r^2$) with that of the inscribed hexagon ($\frac{3\sqrt{3}}{2}r^2 = 2.598r^2$).

Extension. In dimension 3 the analogous comparison is between the simple cubic lattice ($\pi/6 = 0.5236$) and the FCC ($\pi/(3\sqrt{2}) = 0.7405$): the relative loss rises to 29.3%. The gap grows with dimension.

Exercise 14.7: Thirteen spheres: why “free space” is deceptive. *Type:* conceptual with a numerical check. Why can twelve spheres in space touch a thirteenth one, yet there apparently remains “space” sufficient for a fourteenth? Quantify the argument with the computation of spherical caps, and compare with the planar case, where instead the angle count closes with no margin.

Solution. Strategy. The problem is translated into a problem of caps on a sphere and the total area of the caps is compared with the area of the sphere.

Step 1 — translation. If $D(O, 1)$ is the central sphere and the tangent spheres have centres C_j with $|C_j| = 2$ and $|C_j - C_l| \geq 2$, the angle between two centres satisfies, as in Step 2 of Theorem 14.3,

$$4 \leq |C_j - C_l|^2 = 8(1 - \cos \theta_{jl}) \implies \theta_{jl} \geq \frac{\pi}{3} = 60^\circ.$$

Hence the caps of angular radius 30° centred at the directions $C_j/|C_j|$ have disjoint interiors on the unit sphere.

Step 2 — the area computation. A cap of angular radius ϑ on the unit sphere has area $2\pi(1 - \cos \vartheta)$. For $\vartheta = 30^\circ$:

$$2\pi(1 - \cos 30^\circ) = 2\pi(1 - 0.8660254) = 2\pi \cdot 0.1339746 = 0.8417850.$$

The area of the sphere is $4\pi = 12.5663706$. The maximum number of disjoint caps is thus at most

$$\frac{4\pi}{0.8417850} = 14.9282, \quad \text{that is} \quad k \leq 14.$$

Independent check: $4\pi/(2\pi(1 - \cos 30^\circ)) = 2/(1 - \sqrt{3}/2) = 4/(2 - \sqrt{3}) = 4(2 + \sqrt{3}) = 14.9282$.
✓

Step 3 — the answer. The area count gives 14, but the true value is 12: the caps cannot *tile* the sphere, and the uncovered area ($14.93 - 12 = 2.93$ caps’ worth of “space”) is distributed among many small gaps, not in a single hole large enough for a thirteenth cap. It is the Newton–Gregory dispute (1694): Newton maintained 12, Gregory held 13 possible; the answer (12) was obtained only in 1953 by Schütte and van der Waerden, and is here *imported* (Remark 14.5).

Step 4 — comparison with the plane. In the plane the same count is *exact*: arcs of width 60° leave no slack, because $360^\circ/60^\circ = 6$ exactly, and indeed the inequality $2\pi \geq k\pi/3$ of Theorem 14.3 is saturated. That is why in dimension 2 the angle count *proves* the result, while in dimension 3 it leaves a margin of two units that no volume argument can close.

Interpretation. The lesson is methodological: an upper bound obtained by counting a measure is tight only if the optimal configuration tiles. In the plane it tiles; in space it does not, and a completely different argument is needed.

Typical errors. (1) Concluding “14.93, hence 14 spheres are possible”: it is an upper bound, not an attained value. (2) Using the angular radius 60° instead of 30° for the caps (the disjoint caps have radius half the minimum angle). (3) Saying that the centres of the twelve spheres “lie on the vertices of an icosahedron”: it is one of the possible configurations, but not the only one — the FCC arrangement also realizes twelve, and the two are not equivalent under rotation.

Extension. In dimension 4 the kissing number is 24 (Musin, 2008); in dimension 8 it is 240 and in dimension 24 it is 196 560 (Odlyzko–Sloane, Levenshtein, 1979). In all other dimensions the exact value is unknown.

Exercise 14.8: The fourth Descartes circle in a Ford chain. *Type:* symbolic/numerical. Consider the Ford circles of $\frac{1}{3}$ and $\frac{1}{2}$ and the real axis. Determine, with Descartes' theorem, the curvatures of the two circles tangent to all three, and check that one of them is the Ford circle of the mediant.

Solution. Strategy. The formula $k_4 = k_1 + k_2 + k_3 \pm 2\sqrt{k_1k_2 + k_2k_3 + k_3k_1}$ of Remark 14.1 is applied and compared with Definition 14.3.

Step 1 — the starting curvatures. $\frac{1}{3}$ and $\frac{1}{2}$ are Farey neighbours ($1 \cdot 2 - 1 \cdot 3 = -1$), hence their Ford circles are tangent (Theorem 14.2); both are tangent to the real axis. The curvatures are

$$k_1 = 0 \text{ (line)}, \quad k_2 = 2 \cdot 3^2 = 18, \quad k_3 = 2 \cdot 2^2 = 8.$$

Step 2 — the formula.

$$k_1k_2 + k_2k_3 + k_3k_1 = 0 + 144 + 0 = 144, \quad \sqrt{144} = 12,$$

$$k_4 = 0 + 18 + 8 \pm 2 \cdot 12 = 26 \pm 24 = \begin{cases} 50, \\ 2. \end{cases}$$

Step 3 — identification. The solution $k_4 = 50$ corresponds to a circle of radius $1/50$, that is $1/(2q^2)$ with $2q^2 = 50$, $q = 5$: it is the Ford circle of a fraction of denominator 5, and precisely of the mediant $\frac{1+1}{3+2} = \frac{2}{5}$ (Lemma 14.1). The solution $k_4 = 2$ corresponds to $q = 1$: it is the Ford circle of $\frac{0}{1}$ or of $\frac{1}{1}$; since it must be tangent both to $\mathcal{C}(1/3)$ and to $\mathcal{C}(1/2)$, and it is tangent to $\mathcal{C}(1/3)$ only if $|1 \cdot 1 - p \cdot 3| = 1$, one finds $p = 0$: it is $\mathcal{C}(0/1)$. Check: $|0 \cdot 2 - 1 \cdot 1| = 1$, hence $\mathcal{C}(0/1)$ is also tangent to $\mathcal{C}(1/2)$. ✓

Independent check. Direct check of the Descartes relation with the four curvatures $(0, 18, 8, 50)$:

$$(0 + 18 + 8 + 50)^2 = 76^2 = 5776, \quad 2(0 + 324 + 64 + 2500) = 2 \cdot 2888 = 5776. \quad \checkmark$$

And with $(0, 18, 8, 2)$:

$$(0 + 18 + 8 + 2)^2 = 28^2 = 784, \quad 2(0 + 324 + 64 + 4) = 2 \cdot 392 = 784. \quad \checkmark$$

Geometric check of the tangency between $\mathcal{C}(2/5)$ and $\mathcal{C}(1/2)$ with Theorem 14.2: $ps - rq = 2 \cdot 2 - 1 \cdot 5 = -1$, hence $\frac{(-1)^2 - 1}{25 \cdot 4} = 0$: tangent. ✓

Interpretation. The two Descartes solutions correspond to the two circles tangent to the three given ones: one “small”, wedged into the interstice (the mediant, with denominator $q + s = 5$), and one “large” that contains them from the opposite side (here $\mathcal{C}(0/1)$). The sequence of denominators $3, 2 \rightarrow 5$ is exactly the construction of Farey mediants: the arithmetic of Farey is the Descartes iteration.

Typical errors. (1) Forgetting that the line has curvature 0 and not ∞ . (2) Always choosing the + sign: both solutions are tangent circles, and must be interpreted. (3) Confusing $k = 2q^2$ with $k = 1/q^2$: the radius is $1/(2q^2)$, hence the curvature is its reciprocal, $2q^2$.

Extension. Iterating from $(0, 2, 2)$ (line, $\mathcal{C}(0/1)$, $\mathcal{C}(1/1)$) one obtains $k_4 = 0 + 2 + 2 \pm 2\sqrt{4} = 4 \pm 4$, that is 8 (the circle of $\frac{1}{2}$, $q = 2$) and 0 (the line itself). Continuing, all curvatures $2q^2$ with q a Farey denominator are generated: the Apollonian gasket of Ford circles (Remark 14.3).

14.9. Self-assessment quiz

1. (Definition) The Ford circle of the reduced fraction p/q has
 - A) centre $(p/q, 1/q^2)$ and radius $1/q^2$ B) centre $(p/q, 1/(2q^2))$ and radius $1/(2q^2)$ C) centre $(p/q, 0)$ and radius $1/q$ D) centre (p, q) and radius $1/2$
2. (Hypothesis) In Theorem 14.2 the hypothesis that the fractions be *reduced* serves to
 - A) guarantee $q, s \geq 1$ B) guarantee that $ps - rq \neq 0$ for distinct fractions, and hence $(ps - rq)^2 \geq 1$ C) make the radii positive D) make the centres distinct
3. (Symbolic computation) The Ford circles of $\frac{2}{5}$ and $\frac{3}{7}$ are
 - A) tangent B) disjoint C) overlapping D) concentric
4. (Numerical computation) The density of the triangular packing is, to five decimal places,
 - A) 0.78540 B) 0.90690 C) 0.74048 D) 1.00000
5. (Proof step) In the proof that $\tau_2 = 6$, the inequality $\theta_{jl} \geq \pi/3$ is obtained
 - A) from the area formula B) from the cosine theorem applied to the triangle C_jOC_l with $|OC_j| = |OC_l| = 2$ and $|C_jC_l| \geq 2$ C) from the convexity of the disc D) from Descartes' theorem
6. (Error diagnosis) A student writes: “the Voronoi cells of a packing have at most six sides, hence the Hexagon lemma proves Thue–Fejes Tóth.” The error is
 - A) the Hexagon lemma is false B) Voronoi cells can have more than six sides: only the *average* is ≤ 6 C) the cells are not convex D) the cells do not contain the disc
7. (Transfer) The upper bound for the kissing number obtained by counting the areas of the caps on the sphere in $\mathbb{R}^3$ gives
 - A) exactly 12 B) 14, that is a non-tight bound C) 13 D) 6
8. (Source and metacognition) The original proof that $\pi/\sqrt{12}$ is the maximum density in the plane is found in
 - A) Ford, *Fractions*, Amer. Math. Monthly 45 (1938) B) Thue (1910) and Fejes Tóth, *Lagerungen in der Ebene, auf der Kugel und im Raum* (1953) C) Hales, *Annals of Mathematics* 162 (2005) D) Hardy–Wright, Ch. III

14.10. Teacher's key

BEST PRACTICE

Quiz — answers, rationale and diagnosis.

1) **B.** *Rationale:* this is Definition 14.3; the radius equals the ordinate of the centre, and that is why the circle is tangent to the real axis. *Distractors:* A doubles both radius and ordinate, and the circles would overlap (for $\frac{0}{1}$ and $\frac{1}{1}$ one would get two circles of radius 1 centred at distance 1); C puts the centre on the axis, losing tangency; D confuses the fraction with a pair of coordinates. *Diagnosed error:* not linking radius and ordinate. *Source:* Ford, *Fractions*, Monthly 45 (1938), 586–601. *Prerequisite:* equation of the circle. *Remedial work:* draw $\mathcal{C}(0/1)$, $\mathcal{C}(1/2)$, $\mathcal{C}(1/1)$ and check their tangencies.

2) **B.** *Rationale:* the whole proof rests on $(ps - rq)^2 \geq 1$, which holds because $ps - rq$ is a *nonzero* integer; if the fractions were not reduced, two representations of the same fraction would give $ps - rq = 0$ and the formula would give $-1/(q^2s^2) < 0$, that is, overlapping circles — which indeed would be the same circle written twice, or different circles centred

at the same point of the axis. *Distractors*: A, C and D are consequences of the definition of a fraction with $q \geq 1$, not of reducedness. *Diagnosed error*: failing to identify the hypothesis that makes the determinant an integer and nonzero. *Source*: Theorem 14.2, Step 2. *Prerequisite*: uniqueness of the reduced form. *Remedial work*: compute $|Z_1 Z_2|^2 - (\rho_1 + \rho_2)^2$ for $\frac{1}{2}$ and $\frac{2}{4}$ and comment.

3) B. *Rationale*: $ps - rq = 2 \cdot 7 - 3 \cdot 5 = 14 - 15 = -1$... pay attention to the order: with $\frac{p}{q} = \frac{2}{5}$ and $\frac{r}{s} = \frac{3}{7}$ one has $ps - rq = 2 \cdot 7 - 3 \cdot 5 = -1$, hence $|ps - rq| = 1$ and the circles are *tangent*. The correct answer is therefore **A**. *Note for the teacher*: the item is built to catch the hasty computation $2 \cdot 7 - 3 \cdot 5 = 14 - 15$, which many students report as -11 or 1 without checking; it is recommended to have students write out the determinant $\begin{vmatrix} 2 & 3 \\ 5 & 7 \end{vmatrix}$. *Distractors*:

B is the answer of someone who computes $|ps - rq| \geq 2$; C is impossible by Theorem 14.2(i); D is impossible because the centres have different abscissas. *Diagnosed error*: sign error in the determinant. *Source*: Theorem 14.2. *Prerequisite*: 2×2 determinant. *Remedial work*: check that $\frac{2}{5}$ and $\frac{3}{7}$ are consecutive in F_7 .

4) B. *Rationale*: $\pi/\sqrt{12} = 0.90690$ (Theorem 14.4). *Distractors*: A is $\pi/4$, the density of the square lattice (Proposition 14.1); C is $\pi/(3\sqrt{2})$, the density in dimension 3; D is impossible because the circles do not tile. *Diagnosed error*: confusing the square and triangular lattices, or the plane and space. *Source*: Theorem 14.4, Step 5. *Prerequisite*: area of the disc and of the parallelogram. *Remedial work*: recompute $\pi/(2\sqrt{3})$ and $\pi/4$ and compare them.

5) B. *Rationale*: this is Step 2 of Theorem 14.3: $|C_j C_l|^2 = 8(1 - \cos \theta_{jl}) \geq 4$ gives $\cos \theta_{jl} \leq \frac{1}{2}$. *Distractors*: A does not enter the proof; C is true but does not produce the bound; D concerns four mutually tangent circles, a different configuration. *Diagnosed error*: not recognizing the cosine theorem as the engine of the bound. *Source*: Theorem 14.3. *Prerequisite*: the cosine theorem. *Remedial work*: redo the computation with a different central radius (Assigned exercise 14.4).

BEST PRACTICE

Quiz — answers, rationale and diagnosis (continued).

6) B. *Rationale*: this is precisely point (a) declared missing in Remark 14.4: Euler's formula gives an *average* number of sides ≤ 6 , not a maximum, and passing from the average to the bound requires the convexity of $n \mapsto n \tan(\pi/n)$. *Distractors*: A is false, the lemma is proved in full (Lemma 14.3); C is false, Voronoi cells are convex (intersections of half-planes); D is false, every cell contains the disc of its own centre. *Diagnosed error*: mistaking an average for a maximum. *Source*: Remark 14.4 and Chang–Wang, arXiv:1009.4322. *Prerequisite*: Euler's formula for planar graphs. *Remedial work*: exhibit a packing with a seven-sided Voronoi cell.

7) B. *Rationale*: Worked exercise 14.7 computes $4\pi/(2\pi(1 - \cos 30^\circ)) = 4(2 + \sqrt{3}) = 14.93$, hence $k \leq 14$: the bound is not tight, because the true value is 12. *Distractors*: A is the true value, but it is not what the area count gives; C is Gregory's conjecture; D is the value in the plane. *Diagnosed error*: attributing to an upper bound the strength of an exact result. *Source*: Worked exercise 14.7; Conway–Sloane, *SPLAG*, Ch. 1. *Prerequisite*: area of a spherical cap. *Remedial work*: redo the same count in the plane and observe that there it is exact.

8) B. *Rationale*: Thue stated the result in 1910 and Fejes Tóth gave the first complete proof (1940), collected in *Lagerungen* (1953). *Distractors*: A is the source of Ford circles; C is the Kepler conjecture (dimension 3); D is the source of Farey sequences. *Diagnosed error*: attributing a result to the source of a nearby result. *Source*: see the section «Sources». *Prerequisite*: being able to distinguish statement, author and date. *Remedial work*: compile a table “result / author / year / dimension” for the five theorems cited in the chapter.

BEST PRACTICE

Assigned exercise 14.3 — answers. (a) $F_6 = (\frac{0}{1}, \frac{1}{6}, \frac{1}{5}, \frac{1}{4}, \frac{1}{3}, \frac{2}{5}, \frac{1}{2}, \frac{3}{5}, \frac{2}{3}, \frac{3}{4}, \frac{4}{5}, \frac{5}{6}, \frac{1}{1})$ (13 terms); F_7 is obtained by inserting $\frac{1}{7}, \frac{2}{7}, \frac{3}{7}, \frac{4}{7}, \frac{5}{7}, \frac{6}{7}$ (19 terms). Check on all pairs: for example $(\frac{1}{6}, \frac{1}{5})$: $1 \cdot 6 - 1 \cdot 5 = 1$; $(\frac{2}{5}, \frac{3}{7})$: $3 \cdot 5 - 2 \cdot 7 = 1$; $(\frac{3}{7}, \frac{1}{2})$: $1 \cdot 7 - 3 \cdot 2 = 1$. (b) F_n contains $\frac{0}{1}$ and, for every $q = 1, \dots, n$, the reduced fractions p/q with $1 \leq p \leq q$: there are $\varphi(q)$ of them (for $q = 1$ the only one is $\frac{1}{1}$, and $\varphi(1) = 1$). Hence $|F_n| = 1 + \sum_{k=1}^n \varphi(k)$. Values for $n = 1, \dots, 10$: 2, 3, 5, 7, 11, 13, 19, 23, 29, 33. (c) If $q + s \leq n$ held, the mediant $\frac{p+r}{q+s}$ would be reduced (Lemma 14.1(ii)) with denominator $\leq n$, hence it would belong to F_n and would lie strictly between two consecutive terms: absurd. (d) $F_4 = (\frac{0}{1}, \frac{1}{4}, \frac{1}{3}, \frac{1}{2}, \frac{2}{3}, \frac{3}{4}, \frac{1}{1})$; for every consecutive pair $|ps - rq| = 1$ and hence $|Z_1 Z_2|^2 - (\rho_1 + \rho_2)^2 = \frac{1-1}{q^2 s^2} = 0$ (Theorem 14.2). Numerical check in double precision: the six values are 0, $-2.6 \cdot 10^{-18}$, $6.9 \cdot 10^{-18}$, $6.9 \cdot 10^{-18}$, $-2.6 \cdot 10^{-18}$, 0. ✓

BEST PRACTICE

Assigned exercise 14.4 — answers. (a) $|OC_j| = 1 + \varrho$ and $|C_j C_l| \geq 2\varrho$; by the cosine theorem

$$4\varrho^2 \leq |C_j C_l|^2 = 2(1 + \varrho)^2(1 - \cos \theta) \implies \cos \theta \leq 1 - \frac{2\varrho^2}{(1 + \varrho)^2}.$$

(b) Writing $\theta_{\min} = \arccos\left(1 - \frac{2\varrho^2}{(1 + \varrho)^2}\right)$, the same gap argument as in Theorem 14.3 gives $k \leq \lfloor 2\pi/\theta_{\min} \rfloor$. For $\varrho = 1$: $\cos \theta_{\min} \leq 1 - \frac{2}{4} = \frac{1}{2}$, $\theta_{\min} = 60^\circ$, $k \leq 6$. For $\varrho = \frac{1}{2}$: $1 - \frac{2 \cdot 0.25}{2.25} = 1 - 0.2222 = 0.7778$, $\theta_{\min} = 38.9424^\circ$, $k \leq \lfloor 360/38.9424 \rfloor = \lfloor 9.244 \rfloor = 9$. For $\varrho = 2$: $1 - \frac{8}{9} = 0.1111$, $\theta_{\min} = 83.6206^\circ$, $k \leq \lfloor 360/83.6206 \rfloor = \lfloor 4.305 \rfloor = 4$. (c) For $\varrho = 1$ one recovers exactly 6, and the bound is attained (Theorem 14.3, Step 1). ✓ (d) As $\varrho \rightarrow 0^+$ one has $\theta_{\min} \rightarrow 0$ and $k \rightarrow +\infty$ as $\approx 2\pi/(2\varrho) = \pi/\varrho$: very small circles crowd along the circumference of the large circle, and the count becomes a problem of *length* (how many chord arcs 2ϱ fit on a circle of radius $1 + \varrho$) rather than of area.

BEST PRACTICE

Assigned exercise 14.5 — answers. (a) $W = 1000$, $H = 2000$, $d = 100$: $n_c = \lfloor 1000/100 \rfloor = 10$. In grid $n_r = \lfloor 2000/100 \rfloor = 20$, total 200 discs. In honeycomb $d\sqrt{3}/2 = 86.6025$, $n_r = 1 + \lfloor (2000 - 100)/86.6025 \rfloor = 1 + \lfloor 21.9394 \rfloor = 22$; the staggered rows contain 10 discs only if $W \geq n_c d + d/2 = 1050$, and here $W = 1000 < 1050$: hence the staggered rows contain 9. With 11 even rows and 11 odd rows, the total is $11 \cdot 10 + 11 \cdot 9 = 209$ discs. (b) Area of the sheet: $2000 \cdot 1000 = 2.0 \cdot 10^6 \text{ mm}^2$. Area of a disc: $\pi \cdot 50^2 = 7853.98 \text{ mm}^2$. In grid: $200 \cdot 7853.98 = 1.570796 \cdot 10^6$, that is 78.54% used and 21.46% scrap. In honeycomb: $209 \cdot 7853.98 = 1.641482 \cdot 10^6$, that is 82.07% used and 17.93% scrap. (c) The asymptotic densities are $\pi/4 = 78.54\%$ and $\pi/\sqrt{12} = 90.69\%$. The grid reaches exactly the asymptotic value, because 1000 and 2000 are exact multiples of 100: no boundary scrap. The honeycomb instead stays 8.6 points below its asymptotic value, because it loses one disc per row on the staggered rows (the vertical boundary is not compatible with staggering) and because the height 2000 is not a multiple of the pitch 86.6025. (d) With $d = 99$: $n_c = \lfloor 1000/99 \rfloor = 10$; in grid $n_r = \lfloor 2000/99 \rfloor = 20$, total 200; in honeycomb $d\sqrt{3}/2 = 85.7365$, $n_r = 1 + \lfloor 1901/85.7365 \rfloor = 1 + \lfloor 22.1725 \rfloor = 23$, and now $n_c d + d/2 = 990 + 49.5 = 1039.5 > 1000$: the staggered rows still have 9 discs, for a total of $12 \cdot 10 + 11 \cdot 9 = 219$. One millimetre less on the diameter is worth 10 more discs (+4.8%): it is the quantization, not the density, that governs.

14.11. Chapter formulary

Farey and Ford.

$$\frac{p}{q} < \frac{r}{s} \text{ Farey neighbours} \iff rq - ps = 1; \quad \text{mediant} = \frac{p+r}{q+s}; \quad |F_n| = 1 + \sum_{k=1}^n \varphi(k).$$

$$\mathcal{C}\left(\frac{p}{q}\right) = D\left(\left(\frac{p}{q}, \frac{1}{2q^2}\right), \frac{1}{2q^2}\right); \quad |Z_1 Z_2|^2 - (\rho_1 + \rho_2)^2 = \frac{(ps - rq)^2 - 1}{q^2 s^2} \geq 0.$$

Tangent $\iff |ps - rq| = 1$. Descartes (Volume I, Ch. 5): $(k_1 + k_2 + k_3 + k_4)^2 = 2 \sum k_i^2$; for the line $k = 0$, for $\mathcal{C}(p/q)$ it is $k = 2q^2$.

Kissing number and density.

$$\tau_2 = 6; \quad |C_j C_l|^2 = 8(1 - \cos \theta_{jl}) \implies \theta_{jl} \geq \frac{\pi}{3};$$

$$\delta_\Delta = \frac{\pi}{2\sqrt{3}} = \frac{\pi}{\sqrt{12}} = 0.9068997, \quad \delta_\square = \frac{\pi}{4} = 0.7853982, \quad \frac{\delta_\square}{\delta_\Delta} = \frac{\sqrt{3}}{2} = 0.8660254.$$

Triangular cell: area $2\sqrt{3}r^2$; square cell: area $4r^2$. Hexagon lemma: convex polygon with $n \leq 6$ sides containing $D(O, r)$ has area $\geq nr^2 \tan(\pi/n) \geq 2\sqrt{3}r^2$.

Counts on a finite domain.

$$n_c = \left\lfloor \frac{W}{d} \right\rfloor, \quad n_r^{\text{gr}} = \left\lfloor \frac{H}{d} \right\rfloor, \quad n_r^{\text{na}} = 1 + \left\lfloor \frac{H-d}{d\sqrt{3}/2} \right\rfloor, \quad \frac{\sqrt{3}}{2} = 0.8660254.$$

Staggered rows have n_c elements if $W \geq n_c d + \frac{d}{2}$, otherwise $n_c - 1$. Seven circles of radius r (one plus a ring): conduit of radius $R = 3r$, fill ratio $7/9$.

Panorama (imported, never proved here).

$$\text{Thue--Fejes Tóth: } \delta(\mathcal{P}) \leq \frac{\pi}{\sqrt{12}} \quad \forall \mathcal{P}; \quad \text{Kepler/Hales: } \delta_3 \leq \frac{\pi}{3\sqrt{2}} = 0.7404805;$$

$$\tau_3 = 12 \text{ (Schütte--van der Waerden 1953); } \quad \tau_4 = 24, \quad \tau_8 = 240, \quad \tau_{24} = 196\,560.$$

Circle packing theorem (Koebe--Andreev--Thurston): every finite planar graph is the tangency graph of a circle packing.

Part B

Complex and harmonic analysis on the disc

CHAPTER 15

Complex analysis on the disk: from Cauchy to residues

A function that is complex-differentiable on an open set is infinitely differentiable, is the sum of its own Taylor series, is determined by its values on a circle, cannot have an interior maximum of its modulus, and if it is bounded on the whole plane it is constant. None of these properties has a real analogue: they are all consequences of a single fact, that the integral of a holomorphic function along a closed path in a disk vanishes. The circle is not here just one of the many objects under study: it is the *only* contour on which the computation closes explicitly, because the parametrization $\zeta = z_0 + \rho e^{i\theta}$ turns every line integral into an integral over $[0, 2\pi]$, and because on it only one exponent survives, namely -1 .

The chapter follows this chain from beginning to end. It starts from Goursat's theorem (Theorem 15.1), proved by bisection without assuming continuity of the derivative; from it one deduces the existence of a primitive on every convex open set (Theorem 15.2) and hence Cauchy's integral theorem on the disk (Corollary 15.1). From there follow Cauchy's integral formula (Theorem 15.3), analyticity (Theorem 15.6), Cauchy's estimates (Theorem 15.7), Liouville's theorem (Theorem 15.8) and the fundamental theorem of algebra (Corollary 15.2); then the identity principle (Theorem 15.10), the maximum modulus principle in its strong form (Theorem 15.11), Schwarz's lemma with the equality case (Lemma 15.9) and the complete description of the automorphisms of the disk (Theorem 15.12). The second half is computational: Laurent series (Theorem 15.4), classification of isolated singularities, the residue theorem (Theorem 15.5 and Theorem 15.17), the winding number (Definition 15.8), the argument principle (Theorem 15.18) and Rouché's theorem (Theorem 15.19), and finally three real integrals computed with residues, each checked by an independent route.

The material that the Executive Plan moved here from Volume II (Chapter 3, §12) is preserved in full — statements, proofs, worked example, exercises, quiz and formulary — and is found in Section 15.3 and Section 15.10. What Volume II took as known (the Cauchy–Goursat theorem, Riemann's theorem on removable singularities, the contour deformation principle) is proved here.

INFO

Level and prerequisites. Level **C** (undergraduate), with two passages at level **D** (the bisection proof of Goursat's theorem and the classification of the automorphisms of the disk).

Internal prerequisites. Complex numbers, modulus, conjugation, exponential and polar form (Volume II, Chapter 3, and Chapter 6); Möbius transformations and generalized circles (Chapter 6, Definition 6.4, Proposition 6.7, Theorem 6.6); winding number, its analytic form, and the degree of a map of the circle (Chapter 12, Definition 12.6, Theorem 12.6, Definition 12.8); line integrals and the parametrization of plane curves (Chapter 2).

External prerequisites, assumed and not reproved:

- calculus in one and two real variables: the fundamental theorem of calculus, uniform continuity of a continuous function on a compact set, Leibniz's rule for differentiation

under the integral sign with a C^1 integrand on a compact rectangle;

- power series: radius of convergence, uniform convergence on compact subsets of the disk of convergence, term-by-term differentiability, with the derived series having the same radius;
- interchange of series and integral under uniform convergence on a compact set;
- elementary topology: compactness of a closed bounded subset of $\mathbb{C}$, connectedness, the property of the intersection of a decreasing sequence of nonempty compact sets;
- the Fourier inversion theorem for an integrable function with integrable transform (used only once, as a *second* checking method in Example 15.6).

Everything else is proved here.

What you learn. How to construct a primitive and deduce from it the vanishing of the integral over a loop; how to use bisection to prove Goursat's theorem; how to pass from Cauchy's formula to the series expansion and from that to all the estimates; how to recognize when the modulus of a holomorphic function cannot have an interior maximum; how to classify an isolated singularity from the principal part of its Laurent expansion; how to compute a residue and use it for a real integral; how to read a winding number as an integer and use it to count zeros.

Warning. Chapter conventions.

- $D(z_0, r) = \{z \in \mathbb{C} : |z - z_0| < r\}$ is the *open disk*, $\overline{D(z_0, r)} = \{z : |z - z_0| \leq r\}$ the closed one; $\mathbb{D} = D(0, 1)$ is the **unit disk** and $\mathbb{T} = \{|z| = 1\}$ the unit circle.
- Every circle $|\zeta - z_0| = \rho$ is understood to be traversed *exactly once, counterclockwise*, i.e., parametrized by $\zeta(\theta) = z_0 + \rho e^{i\theta}$ with $\theta \in [0, 2\pi]$. The notation $\oint_{|\zeta - z_0| = \rho}$ carries this orientation implicitly.
- “Path” always means a *piecewise regular path*: a continuous function $\gamma : [a, b] \rightarrow \mathbb{C}$ that is C^1 on each of a finite number of subintervals. It is a **loop** (or closed path) if $\gamma(a) = \gamma(b)$. $\gamma^* = \gamma([a, b])$ is its *support*.
- $[p, q]$ denotes the oriented segment from p to q , i.e., the path $t \mapsto p + t(q - p)$, $t \in [0, 1]$; $\Delta(p, q, s)$ is the *solid triangle* (convex hull) with vertices p, q, s , and $\partial\Delta(p, q, s)$ the loop $[p, q] + [q, s] + [s, p]$.
- An open set is **connected** if it is path-connected; a connected open set is called a *domain*. An open set Ω is **convex** if it contains the segment between any two of its points.
- Re , Im , $\bar{z}$ and $|z|$ have their usual meaning; $\bar{}$ over a set denotes instead its topological closure: context distinguishes the two uses.
- Numerical values are rounded to the seventh decimal digit and recomputed twice by independent routes.

15.1. Holomorphy, paths, and the two fundamental estimates

This section fixes the language and proves the only two elementary tools that we will use everywhere: bounding a line integral by the product “maximum times length”, and the fact that the integral of a derivative over a loop vanishes.

Definition 15.1: Complex derivative and holomorphic function. Let $\Omega \subseteq \mathbb{C}$ be open and $f : \Omega \rightarrow \mathbb{C}$. We say that f is **complex-differentiable** at $z \in \Omega$ if the finite limit

$$f'(z) = \lim_{h \rightarrow 0, h \in \mathbb{C} \setminus \{0\}} \frac{f(z+h) - f(z)}{h}$$

exists. f is **holomorphic** on Ω if it is complex-differentiable at every point of Ω . It is **entire** if it is holomorphic on the whole of $\mathbb{C}$.

Remark 15.1: Complex differentiability is a strong requirement. In the limit of Definition 15.1 the increment h tends to zero from every direction of the plane, and the quotient is a complex division, not a division by a scalar. This is the difference with real differentiability in two variables: the function $f(z) = \bar{z}$ is smooth as a map $\mathbb{R}^2 \rightarrow \mathbb{R}^2$ but is not complex-differentiable at any point, because for $h = t$ real the quotient equals $\bar{t}/t = 1$ while for $h = it$ it equals $\overline{it}/(it) = -1$: two different directional limits. A first consequence, immediate and used constantly, is that a function that is complex-differentiable at z is there continuous, because $f(z+h) - f(z) = h \cdot \frac{f(z+h)-f(z)}{h} \rightarrow 0 \cdot f'(z) = 0$.

Lemma 15.1: Cauchy–Riemann equations. Let $f = u + iv$ be holomorphic on an open set Ω , with $u = \operatorname{Re} f$ and $v = \operatorname{Im} f$ real functions of the real variables x, y ($z = x + iy$). Then at every point of Ω the four partial derivatives of u and v exist and satisfy

$$u_x = v_y, \quad u_y = -v_x, \quad f' = u_x + iv_x = v_y - iu_y.$$

In particular, if f is holomorphic on Ω and takes only real values, then $f' \equiv 0$; and if Ω is connected, f is constant.

Proof. Step 1 — the two directional limits. Let $z = x + iy \in \Omega$. Since the limit of Definition 15.1 exists, it coincides with the limit along any sequence $h \rightarrow 0$. Taking $h = t$ real, $t \rightarrow 0$:

$$f'(z) = \lim_{t \rightarrow 0} \frac{f(z+t) - f(z)}{t} = \lim_{t \rightarrow 0} \frac{u(x+t, y) - u(x, y)}{t} + i \lim_{t \rightarrow 0} \frac{v(x+t, y) - v(x, y)}{t} = u_x(x, y) + i v_x(x, y),$$

where the existence of the two real limits follows from the existence of the complex limit (the real and imaginary parts of a convergent sequence converge to the real and imaginary parts of the limit). Taking instead $h = it$ with $t \rightarrow 0$ real, and using $1/i = -i$:

$$f'(z) = \lim_{t \rightarrow 0} \frac{f(z+it) - f(z)}{it} = -i(u_y(x, y) + i v_y(x, y)) = v_y(x, y) - i u_y(x, y).$$

Step 2 — comparison. The two values obtained are the same complex number, hence have the same real part and the same imaginary part: $u_x = v_y$ and $v_x = -u_y$, i.e. $u_y = -v_x$. The two expressions for f' are those of the statement.

Step 3 — real-valued functions. If f is real-valued then $v \equiv 0$, hence $v_x = v_y = 0$ everywhere. From the relations of Step 2 it follows that $u_x = v_y = 0$ and $u_y = -v_x = 0$, so $f' = u_x + iv_x = 0$ at every point of Ω .

Step 4 — from $f' \equiv 0$ to constancy. Let Ω be connected and $f' \equiv 0$. Then $u_x = u_y = v_x = v_y = 0$ on Ω . Fix $z_1, z_2 \in \Omega$: there is a polygonal path in Ω joining them — a connected open subset of $\mathbb{C}$ is polygonally connected (the set of points reachable from z_1 by a polygonal path in Ω is open, because every disk contained in Ω is convex, and its complement in Ω is open for the same reason; being nonempty, and Ω being connected, it equals Ω). On each segment $[p, q]$ of the polygonal path, the function $t \mapsto f(p + t(q-p))$ has derivative $f'(p + t(q-p))(q-p) = 0$ by the chain rule, hence constant real and imaginary parts on the segment. Concatenating the segments, $f(z_1) = f(z_2)$. $\square$

Definition 15.2: Complex line integral. Let $\gamma : [a, b] \rightarrow \mathbb{C}$ be a piecewise regular path and g a continuous function on γ^* . Set

$$\int_{\gamma} g(z) dz = \int_a^b g(\gamma(t)) \gamma'(t) dt,$$

the integral of a piecewise continuous complex-valued function, defined real part by real part. Also set

$$\int_{\gamma} g(z) |dz| = \int_a^b g(\gamma(t)) |\gamma'(t)| dt, \quad L(\gamma) = \int_a^b |\gamma'(t)| dt$$

($L(\gamma)$ is the **length** of γ , the same as in Chapter 2). If γ is a loop we write $\oint_{\gamma}$. The sum $\gamma_1 + \gamma_2$ of two consecutive paths and the reverse $-\gamma$ (same support, reversed direction) satisfy $\int_{\gamma_1 + \gamma_2} = \int_{\gamma_1} + \int_{\gamma_2}$ and $\int_{-\gamma} = -\int_{\gamma}$, by additivity of the integral with respect to the interval and by the substitution $t \mapsto a + b - t$.

Lemma 15.2: ML estimate. Let γ be a piecewise regular path and g continuous on γ^* . Then

$$\left| \int_{\gamma} g(z) dz \right| \leq \int_{\gamma} |g(z)| |dz| \leq \left(\max_{z \in \gamma^*} |g(z)| \right) \cdot L(\gamma).$$

Proof. Step 1 — reduction to the real case. Let $I = \int_{\gamma} g(z) dz$. If $I = 0$ the first inequality is trivial. If $I \neq 0$, write $I = |I|e^{i\alpha}$ and set $\lambda = e^{-i\alpha}$, so that $|\lambda| = 1$ and $\lambda I = |I|$ is real and nonnegative. Then

$$|I| = \lambda I = \int_a^b \lambda g(\gamma(t)) \gamma'(t) dt = \int_a^b \operatorname{Re} [\lambda g(\gamma(t)) \gamma'(t)] dt,$$

where the last equality holds because the left-hand side is real, hence the imaginary part of the integral is zero, and the integrand can be replaced by its real part.

Step 2 — monotonicity of the real integral. For every $w \in \mathbb{C}$ we have $\operatorname{Re} w \leq |w|$; applying this to the integrand and using the monotonicity of the integral of piecewise continuous real functions,

$$|I| \leq \int_a^b |\lambda g(\gamma(t)) \gamma'(t)| dt = \int_a^b |g(\gamma(t))| |\gamma'(t)| dt = \int_{\gamma} |g(z)| |dz|,$$

having used $|\lambda| = 1$ and the multiplicativity of the modulus.

Step 3 — the bound by the maximum. $|g|$ is continuous on the compact set γ^* (continuous image of a compact set), hence attains a maximum M there. Then $\int_a^b |g(\gamma(t))| |\gamma'(t)| dt \leq M \int_a^b |\gamma'(t)| dt = M L(\gamma)$. $\square$

Lemma 15.3: Integral of a derivative; vanishing on loops. Let $\Omega \subseteq \mathbb{C}$ be open, $F : \Omega \rightarrow \mathbb{C}$ holomorphic with $F' = g$ continuous on Ω , and let $\gamma : [a, b] \rightarrow \Omega$ be a piecewise regular path. Then

$$\int_{\gamma} g(z) dz = F(\gamma(b)) - F(\gamma(a)).$$

In particular $\oint_{\gamma} g(z) dz = 0$ for every loop γ in Ω .

Proof. Step 1 — the C^1 case. Suppose first that γ is of class C^1 on the whole of $[a, b]$. The function $\varphi(t) = F(\gamma(t))$ is differentiable with $\varphi'(t) = F'(\gamma(t)) \gamma'(t) = g(\gamma(t)) \gamma'(t)$: this is the

chain rule, valid because F is complex-differentiable at $\gamma(t)$ and γ is differentiable at t — write $F(\gamma(t+s)) - F(\gamma(t)) = [F'(\gamma(t)) + \varepsilon(s)](\gamma(t+s) - \gamma(t))$ with $\varepsilon(s) \rightarrow 0$, divide by s and pass to the limit. Moreover φ' is continuous, because g and γ' are. By the fundamental theorem of calculus applied separately to $\operatorname{Re} \varphi$ and $\operatorname{Im} \varphi$,

$$\int_{\gamma} g dz = \int_a^b \varphi'(t) dt = \varphi(b) - \varphi(a) = F(\gamma(b)) - F(\gamma(a)).$$

Step 2 — the piecewise regular case. Let $a = t_0 < t_1 < \cdots < t_N = b$ be a subdivision on each subinterval of which γ is of class C^1 . Applying Step 1 to each piece and summing, the telescoping sum leaves $F(\gamma(t_N)) - F(\gamma(t_0)) = F(\gamma(b)) - F(\gamma(a))$.

Step 3 — loops. If $\gamma(a) = \gamma(b)$ the right-hand side is zero. $\square$

***Remark 15.2: Simple connectedness: what is assumed and what is proved.** An open set $\Omega \subseteq \mathbb{C}$ is called **simply connected** if it is connected and every loop in Ω is homotopic in Ω to a constant loop (Definition 12.7). Cauchy's integral theorem holds, in its most general form, exactly on such open sets: $\oint_{\gamma} f = 0$ for every f holomorphic on Ω and every loop γ in Ω .*

*In this chapter the hypothesis of simple connectedness is stated but not exploited in general: every proof takes place on a **convex** open set — a disk, a rectangle, a half-plane, an intersection of these — which is simply connected (every loop contracts linearly onto its starting point) but is far more manageable, because the primitive is built by integrating along segments. The general version, for arbitrary simply connected open sets, is given as a panorama in Observation 15.3, with its source: it is not needed for anything that follows.*

15.2. Goursat's theorem and Cauchy's theorem on the disk

The starting point of all of complex analysis is a statement of modest appearance: the integral of a holomorphic function over the boundary of a *triangle* vanishes. The derivative is not assumed continuous — and this is the difficulty, overcome by Goursat in 1900 with the bisection argument that follows.

***Theorem 15.1: Goursat's theorem (triangle).** Let $\Omega \subseteq \mathbb{C}$ be open, f holomorphic on Ω , and let $\Delta = \Delta(p, q, s) \subset \Omega$ be a solid triangle contained in Ω . Then*

$$\oint_{\partial\Delta} f(z) dz = 0.$$

***Proof. Step 1 — bisection.** Let $m_1 = \frac{p+q}{2}$, $m_2 = \frac{q+s}{2}$, $m_3 = \frac{s+p}{2}$ be the midpoints of the sides. The four triangles*

$$\Delta^{(1)} = \Delta(p, m_1, m_3), \quad \Delta^{(2)} = \Delta(m_1, q, m_2), \quad \Delta^{(3)} = \Delta(m_3, m_2, s), \quad \Delta^{(4)} = \Delta(m_1, m_2, m_3)$$

are contained in Δ (convex hull of points of Δ) and cover Δ . Summing the four boundary integrals, each of the six internal segments $[m_1, m_3]$, $[m_3, m_2]$, $[m_2, m_1]$ appears exactly twice with opposite orientations, and the two contributions cancel by Definition 15.2; what remains is the three sides of Δ , each traversed once, in the direction of $\partial\Delta$. Hence

$$\oint_{\partial\Delta} f = \sum_{k=1}^4 \oint_{\partial\Delta^{(k)}} f.$$

Setting $I = |\oint_{\partial\Delta} f|$, the triangle inequality shows that at least one of the four terms has modulus $\geq I/4$: call Δ_1 the corresponding triangle.

Step 2 — the nested sequence. Iterating the construction gives a sequence of solid triangles $\Delta = \Delta_0 \supseteq \Delta_1 \supseteq \Delta_2 \supseteq \cdots$ with

$$\left| \oint_{\partial\Delta_n} f \right| \geq \frac{I}{4^n}, \quad \text{diam } \Delta_n = \frac{d}{2^n}, \quad L(\partial\Delta_n) = \frac{L}{2^n},$$

where $d = \text{diam } \Delta$ and $L = L(\partial\Delta)$. The two equalities hold because the sides of each sub-triangle of the bisection are half the corresponding sides (segments joining midpoints: they are parallel and half as long, by Thales's theorem, and the two “short” sides are half the original sides), and the diameter of a triangle is its longest side.

Step 3 — the limit point. The Δ_n are nonempty compact sets, decreasing, hence $\bigcap_{n \geq 0} \Delta_n \neq \emptyset$; let z^* be a point of the intersection. Since $\text{diam } \Delta_n \rightarrow 0$, the intersection is the single point z^* , and $z^* \in \Delta \subseteq \Omega$.

Step 4 — the estimate using differentiability at z^* . Let $\varepsilon > 0$. By Definition 15.1 applied at z^* there is $\delta > 0$ with $D(z^*, \delta) \subseteq \Omega$ and

$$|f(z) - f(z^*) - f'(z^*)(z - z^*)| \leq \varepsilon |z - z^*| \quad \text{for } |z - z^*| < \delta.$$

The affine function $z \mapsto f(z^*) + f'(z^*)(z - z^*)$ is the derivative of the polynomial $P(z) = f(z^*)z + \frac{1}{2}f'(z^*)(z - z^*)^2$, which is holomorphic on $\mathbb{C}$ with continuous derivative; by Lemma 15.3 its integral over the loop $\partial\Delta_n$ vanishes. Hence, for every n ,

$$\oint_{\partial\Delta_n} f(z) dz = \oint_{\partial\Delta_n} [f(z) - f(z^*) - f'(z^*)(z - z^*)] dz.$$

Step 5 — conclusion. Let n be large enough that $\text{diam } \Delta_n = d/2^n < \delta$: since $z^* \in \Delta_n$, we have $\Delta_n \subset D(z^*, \delta)$ and for every $z \in \partial\Delta_n$, $|z - z^*| \leq \text{diam } \Delta_n = d/2^n$. By the ML estimate (Lemma 15.2),

$$\frac{I}{4^n} \leq \left| \oint_{\partial\Delta_n} f \right| \leq \varepsilon \cdot \frac{d}{2^n} \cdot \frac{L}{2^n} = \varepsilon \frac{dL}{4^n},$$

whence $I \leq \varepsilon dL$. Since $\varepsilon > 0$ is arbitrary and dL does not depend on ε , we conclude $I = 0$. $\square$

Figure 15.1: The bisection of Theorem 15.1 on the triangle with vertices $p = (0, 0)$, $q = (6, 0)$, $s = (2, 4)$. The midpoints are $m_1 = (3, 0)$, $m_2 = (4, 2)$, $m_3 = (1, 2)$. The sides measure $|pq| = 6$, $|qs| = \sqrt{16 + 16} = 4\sqrt{2} = 5.6568542$, $|sp| = \sqrt{4 + 16} = 2\sqrt{5} = 4.4721360$, for a perimeter $L = 16.1289902$; the sub-triangle $\Delta^{(1)} = \Delta(p, m_1, m_3)$ has sides 3, $2\sqrt{2} = 2.8284271$, $\sqrt{5} = 2.2360680$ and perimeter $8.0644951 = L/2$. $\checkmark$ The three internal medians (in blue) are each traversed twice in opposite directions and cancel.

Lemma 15.4: Strengthened Goursat: one exceptional point. Let $\Omega \subseteq \mathbb{C}$ be open, $\pi \in \Omega$, and let $f : \Omega \rightarrow \mathbb{C}$ be continuous on Ω and holomorphic on $\Omega \setminus \{\pi\}$. Then $\oint_{\partial\Delta} f = 0$ for every solid triangle $\Delta \subseteq \Omega$.

Proof. **Step 1 — the point does not lie in the triangle.** If $\pi \notin \Delta$, then Δ is contained in the open set $\Omega \setminus \{\pi\}$, on which f is holomorphic, and the claim is Theorem 15.1.

Step 2 — the point is a vertex. Let $\Delta = \Delta(\pi, q, s)$. For $\lambda \in (0, 1)$ set $x_\lambda = \pi + \lambda(q - \pi)$ and $y_\lambda = \pi + \lambda(s - \pi)$, points on the sides $[\pi, q]$ and $[\pi, s]$. Then

$$\Delta(\pi, q, s) = \Delta(\pi, x_\lambda, y_\lambda) \cup \Delta(x_\lambda, q, y_\lambda) \cup \Delta(q, s, y_\lambda),$$

and the three boundaries, summed with the induced orientation, give $\partial\Delta$ because the internal segments $[x_\lambda, y_\lambda]$ and $[q, y_\lambda]$ each appear twice with opposite direction. The last two triangles do not contain π : indeed every point of theirs is a convex combination of $x_\lambda, q, y_\lambda, s$, all belonging to the subset of Δ where the barycentric coordinate relative to π is $\leq 1 - \lambda < 1$, while π has barycentric coordinate 1. By Step 1 their integrals vanish, and what remains is

$$\oint_{\partial\Delta} f = \oint_{\partial\Delta(\pi, x_\lambda, y_\lambda)} f.$$

Step 3 — the small triangle shrinks. f is continuous on the compact set Δ , hence bounded there: let $M = \max_\Delta |f|$. The perimeter of $\Delta(\pi, x_\lambda, y_\lambda)$ equals $\lambda(|q - \pi| + |s - \pi|) + \lambda|q - s| = \lambda L(\partial\Delta)$, because the three sides are homothetic with ratio λ about the center π . By the ML estimate (Lemma 15.2),

$$\left| \oint_{\partial\Delta} f \right| = \left| \oint_{\partial\Delta(\pi, x_\lambda, y_\lambda)} f \right| \leq M \lambda L(\partial\Delta) \xrightarrow{\lambda \rightarrow 0^+} 0.$$

The left-hand side does not depend on λ : hence it is zero.

Step 4 — the general case. If $\pi \in \Delta(p, q, s)$ is not a vertex, join it to the three vertices: if π is interior we obtain the three triangles $\Delta(\pi, p, q)$, $\Delta(\pi, q, s)$, $\Delta(\pi, s, p)$, whose boundaries sum to $\partial\Delta$ (the three segments $[\pi, p]$, $[\pi, q]$, $[\pi, s]$ each appear twice with opposite direction); if π lies on a side, for instance on $[p, q]$, we obtain the two triangles $\Delta(p, \pi, s)$ and $\Delta(\pi, q, s)$. In every case π is a vertex of every piece, and Step 3 gives a vanishing integral on each; summing gives the conclusion. $\square$

Theorem 15.2: Existence of a primitive on a convex open set. Let $\Omega \subseteq \mathbb{C}$ be open and convex, $\pi \in \Omega$, and let $f : \Omega \rightarrow \mathbb{C}$ be continuous on Ω and holomorphic on $\Omega \setminus \{\pi\}$ (in particular: f holomorphic on Ω). Then there exists $F : \Omega \rightarrow \mathbb{C}$ holomorphic with $F' = f$ on the whole of Ω .

Proof. **Step 1 — definition of F .** Fix $a \in \Omega$ and set

$$F(z) = \int_{[a, z]} f(\zeta) d\zeta, \quad z \in \Omega,$$

a well-defined integral because $[a, z] \subseteq \Omega$ by convexity and f is continuous.

Step 2 — the increment is an integral over the segment. Let $z \in \Omega$ and $h \in \mathbb{C}$ with $z + h \in \Omega$. The solid triangle $\Delta(a, z, z + h)$ is contained in Ω , because Ω is convex and contains the three vertices. By Lemma 15.4,

$$\int_{[a, z]} f + \int_{[z, z+h]} f + \int_{[z+h, a]} f = 0,$$

that is, since $\int_{[z+h, a]} f = -\int_{[a, z+h]} f = -F(z + h)$,

$$F(z + h) - F(z) = \int_{[z, z+h]} f(\zeta) d\zeta.$$

Step 3 — the difference quotient. For $h \neq 0$, since $\int_{[z, z+h]} d\zeta = h$ (the segment is the path $t \mapsto z + th$, and $\int_0^1 h dt = h$),

$$\frac{F(z+h) - F(z)}{h} - f(z) = \frac{1}{h} \int_{[z, z+h]} [f(\zeta) - f(z)] d\zeta.$$

Let $\varepsilon > 0$. By continuity of f at z there is $\delta > 0$ such that $|f(\zeta) - f(z)| \leq \varepsilon$ for $|\zeta - z| < \delta$, $\zeta \in \Omega$. If $0 < |h| < \delta$, every point of $[z, z+h]$ is at distance from z less than δ , and the ML estimate (Lemma 15.2) with $L([z, z+h]) = |h|$ gives

$$\left| \frac{F(z+h) - F(z)}{h} - f(z) \right| \leq \frac{1}{|h|} \cdot \varepsilon \cdot |h| = \varepsilon.$$

Hence the limit of the difference quotient exists and equals $f(z)$: F is holomorphic on Ω with $F' = f$. $\square$

Corollary 15.1: Cauchy's integral theorem for the disk (and for any convex set).

Let $\Omega \subseteq \mathbb{C}$ be open and convex — for example a disk $D(z_0, r)$ — and let f be continuous on Ω and holomorphic on $\Omega \setminus \{\pi\}$ for some $\pi \in \Omega$ (in particular: f holomorphic on Ω). Then

$$\oint_{\gamma} f(z) dz = 0$$

for every piecewise regular loop γ contained in Ω .

Proof. By Theorem 15.2 there exists F holomorphic on Ω with $F' = f$; the derivative f is continuous by hypothesis. Lemma 15.3, with $g = f$, gives $\oint_{\gamma} f = F(\gamma(b)) - F(\gamma(a)) = 0$ because γ is a loop. $\square$

Remark 15.3: The general version, and what remains imported. Corollary 15.1 is all that is needed in this chapter, because every contour that we use (circles, boundaries of triangles, D -shaped contours) lies in a disk, a rectangle, or an intersection of half-planes with a disk, i.e., in a convex set. The general form of Cauchy's theorem — $\oint_{\gamma} f = 0$ for every f holomorphic on a simply connected open set Ω and every loop γ in Ω , and the homological version $\oint_{\gamma} f = 0$ for every cycle homologous to zero in Ω — is not proved here: it is **imported** from Ahlfors, Chapter 4, §4 (“The General Form of Cauchy's Theorem”, with the paragraphs Homology, Simple Connectivity and Proof of Cauchy's Theorem”) and from Rudin, Chapter 10 (“The global Cauchy theorem”). What is missing, relative to what is proved here, is exactly the passage from the convex case to the general case: the construction of a chain of disks along a homotopy, or Dixon's homological argument. No result of this chapter depends on that passage.

15.3. Holomorphic functions and the circle: from Cauchy to residues

Remark 15.4: Prerequisites and level. This is the most advanced section of the chapter. It presupposes the notion of the complex derivative and the Cauchy–Goursat theorem (vanishing integral of a holomorphic function along a closed contour in a simply connected domain), which we take as known and for which we refer to Ahlfors, Chapter 4. From the present treatise we use Chapter 2 (line integrals and the contour deformation principle, Ex-

ercise S5) and the Cauchy–Goursat theorem. A first-time reader may confine attention to the statements, the step box on computing residues, and the final worked example.

Remark 15.5: Update: what is no longer assumed. Observation 15.4 is the text with which this section made its entrance in Volume II, where it was the last and most advanced part of an introductory chapter; it is reproduced here unchanged. In Volume III the picture has changed, and the three results that it declared as assumed are now proved in this very chapter:

- the **Cauchy–Goursat theorem** is Theorem 15.1 (triangle, by bisection) together with Corollary 15.1 (disk and convex open sets), proved in Section 15.2 without assuming the continuity of f' ;
- **Riemann’s theorem on removable singularities**, used in the proof below of Theorem 15.3, is Theorem 15.13 of Section 15.7;
- the **contour deformation principle** between concentric circles is Lemma 15.6 of Section 15.4.

Since Theorem 15.13 is proved downstream of Cauchy’s formula (it goes through the Laurent expansion, which in turn goes through Cauchy’s formula), the inherited proof of Theorem 15.3 cannot be taken as a foundational proof: it is kept because it is the shortest route once the whole edifice is standing, and alongside it, right after, stands the Alternative proof, which uses only Corollary 15.1 and Lemma 15.5 and is therefore not circular. The complete logical order is given in Observation 15.10.

Lemma 15.5: Integral of $(\zeta - z_0)^m$ over a circle. For every $m \in \mathbb{Z}$ and every $\rho > 0$:

$$\oint_{|\zeta - z_0| = \rho} (\zeta - z_0)^m d\zeta = \begin{cases} 2\pi i & \text{if } m = -1, \\ 0 & \text{if } m \neq -1, \end{cases}$$

the circle being traversed counterclockwise.

Proof. Parametrize $\zeta = z_0 + \rho e^{i\theta}$, $\theta \in [0, 2\pi]$, so that $d\zeta = i\rho e^{i\theta} d\theta$ (derivative of the parametrization, Chapter 1). Then

$$\oint (\zeta - z_0)^m d\zeta = \int_0^{2\pi} \rho^m e^{im\theta} \cdot i\rho e^{i\theta} d\theta = i\rho^{m+1} \int_0^{2\pi} e^{i(m+1)\theta} d\theta.$$

For $m \neq -1$ the exponent $m+1$ is a nonzero integer and the integral vanishes, since a primitive of $e^{i(m+1)\theta}$ is $e^{i(m+1)\theta} / (i(m+1))$, which takes the same value at the endpoints 0 and 2π by periodicity. For $m = -1$ the integrand is $e^0 = 1$ and one gets $i\rho^0 \cdot 2\pi = 2\pi i$. $\square$

Remark 15.6: The thread running through the treatise. This lemma is the continuous version of Theorem (Volume II, Chapter 3): in the discrete case one sums over n roots of unity, here one integrates over the whole circle, and in both cases a single index survives. It is the fourth appearance of the master identity listed in Observation (Volume II, Chapter 3), and in complex analysis it goes by the name of the basis for the residue calculus.

Theorem 15.3: Cauchy’s integral formula (circle case). If f is holomorphic on an open set containing $\overline{D}(z_0, r)$, then for every $z \in D(z_0, r)$:

$$f(z) = \frac{1}{2\pi i} \oint_{|\zeta - z_0| = r} \frac{f(\zeta)}{\zeta - z} d\zeta.$$

Proof. [via removable singularity] Fix $z \in D(z_0, r)$, and define

$$g(\zeta) = \begin{cases} \frac{f(\zeta) - f(z)}{\zeta - z}, & \zeta \neq z, \\ f'(z), & \zeta = z. \end{cases}$$

For $\zeta \neq z$, g is holomorphic (quotient of holomorphic functions with nonvanishing denominator). At $\zeta = z$, g is continuous by the very definition of the complex derivative, hence bounded near z : by Riemann's theorem on removable singularities, g extends to a function holomorphic on all of $D(z_0, r)$. By the Cauchy–Goursat theorem,

$$\oint_{|\zeta - z_0| = r} g(\zeta) d\zeta = 0.$$

On the other hand, by definition of g ,

$$\oint \frac{f(\zeta)}{\zeta - z} d\zeta = f(z) \oint \frac{d\zeta}{\zeta - z} + \oint g(\zeta) d\zeta = f(z) \oint \frac{d\zeta}{\zeta - z}.$$

It remains to show that $\oint_{|\zeta - z_0| = r} \frac{d\zeta}{\zeta - z} = 2\pi i$ for z interior. The function $1/(\zeta - z)$ is holomorphic everywhere except at $\zeta = z$; applying the contour deformation principle (Chapter 2, Exercise S5) to the annular region between $|\zeta - z_0| = r$ and a small circle $|\zeta - z| = \varepsilon$ entirely contained in $D(z_0, r)$, the two integrals coincide. But on the small circle, by Lemma 15.5 with $m = -1$ and center z ,

$$\oint_{|\zeta - z| = \varepsilon} \frac{d\zeta}{\zeta - z} = 2\pi i.$$

Substituting gives the conclusion. $\square$

Second proof, foundational: only Goursat and the power lemma. This proof uses neither Riemann's theorem on removable singularities nor the deformation principle: it relies only on Corollary 15.1 and Lemma 15.5. It is this proof that makes the logical chain of the chapter non-circular.

Step 1 — a convex set slightly larger than the closed disk. Let A be the open set on which f is holomorphic, with $\overline{D(z_0, r)} \subset A$. The set $\overline{D(z_0, r)}$ is compact and $\mathbb{C} \setminus A$ is closed and disjoint from it, so the continuous function $w \mapsto \text{dist}(w, \mathbb{C} \setminus A)$ attains a minimum $\eta > 0$ on $\overline{D(z_0, r)}$ (if $A = \mathbb{C}$ take $\eta = 1$). Setting $R = r + \eta/2$, the disk $D(z_0, R)$ is contained in A : every point w of it is at distance less than $\eta/2$ from $\overline{D(z_0, r)}$, hence at distance more than $\eta/2 > 0$ from $\mathbb{C} \setminus A$. $D(z_0, R)$ is open and convex.

Step 2 — the auxiliary function. Fix $z \in D(z_0, r)$ and set

$$g(\zeta) = \begin{cases} \frac{f(\zeta) - f(z)}{\zeta - z}, & \zeta \in D(z_0, R) \setminus \{z\}, \\ f'(z), & \zeta = z. \end{cases}$$

On $D(z_0, R) \setminus \{z\}$ the function g is holomorphic, a quotient of holomorphic functions with nonvanishing denominator. At $\zeta = z$ it is *continuous*, by the very definition of the complex derivative (Definition 15.1): the quotient tends to $f'(z)$. So g is continuous on $D(z_0, R)$ and holomorphic on $D(z_0, R) \setminus \{z\}$: this is exactly the hypothesis of Corollary 15.1 with $\pi = z$. Since the circle $|\zeta - z_0| = r$ is a loop contained in $D(z_0, R)$,

$$\oint_{|\zeta - z_0| = r} g(\zeta) d\zeta = 0, \quad \text{i.e.} \quad \oint_{|\zeta - z_0| = r} \frac{f(\zeta)}{\zeta - z} d\zeta = f(z) \oint_{|\zeta - z_0| = r} \frac{d\zeta}{\zeta - z}.$$

Step 3 — the integral of the kernel equals $2\pi i$. It remains to compute $\oint_{|\zeta-z_0|=r} \frac{d\zeta}{\zeta-z}$ for z interior. Set $w = \frac{z-z_0}{\zeta-z_0}$; for $|\zeta-z_0|=r$ we have $|w| = \frac{|z-z_0|}{r} =: q < 1$, constant in ζ . Then

$$\frac{1}{\zeta-z} = \frac{1}{(\zeta-z_0)-(z-z_0)} = \frac{1}{\zeta-z_0} \cdot \frac{1}{1-w} = \sum_{n=0}^{\infty} \frac{(z-z_0)^n}{(\zeta-z_0)^{n+1}},$$

and the series converges *uniformly* in ζ on the circle, because the modulus of the n -th term equals q^n/r and $\sum q^n/r < \infty$ (Weierstrass's test). One can therefore integrate term by term:

$$\oint_{|\zeta-z_0|=r} \frac{d\zeta}{\zeta-z} = \sum_{n=0}^{\infty} (z-z_0)^n \oint_{|\zeta-z_0|=r} (\zeta-z_0)^{-n-1} d\zeta.$$

By Lemma 15.5 the integral on the right equals $2\pi i$ if $-n-1 = -1$, i.e. $n = 0$, and 0 otherwise: only the term $n = 0$ survives, giving $2\pi i$.

Step 4 — conclusion. Substituting into Step 2, $\oint \frac{f(\zeta)}{\zeta-z} d\zeta = 2\pi i f(z)$, which is the claim. $\square$

Remark 15.7: The Cauchy kernel at exterior points. The same computation of Step 3 gives the value of the integral when z is exterior to the circle. If $|z-z_0| > r$ one expands in the reciprocal variable:

$$\frac{1}{\zeta-z} = \frac{-1}{(z-z_0)-(\zeta-z_0)} = -\frac{1}{z-z_0} \sum_{n=0}^{\infty} \left(\frac{\zeta-z_0}{z-z_0} \right)^n = -\sum_{n=0}^{\infty} \frac{(\zeta-z_0)^n}{(z-z_0)^{n+1}},$$

a series uniformly convergent on $|\zeta-z_0|=r$ because the modulus of the n -th term is $r^n/|z-z_0|^{n+1}$ and $r/|z-z_0| < 1$. Every exponent n is ≥ 0 , hence different from -1 : by Lemma 15.5 every term gives a vanishing integral and

$$\oint_{|\zeta-z_0|=r} \frac{d\zeta}{\zeta-z} = 0 \quad \text{for } |z-z_0| > r.$$

The two computations together are Proposition 15.3: the index of the circle equals 1 inside and 0 outside.

Remark 15.8: Other routes to the proof. The proof above chooses the removable-singularity route, which directly reuses Lemma 15.5. At least two others appear in the literature, equivalent in conclusion but illuminating different aspects:

- a direct estimate with the ML inequality, which explicitly bounds $|\oint|$, letting the radius of the small circle tend to zero without invoking Riemann's theorem (Rudin, Real and Complex Analysis, Chapter 10);
- a route that differentiates under the integral sign, particularly efficient because it yields as an immediate corollary the formula for the derivatives

$$f^{(k)}(z) = \frac{k!}{2\pi i} \oint \frac{f(\zeta)}{(\zeta-z)^{k+1}} d\zeta$$

(Ahlfors, Chapter 4, §2).

Remark 15.9: Why the circle is the natural contour. The proof systematically uses the parametrization $\zeta = z_0 + \rho e^{i\theta}$: the circle is the simplest and most symmetric closed curve on which the integral can be computed explicitly, thanks to $d\zeta = i\rho e^{i\theta} d\theta$, which turns the complex line integral into a real integral over $[0, 2\pi]$ — the same mechanism already seen in

15.3.1 Laurent series and residues

Just as a periodic function expands in a Fourier series (Chapter 4), a function holomorphic on an annulus centered at z_0 expands in a series of both positive and negative powers of $(z - z_0)$. The coefficient of the power $(z - z_0)^{-1}$ plays a special role, by Lemma 15.5: it is the only one that survives integration over a circle.

Theorem 15.4: Laurent series. *If f is holomorphic on the annulus $A = \{z : r_1 < |z - z_0| < r_2\}$, then f admits one and only one representation*

$$f(z) = \sum_{n=-\infty}^{\infty} a_n (z - z_0)^n, \quad a_n = \frac{1}{2\pi i} \oint_{|\zeta - z_0|=\rho} \frac{f(\zeta)}{(\zeta - z_0)^{n+1}} d\zeta,$$

for any $\rho \in (r_1, r_2)$, with uniform convergence on every closed sub-annulus. The part with $n \geq 0$ is called the regular part, that with $n < 0$ the principal part.

Proof. Step 1 — Cauchy's formula on the annulus. Fix $z \in A$ and choose ρ_1, ρ_2 with $r_1 < \rho_1 < |z - z_0| < \rho_2 < r_2$; let γ_1, γ_2 be the circles $|\zeta - z_0| = \rho_1, \rho_2$, both traversed counterclockwise. Cutting the annular region between γ_1 and γ_2 along a segment joining them — so as to make it simply connected — and applying Theorem 15.3 to the boundary of the cut region (the two sides of the cut are traversed in opposite directions and their contributions cancel), one obtains

$$f(z) = \frac{1}{2\pi i} \oint_{\gamma_2} \frac{f(\zeta)}{\zeta - z} d\zeta - \frac{1}{2\pi i} \oint_{\gamma_1} \frac{f(\zeta)}{\zeta - z} d\zeta.$$

Step 2 — regular part, from the outer circle. For $\zeta \in \gamma_2$ we have $|z - z_0| < \rho_2 = |\zeta - z_0|$, hence $|\frac{z - z_0}{\zeta - z_0}| < 1$ and the geometric series converges uniformly in ζ on γ_2 :

$$\frac{1}{\zeta - z} = \frac{1}{(\zeta - z_0) - (z - z_0)} = \frac{1}{\zeta - z_0} \sum_{n=0}^{\infty} \left(\frac{z - z_0}{\zeta - z_0} \right)^n.$$

Integrating term by term (legitimate by uniform convergence):

$$\frac{1}{2\pi i} \oint_{\gamma_2} \frac{f(\zeta)}{\zeta - z} d\zeta = \sum_{n=0}^{\infty} a_n (z - z_0)^n, \quad a_n = \frac{1}{2\pi i} \oint_{\gamma_2} \frac{f(\zeta)}{(\zeta - z_0)^{n+1}} d\zeta.$$

Step 3 — principal part, from the inner circle. For $\zeta \in \gamma_1$ we have $|\zeta - z_0| = \rho_1 < |z - z_0|$, so one expands in the reciprocal variable:

$$\frac{1}{\zeta - z} = \frac{-1}{(z - z_0) - (\zeta - z_0)} = \frac{-1}{z - z_0} \sum_{m=0}^{\infty} \left(\frac{\zeta - z_0}{z - z_0} \right)^m.$$

Integrating term by term and setting $n = -m - 1$ (so that $m = 0, 1, 2, \dots$ corresponds to $n = -1, -2, -3, \dots$):

$$-\frac{1}{2\pi i} \oint_{\gamma_1} \frac{f(\zeta)}{\zeta - z} d\zeta = \sum_{n=-\infty}^{-1} a_n (z - z_0)^n, \quad a_n = \frac{1}{2\pi i} \oint_{\gamma_1} \frac{f(\zeta)}{(\zeta - z_0)^{n+1}} d\zeta.$$

Step 4 — independence of ρ . The function $\zeta \mapsto f(\zeta)/(\zeta - z_0)^{n+1}$ is holomorphic on the whole annulus, which contains no singularity between γ_1 and γ_2 : by the contour deformation

principle the integral defining a_n has the same value on *any* circle $|\zeta - z_0| = \rho$ with $\rho \in (r_1, r_2)$. Hence the single formula of the statement.

Step 5 — uniqueness. Let $f(z) = \sum_n b_n(z - z_0)^n$ be another representation, uniformly convergent on compact sub-annuli. Multiply both sides by $(z - z_0)^{-k-1}$ and integrate over $|z - z_0| = \rho$, exchanging series and integral:

$$\oint \frac{f(z)}{(z - z_0)^{k+1}} dz = \sum_n b_n \oint (z - z_0)^{n-k-1} dz.$$

By Lemma 15.5 the integral on the right equals $2\pi i$ only when $n - k - 1 = -1$, i.e. $n = k$, and 0 otherwise: only the term $n = k$ survives, giving $b_k = a_k$ for every k . $\square$

Remark 15.10: The logical order of the chapter. The inherited proof of Theorem 15.4 twice uses a classical argument that deserves to be located precisely.

(a) The cut in the annulus (Step 1). This is Cauchy's integral formula on the annulus: for z in the annulus, $f(z) = \frac{1}{2\pi i} \oint_{\gamma_2} \frac{f(\zeta)}{\zeta - z} d\zeta - \frac{1}{2\pi i} \oint_{\gamma_1} \frac{f(\zeta)}{\zeta - z} d\zeta$. The full justification of the argument “cut the annulus along a segment and the two sides cancel” requires the homological form of Cauchy's theorem, which this chapter does not prove (Observation 15.3). The same statement is, however, proved here, by a different route and with no cut at all, in Proposition 15.1: Step 1 is therefore not left hanging.

(b) Independence of ρ (Step 4). This is the deformation principle between concentric circles, proved here in Lemma 15.6.

(c) The foundational chain. In order, without circularity: Lemma 15.2 and Lemma 15.3 $\rightarrow$ Theorem 15.1 $\rightarrow$ Lemma 15.4 $\rightarrow$ Theorem 15.2 $\rightarrow$ Corollary 15.1 $\rightarrow$ Theorem 15.3 (in the Alternative proof) $\rightarrow$ Theorem 15.6 (analyticity) $\rightarrow$ Lemma 15.6 and Proposition 15.1 $\rightarrow$ Theorem 15.4 $\rightarrow$ Theorem 15.13 and the classification of singularities $\rightarrow$ Theorem 15.17 (of which Theorem 15.5 is the circle case) $\rightarrow$ the argument principle and Rouché's theorem. The only **imported** link is the one declared in Observation 15.3: the passage from the convex case to the general simply connected case, which is not needed here.

Definition 15.3: Isolated singularity and residue. A point z_0 is an **isolated singularity** of f if f is holomorphic on an annulus $0 < |z - z_0| < r$ but not (necessarily) at z_0 . The **residue** of f at z_0 , written $\text{Res}(f, z_0)$, is the coefficient a_{-1} of its Laurent expansion about z_0 .

Theorem 15.5: Residue theorem. Let f be holomorphic on an open set containing $\overline{D}(z_0, r)$ except at finitely many isolated singularities $\xi_1, \dots, \xi_p$ interior to the circle $|z - z_0| = r$. Then

$$\oint_{|z - z_0| = r} f(z) dz = 2\pi i \sum_{j=1}^p \text{Res}(f, \xi_j).$$

Proof. Around each ξ_j , f admits a Laurent expansion $f(z) = \sum_n a_n^{(j)}(z - \xi_j)^n$ by Theorem 15.4. Surround each singularity with a small circle $|z - \xi_j| = \varepsilon_j$, chosen small enough not to meet the others nor to leave $D(z_0, r)$. Applying the contour deformation principle (Chapter 2, Exercise S5) p times to the region obtained by removing the p small disks from $D(z_0, r)$ — a region on which f is holomorphic, and whose oriented boundary is the big circle counterclockwise together with the p small circles clockwise —

$$\oint_{|z - z_0| = r} f(z) dz = \sum_{j=1}^p \oint_{|z - \xi_j| = \varepsilon_j} f(z) dz.$$

On each small circle we integrate the Laurent series term by term (legitimate by uniform convergence) and apply Lemma 15.5 to each power $(z - \xi_j)^n$: only $n = -1$ survives, giving

$$\oint_{|z-\xi_j|=\varepsilon_j} f(z) dz = 2\pi i a_{-1}^{(j)} = 2\pi i \operatorname{Res}(f, \xi_j).$$

Summing over the p small circles gives the claim. $\square$

Second proof, without the deformation principle. Theorem 15.5 is the special case of Theorem 15.17 in which Ω is an open disk containing $\overline{D(z_0, r)}$ (it exists by Step 1 of the Alternative proof of Theorem 15.3), γ is the circle $|z - z_0| = r$, and each index $\operatorname{Ind}_\gamma(\xi_j)$ equals 1 because ξ_j is interior to the circle (Proposition 15.3). The proof of Theorem 15.17, in Section 15.8, does not use the contour deformation principle: it subtracts from f the principal parts of the Laurent expansions at the singularities, obtains a function holomorphic on the whole of Ω , and applies Corollary 15.1 to it. The two proofs are therefore independent of each other, and the second requires nothing that is not proved in this chapter. $\square$

Practical computation of a residue Simple pole. If ξ is a simple pole (i.e. $a_{-1} \neq 0$ but $a_n = 0$ for $n < -1$):

$$\operatorname{Res}(f, \xi) = \lim_{z \rightarrow \xi} (z - \xi) f(z).$$

Quotient with a simple zero in the denominator. If $f = p/q$ with $p(\xi) \neq 0$, $q(\xi) = 0$ and $q'(\xi) \neq 0$:

$$\operatorname{Res}(f, \xi) = \frac{p(\xi)}{q'(\xi)},$$

which follows from the previous formula by writing $(z - \xi) \frac{p(z)}{q(z)} = \frac{p(z)}{\frac{q(z) - q(\xi)}{z - \xi}}$ and passing to the limit. **Pole of order k .**

$$\operatorname{Res}(f, \xi) = \frac{1}{(k-1)!} \lim_{z \rightarrow \xi} \frac{d^{k-1}}{dz^{k-1}} [(z - \xi)^k f(z)].$$

$\square$

Remark 15.11: The three formulas of the box are a theorem. The box above lists three operative recipes, with a hint of justification for the second. In Section 15.7 the three formulas are stated and proved in full, with the exact hypothesis under which they hold (Proposition 15.2): the key word is the order of the pole, and the proof consists in multiplying the Laurent expansion by $(z - \xi)^k$ and reading off the right coefficient of the power series so obtained. The third formula requires $q(\xi) = 0$ and $q'(\xi) \neq 0$, i.e. a simple zero of the denominator: with a double zero the formula $p(\xi)/q'(\xi)$ becomes $p(\xi)/0$ and is meaningless.

Example 15.1: A real integral computed on the unit circle. Compute $I = \int_0^{2\pi} \frac{d\theta}{a + \cos \theta}$ for $a > 1$.

Step 1 — from the real line to a contour. Put $z = e^{i\theta}$, the parametrization of $\mathbb{T}$ of the Corollary (Volume II, Chapter 3). By the Theorem (Volume II, Chapter 3), $\cos \theta = \frac{1}{2}(z + z^{-1})$, and differentiating $z = e^{i\theta}$ gives $dz = iz d\theta$, i.e. $d\theta = dz/(iz)$. Hence

$$I = \oint_{\mathbb{T}} \frac{1}{a + \frac{1}{2}(z + z^{-1})} \cdot \frac{dz}{iz}.$$

Step 2 — simplification. Multiplying numerator and denominator by $2z$:

$$\frac{1}{a + \frac{z^2+1}{2z}} = \frac{2z}{2az + z^2 + 1},$$

hence

$$I = \oint_{\mathbb{T}} \frac{2z}{z^2 + 2az + 1} \cdot \frac{dz}{iz} = \frac{2}{i} \oint_{\mathbb{T}} \frac{dz}{z^2 + 2az + 1}.$$

Step 3 — the poles. The roots of $z^2 + 2az + 1 = 0$ are

$$z_{1,2} = -a \pm \sqrt{a^2 - 1},$$

both real since $a > 1$. Their product is $z_1 z_2 = 1$ (constant term), so one lies inside and the other outside $\mathbb{T}$. Since $|z_2| = a + \sqrt{a^2 - 1} > 1$, the interior pole is

$$z_1 = -a + \sqrt{a^2 - 1}, \quad |z_1| = \frac{1}{|z_2|} < 1.$$

Step 4 — the residue. With $p(z) = 2/i$ and $q(z) = z^2 + 2az + 1$, $q'(z) = 2z + 2a$:

$$\text{Res}(f, z_1) = \frac{2/i}{2z_1 + 2a} = \frac{1}{i(z_1 + a)} = \frac{1}{i\sqrt{a^2 - 1}},$$

since $z_1 + a = \sqrt{a^2 - 1}$.

Step 5 — the residue theorem.

$$I = 2\pi i \cdot \frac{1}{i\sqrt{a^2 - 1}} = \frac{2\pi}{\sqrt{a^2 - 1}}.$$

Step 6 — independent check. The same integral was computed in Chapter 2, Exercise S10, by the Weierstrass substitution, giving $2\pi/\sqrt{a^2 - b^2}$ with $b = 1$: identical. ✓ For $a = 2$ both give $2\pi/\sqrt{3} = 3.6275987$, which also matches the value obtained by periodic quadrature in Example (Volume II, Chapter 2) of Chapter 2.

Typical error. Including *both* poles in the computation. Theorem 15.5 counts only the singularities *interior* to the contour: here z_2 lies outside $\mathbb{T}$ and contributes nothing. The check $z_1 z_2 = 1$ is the quickest way to decide which of the two is interior, without computing its numerical value.

15.4. Derivatives, analyticity, and Cauchy's estimates

Cauchy's integral formula says that the values of f inside a circle are determined by the values on the circle. Expanding the kernel $1/(\zeta - z)$ in a geometric series yields much more: f is the sum of a power series, hence infinitely differentiable, and each of its derivatives is written as an integral over the circle. From that expression, with the ML estimate alone, one derives in three lines Cauchy's estimates, Liouville's theorem, and the fundamental theorem of algebra.

Theorem 15.6: Analyticity and the formula for the derivatives. Let f be holomorphic on an open set $A \subseteq \mathbb{C}$, let $w \in A$ and let $\rho > 0$ be such that $D(w, \rho) \subset A$. Then:

(i) for every $z \in D(w, \rho)$, $f(z) = \sum_{n=0}^{\infty} a_n (z - w)^n$, with

$$a_n = \frac{1}{2\pi i} \oint_{|\zeta - w| = \rho} \frac{f(\zeta)}{(\zeta - w)^{n+1}} d\zeta,$$

and the series converges on the whole of $D(w, \rho)$;

(ii) f is infinitely complex-differentiable on A , each derivative $f^{(k)}$ is holomorphic (hence continuous) on A , and $a_n = f^{(n)}(w)/n!$;

(iii) **Cauchy's formula for the derivatives:** for every $k \geq 0$

$$f^{(k)}(w) = \frac{k!}{2\pi i} \oint_{|\zeta-w|=\rho} \frac{f(\zeta)}{(\zeta-w)^{k+1}} d\zeta.$$

Proof. Step 1 — Cauchy's formula on the circle centered at w . By hypothesis $\overline{D(w, \rho)} \subset A$ and f is holomorphic on A : Theorem 15.3 (in the Alternative proof, which depends only on Corollary 15.1 and Lemma 15.5) gives, for every $z \in D(w, \rho)$,

$$f(z) = \frac{1}{2\pi i} \oint_{|\zeta-w|=\rho} \frac{f(\zeta)}{\zeta-z} d\zeta.$$

Step 2 — expansion of the kernel and uniform convergence. Fix $z \in D(w, \rho)$ and let $q = |z-w|/\rho < 1$. As in Step 3 of the Alternative proof of Theorem 15.3,

$$\frac{f(\zeta)}{\zeta-z} = \sum_{n=0}^{\infty} \frac{f(\zeta)(z-w)^n}{(\zeta-w)^{n+1}} \quad \text{for } |\zeta-w|=\rho.$$

Setting $M = \max_{|\zeta-w|=\rho} |f(\zeta)|$ (it exists: f is continuous on the compact circle), the modulus of the n -th term is $\leq Mq^n/\rho$, and $\sum_n Mq^n/\rho$ converges because $q < 1$. By Weierstrass's test the series converges uniformly in ζ on the circle, and series and integral may be interchanged:

$$f(z) = \sum_{n=0}^{\infty} \left(\frac{1}{2\pi i} \oint_{|\zeta-w|=\rho} \frac{f(\zeta)}{(\zeta-w)^{n+1}} d\zeta \right) (z-w)^n = \sum_{n=0}^{\infty} a_n (z-w)^n.$$

The coefficients a_n do not depend on z : the power series $\sum a_n(z-w)^n$ therefore converges at every point of $D(w, \rho)$ and its radius of convergence is $\geq \rho$. This proves (i).

Step 3 — infinite differentiability. A power series is infinitely complex-differentiable inside its own disk of convergence, with derivatives obtained by term-by-term differentiation (a prerequisite stated in the opening infobox). Hence f is infinitely differentiable on $D(w, \rho)$, and evaluating the k -th derivative of the series at $z = w$,

$$f^{(k)}(w) = k! a_k.$$

Since A is open, every point w of it admits some $\rho > 0$ with $\overline{D(w, \rho)} \subset A$: take $\rho = \frac{1}{2} \text{dist}(w, \mathbb{C} \setminus A)$ if $A \neq \mathbb{C}$, and $\rho = 1$ if $A = \mathbb{C}$. So f is infinitely differentiable on the whole of A ; in particular every $f^{(k)}$ is holomorphic, hence continuous (Observation 15.1). This proves (ii).

Step 4 — the formula for the derivatives. Substituting $a_k = f^{(k)}(w)/k!$ into the integral expression for a_k of Step 2 gives (iii). $\square$

Remark 15.12: Why this is a fact with no real analogue. The real function $\varphi(x) = x^2 \sin(1/x)$ for $x \neq 0$, $\varphi(0) = 0$, is differentiable on the whole of $\mathbb{R}$ but its derivative is not continuous at 0: real differentiability once implies nothing about higher derivatives. In the complex setting, differentiability once on an open set implies differentiability infinitely many times and analyticity: this is Theorem 15.6. The reason lies entirely in Step 1, namely in the fact that the value at an interior point is reconstructed from an integral over the boundary — and an integral depends smoothly on the parameter z because the kernel $1/(\zeta-z)$ does.

Theorem 15.7: Cauchy's estimates. Under the hypotheses and notation of Theorem 15.6, let $M(\rho) = \max_{|\zeta-w|=\rho} |f(\zeta)|$. Then for every $n \geq 0$

$$|a_n| \leq \frac{M(\rho)}{\rho^n}, \quad \text{equivalently} \quad |f^{(n)}(w)| \leq \frac{n! M(\rho)}{\rho^n}.$$

Both inequalities are sharp: for $f(z) = c(z-w)^n$ they hold with equality.

Proof. Step 1 — ML estimate on the coefficient. On the circle $|\zeta - w| = \rho$ we have $|f(\zeta)| \leq M(\rho)$ and $|(\zeta - w)^{n+1}| = \rho^{n+1}$, hence

$$\left| \frac{f(\zeta)}{(\zeta - w)^{n+1}} \right| \leq \frac{M(\rho)}{\rho^{n+1}}.$$

The length of the circle is $2\pi\rho$ (Definition 15.2 with $\zeta(\theta) = w + \rho e^{i\theta}$, $|\zeta'(\theta)| = \rho$). By Lemma 15.2,

$$|a_n| = \frac{1}{2\pi} \left| \oint_{|\zeta-w|=\rho} \frac{f(\zeta)}{(\zeta - w)^{n+1}} d\zeta \right| \leq \frac{1}{2\pi} \cdot \frac{M(\rho)}{\rho^{n+1}} \cdot 2\pi\rho = \frac{M(\rho)}{\rho^n}.$$

Step 2 — the form with derivatives. It suffices to multiply by $n!$ and use $f^{(n)}(w) = n! a_n$ (Theorem 15.6(ii)).

Step 3 — sharpness. Let $f(z) = c(z-w)^n$ with $c \neq 0$. Then $a_n = c$ and $a_m = 0$ for $m \neq n$ (uniqueness of the coefficients of a power series), while $M(\rho) = \max_{|\zeta-w|=\rho} |c| \rho^n = |c| \rho^n$. Hence $M(\rho)/\rho^n = |c| = |a_n|$: the inequality is an equality. $\square$

Example 15.2: Cauchy's estimates on $1/(1-z)$, with a numerical check. Let $f(z) = \frac{1}{1-z}$, holomorphic on $A = \mathbb{C} \setminus \{1\}$, and take $w = 0$, $\rho = \frac{1}{2}$, so that $\overline{D(0, \frac{1}{2})} \subset A$.

Exact coefficients. For $|z| < 1$ we have $f(z) = \sum_{n \geq 0} z^n$ (geometric series), hence $a_n = 1$ for every n .

The maximum on the circle. For $|\zeta| = \frac{1}{2}$ we have $|1 - \zeta| \geq 1 - |\zeta| = \frac{1}{2}$, with equality at $\zeta = \frac{1}{2}$; hence $M(\frac{1}{2}) = \max |f| = \frac{1}{1/2} = 2$, attained at $\zeta = \frac{1}{2}$.

The estimates. Theorem 15.7 gives $|a_n| \leq M(\rho)/\rho^n = 2 \cdot 2^n$:

n	0	1	2	3	4
$ a_n $	1	1	1	1	1
$2 \cdot 2^n$	2	4	8	16	32

All verified. $\checkmark$

Independent check. The same estimates with $\rho \rightarrow 1^-$: $M(\rho) = 1/(1-\rho)$ and the bound becomes $|a_n| \leq \frac{1}{(1-\rho)\rho^n}$. Minimizing over ρ (logarithmic derivative zero: $\frac{1}{1-\rho} = \frac{n}{\rho}$, i.e. $\rho = \frac{n}{n+1}$) gives

$$|a_n| \leq (n+1) \left(1 + \frac{1}{n}\right)^n \quad (n \geq 1),$$

for instance $|a_4| \leq 5 \cdot (1.25)^4 = 5 \cdot 2.4414063 = 12.2070313$, still compatible with $|a_4| = 1$ and better than the estimate with $\rho = \frac{1}{2}$ (which gave 32). $\checkmark$ Cauchy's estimates are sharp on the class of functions with that maximum, not on a single function: here the function $z \mapsto 2(2z)^n$ saturates them, $1/(1-z)$ does not.

Theorem 15.8: Liouville's theorem. A bounded entire function is constant. More precisely: if f is holomorphic on the whole of $\mathbb{C}$ and there is $M \geq 0$ with $|f(z)| \leq M$ for every $z \in \mathbb{C}$, then f is constant.

Proof. **Step 1 — coefficients and an arbitrary radius.** Let $w \in \mathbb{C}$ be arbitrary. For every $\rho > 0$ we have $\overline{D}(w, \rho) \subset \mathbb{C}$, so Theorem 15.7 applies with $M(\rho) \leq M$:

$$|f'(w)| \leq \frac{1! \cdot M(\rho)}{\rho} \leq \frac{M}{\rho}.$$

Step 2 — letting ρ tend to infinity. The left-hand side does not depend on ρ , the right-hand side tends to 0 as $\rho \rightarrow +\infty$. Hence $f'(w) = 0$.

Step 3 — conclusion. $f' \equiv 0$ on $\mathbb{C}$, which is connected; by Lemma 15.1, Step 4, f is constant. $\square$

Corollary 15.2: Fundamental theorem of algebra. Every polynomial $P(z) = c_n z^n + c_{n-1} z^{n-1} + \cdots + c_0$ with complex coefficients, $n \geq 1$ and $c_n \neq 0$, has at least one root in $\mathbb{C}$. Consequently P factors as $P(z) = c_n \prod_{j=1}^n (z - \lambda_j)$ with $\lambda_1, \dots, \lambda_n \in \mathbb{C}$ not necessarily distinct.

Proof. **Step 1 — growth at infinity.** For $z \neq 0$,

$$|P(z)| = |z|^n \left| c_n + \frac{c_{n-1}}{z} + \cdots + \frac{c_0}{z^n} \right| \geq |z|^n \left(|c_n| - \sum_{k=0}^{n-1} \frac{|c_k|}{|z|^{n-k}} \right).$$

Let $R = \max \left\{ 1, \frac{2}{|c_n|} \sum_{k=0}^{n-1} |c_k| \right\}$. For $|z| \geq R$ we have $|z|^{n-k} \geq |z|$ for every $k \leq n-1$ (because $|z| \geq 1$ and $n-k \geq 1$), hence

$$\sum_{k=0}^{n-1} \frac{|c_k|}{|z|^{n-k}} \leq \frac{1}{|z|} \sum_{k=0}^{n-1} |c_k| \leq \frac{1}{R} \sum_{k=0}^{n-1} |c_k| \leq \frac{|c_n|}{2},$$

and hence $|P(z)| \geq \frac{|c_n|}{2} |z|^n \geq \frac{|c_n|}{2} R^n > 0$ for $|z| \geq R$.

Step 2 — by contradiction. Suppose P has no roots. Then $g = 1/P$ is holomorphic on the whole of $\mathbb{C}$ (quotient of holomorphic functions with nowhere-vanishing denominator: P is holomorphic being a sum of powers). By Step 1, $|g(z)| \leq \frac{2}{|c_n| R^n}$ for $|z| \geq R$. On the compact set $\overline{D}(0, R)$, the continuous function $|g|$ attains a maximum M_0 . Setting $M = \max\{M_0, 2/(|c_n| R^n)\}$, we have $|g| \leq M$ on the whole of $\mathbb{C}$.

Step 3 — Liouville. By Theorem 15.8, g is constant, hence $P = 1/g$ is constant: a contradiction with $n \geq 1$ and $c_n \neq 0$, because $|P(z)| \rightarrow +\infty$ as $|z| \rightarrow +\infty$ (Step 1). Hence P has a root λ_1 .

Step 4 — factorization. Euclidean division of P by $z - \lambda_1$ gives $P(z) = (z - \lambda_1)Q(z) + P(\lambda_1) = (z - \lambda_1)Q(z)$ with Q a polynomial of degree $n-1$ and leading coefficient c_n . Iterating n times (at each step the degree drops by one; when the degree is 0 the remaining polynomial is the constant c_n) gives the factorization of the statement. $\square$

Remark 15.13: A theorem of algebra with no algebra. Corollary 15.2 uses no algebraic property of $\mathbb{C}$ beyond those of a field: it uses the compactness of closed disks, the ML estimate, and the fact that a polynomial grows like $|z|^n$. This is why the “fundamental theorem of algebra” has, and can have, no purely algebraic proof: the completeness of $\mathbb{R}$ must enter somewhere. In Section 15.8 a second, entirely different proof is given, with Rouché's

theorem (Corollary 15.9); and in Chapter 12 a third one is found, topological, based on the winding number and on Lemma 12.8.

15.4.1 Deformation between concentric circles and Cauchy's formula on an annulus

Lemma 15.6: Invariance under deformation between concentric circles. Let $0 \leq r_1 < r_2 \leq +\infty$, $z_0 \in \mathbb{C}$, and let $A = \{\zeta \in \mathbb{C} : r_1 < |\zeta - z_0| < r_2\}$ be the corresponding open annulus. Let $g : A \rightarrow \mathbb{C}$ be continuous on A and holomorphic on $A \setminus \{\pi\}$ for some point $\pi \in A$ (in particular: g holomorphic on A). Then the function

$$I(\rho) = \oint_{|\zeta - z_0| = \rho} g(\zeta) d\zeta, \quad \rho \in (r_1, r_2),$$

is constant.

Proof. **Step 1 — writing it as an integral over $[0, 2\pi]$.** By Definition 15.2,

$$I(\rho) = \int_0^{2\pi} G(\rho, \theta) d\theta, \quad G(\rho, \theta) = i\rho e^{i\theta} g(z_0 + \rho e^{i\theta}).$$

Step 2 — I is continuous. Let $r_1 < \alpha < \beta < r_2$. The set $K = \{\zeta : \alpha \leq |\zeta - z_0| \leq \beta\}$ is a compact subset of A , and g is continuous there, hence uniformly continuous. Therefore G is uniformly continuous on $[\alpha, \beta] \times [0, 2\pi]$, and from $|I(\rho) - I(\rho')| \leq \int_0^{2\pi} |G(\rho, \theta) - G(\rho', \theta)| d\theta \leq 2\pi \sup_{\theta} |G(\rho, \theta) - G(\rho', \theta)|$ it follows that I is continuous on $[\alpha, \beta]$. Since α, β are arbitrary, I is continuous on (r_1, r_2) .

Step 3 — I is locally constant away from the exceptional radius. Let $\rho_\pi = |\pi - z_0| \in (r_1, r_2)$ and let J be one of the two open intervals (r_1, ρ_π) and (ρ_π, r_2) (if g is holomorphic on all of A , take $J = (r_1, r_2)$ and skip the distinction). Fix $\rho \in J$ and choose $\alpha < \rho < \beta$ with $[\alpha, \beta] \subset J$. On the compact set $K = \{\alpha \leq |\zeta - z_0| \leq \beta\}$, contained in $A \setminus \{\pi\}$, the function g is holomorphic; by Theorem 15.6, g' is holomorphic too, hence continuous, on an open set containing K . It follows that

$$\frac{\partial G}{\partial \rho}(\rho, \theta) = ie^{i\theta} g(z_0 + \rho e^{i\theta}) + i\rho e^{2i\theta} g'(z_0 + \rho e^{i\theta})$$

exists and is continuous on $[\alpha, \beta] \times [0, 2\pi]$. By Leibniz's rule for differentiation under the integral sign, $I'(\rho) = \int_0^{2\pi} \frac{\partial G}{\partial \rho} d\theta$.

Step 4 — the identity that closes the computation. Consider $H(\rho, \theta) = \rho e^{i\theta} g(z_0 + \rho e^{i\theta})$. Differentiating in θ (chain rule, with $\partial_\theta(z_0 + \rho e^{i\theta}) = i\rho e^{i\theta}$):

$$\frac{\partial H}{\partial \theta} = i\rho e^{i\theta} g + \rho e^{i\theta} \cdot g' \cdot i\rho e^{i\theta} = \rho (ie^{i\theta} g + i\rho e^{2i\theta} g') = \rho \frac{\partial G}{\partial \rho}.$$

Hence

$$I'(\rho) = \frac{1}{\rho} \int_0^{2\pi} \frac{\partial H}{\partial \theta} d\theta = \frac{1}{\rho} [H(\rho, \theta)]_{\theta=0}^{\theta=2\pi} = 0,$$

because $H(\rho, 2\pi) = H(\rho, 0)$ ($e^{i\theta}$ is 2π -periodic). Hence I is constant on each of the two intervals J .

Step 5 — pasting. I equals a constant c_1 on (r_1, ρ_π) and a constant c_2 on (ρ_π, r_2) ; being continuous at ρ_π by Step 2, $c_1 = I(\rho_\pi) = c_2$. Hence I is constant on (r_1, r_2) . $\square$

Proposition 15.1: Cauchy's integral formula on an annulus. Let f be holomorphic on the annulus $A = \{r_1 < |z - z_0| < r_2\}$ and let $r_1 < \rho_1 < \rho_2 < r_2$. Then for every z with $\rho_1 < |z - z_0| < \rho_2$,

$$f(z) = \frac{1}{2\pi i} \oint_{|\zeta - z_0| = \rho_2} \frac{f(\zeta)}{\zeta - z} d\zeta - \frac{1}{2\pi i} \oint_{|\zeta - z_0| = \rho_1} \frac{f(\zeta)}{\zeta - z} d\zeta.$$

Proof. **Step 1 — the auxiliary function.** Fix z in the annulus $\rho_1 < |z - z_0| < \rho_2$, and set, for $\zeta \in A$,

$$g(\zeta) = \begin{cases} \frac{f(\zeta) - f(z)}{\zeta - z}, & \zeta \neq z, \\ f'(z), & \zeta = z. \end{cases}$$

As in Step 2 of the Alternative proof of Theorem 15.3, g is continuous on A and holomorphic on $A \setminus \{z\}$.

Step 2 — deformation. By Lemma 15.6 (with $\pi = z$),

$$\oint_{|\zeta - z_0| = \rho_1} g(\zeta) d\zeta = \oint_{|\zeta - z_0| = \rho_2} g(\zeta) d\zeta.$$

Step 3 — separating the term with $f(z)$. For $j = 1, 2$,

$$\oint_{|\zeta - z_0| = \rho_j} g(\zeta) d\zeta = \oint_{|\zeta - z_0| = \rho_j} \frac{f(\zeta)}{\zeta - z} d\zeta - f(z) \oint_{|\zeta - z_0| = \rho_j} \frac{d\zeta}{\zeta - z}.$$

The point z is *interior* to the circle of radius ρ_2 and *exterior* to that of radius ρ_1 ; by Step 3 of the Alternative proof of Theorem 15.3 and by Observation 15.7,

$$\oint_{|\zeta - z_0| = \rho_2} \frac{d\zeta}{\zeta - z} = 2\pi i, \quad \oint_{|\zeta - z_0| = \rho_1} \frac{d\zeta}{\zeta - z} = 0.$$

Step 4 — conclusion. Equating the two expressions of Step 3 according to Step 2,

$$\oint_{|\zeta - z_0| = \rho_2} \frac{f(\zeta)}{\zeta - z} d\zeta - 2\pi i f(z) = \oint_{|\zeta - z_0| = \rho_1} \frac{f(\zeta)}{\zeta - z} d\zeta,$$

whence the claim, dividing by $2\pi i$. □

Remark 15.14: What this proposition repairs. Proposition 15.1 is, word for word, the statement of Step 1 of the inherited proof of Theorem 15.4, obtained however without cutting the annulus along a segment and without invoking the general form of Cauchy's theorem: the only nonelementary ingredient is Lemma 15.6, which in turn rests on Leibniz's rule and on 2π -periodicity. With it, and with Lemma 15.6 in place of the deformation principle of Step 4, the proof of Theorem 15.4 is complete and imports nothing.

15.5. Isolated zeros, the identity principle, and maximum modulus

Analyticity (Theorem 15.6) has two consequences of opposite and complementary nature. The first is one of *rigidity*: if a holomorphic function vanishes on a set that accumulates, it is identically zero; there are no nonzero holomorphic functions “with compact support”. The second is one of *openness*: the modulus of a nonconstant holomorphic function has no interior maxima, and so the maximum must be sought on the boundary. Both are proved here in full.

Theorem 15.9: Order of a zero and local factorization. Let $\Omega \subseteq \mathbb{C}$ be open, f holomorphic on Ω , $w \in \Omega$ with $f(w) = 0$, and suppose f is not identically zero on any neighborhood of w . Then there exist a unique integer $m \geq 1$, called the **order** (or multiplicity) of the zero, a radius $\rho > 0$ with $D(w, \rho) \subseteq \Omega$, and a function g holomorphic on $D(w, \rho)$ with $g(w) \neq 0$, such that

$$f(z) = (z - w)^m g(z) \quad \text{for every } z \in D(w, \rho).$$

In particular w is an isolated zero: there is $\rho' > 0$ such that $f(z) \neq 0$ for $0 < |z - w| < \rho'$.

Proof. Step 1 — the expansion. Choose $\rho > 0$ with $\overline{D(w, \rho)} \subset \Omega$. By Theorem 15.6, $f(z) = \sum_{n \geq 0} a_n(z - w)^n$ on $D(w, \rho)$, with $a_n = f^{(n)}(w)/n!$.

Step 2 — the first nonzero coefficient. If $a_n = 0$ for every n , then f would be identically zero on $D(w, \rho)$, against the hypothesis. Let therefore $m = \min\{n \geq 0 : a_n \neq 0\}$. Since $a_0 = f(w) = 0$, we have $m \geq 1$. The integer m is unique because the coefficients of a power series are unique (they are $f^{(n)}(w)/n!$).

Step 3 — the factorization. For $z \in D(w, \rho)$,

$$f(z) = \sum_{n \geq m} a_n(z - w)^n = (z - w)^m \sum_{k \geq 0} a_{m+k}(z - w)^k.$$

The series $\sum_k a_{m+k} \xi^k$ converges for every ξ with $|\xi| < \rho$: indeed for $0 < |\xi| < \rho$ it equals $f(w + \xi)/\xi^m$, and convergence follows from the convergence of $\sum_n a_n \xi^n$ divided by ξ^m ; for $\xi = 0$ it is trivial. Hence its radius of convergence is $\geq \rho$ and it defines a function g holomorphic on $D(w, \rho)$ (Theorem 15.6, Step 3, and the prerequisite on power series), with $g(w) = a_m \neq 0$.

Step 4 — isolation. g is continuous and $g(w) \neq 0$: there is $\rho' \in (0, \rho]$ such that $|g(z)| > |g(w)|/2 > 0$ for $|z - w| < \rho'$. Then for $0 < |z - w| < \rho'$ we have $f(z) = (z - w)^m g(z) \neq 0$, a product of two nonzero factors. $\square$

Theorem 15.10: Identity principle. Let $\Omega \subseteq \mathbb{C}$ be a connected open set and f holomorphic on Ω . The following three conditions are equivalent:

- (a) $f \equiv 0$ on Ω ;
- (b) the set $Z(f) = \{z \in \Omega : f(z) = 0\}$ has an accumulation point belonging to Ω ;
- (c) there is $w \in \Omega$ such that $f^{(n)}(w) = 0$ for every $n \geq 0$.

Proof. Step 1 — (a) $\Rightarrow$ (b) and (a) $\Rightarrow$ (c). Immediate: if $f \equiv 0$ then $Z(f) = \Omega$, which is a nonempty open set and so every point of it is an accumulation point; and all derivatives vanish.

Step 2 — (b) $\Rightarrow$ (c). Let $w \in \Omega$ be an accumulation point of $Z(f)$: there is a sequence $z_k \in Z(f) \setminus \{w\}$ with $z_k \rightarrow w$. By continuity $f(w) = \lim f(z_k) = 0$, so $w \in Z(f)$. If not all derivatives of f at w were zero, f would not be identically zero on any neighborhood of w (because the coefficients $f^{(n)}(w)/n!$ of the expansion would not all be zero); by Theorem 15.9, w would be an isolated zero, i.e. there would be $\rho' > 0$ with $f(z) \neq 0$ for $0 < |z - w| < \rho'$. But $z_k \rightarrow w$ with $z_k \neq w$ and $f(z_k) = 0$: a contradiction. Hence $f^{(n)}(w) = 0$ for every n .

Step 3 — (c) $\Rightarrow$ (a). Set

$$E = \{v \in \Omega : f^{(n)}(v) = 0 \text{ for every } n \geq 0\}.$$

E is closed in Ω : it is the intersection of the sets $\{v : f^{(n)}(v) = 0\}$, each closed in Ω because $f^{(n)}$ is continuous (Theorem 15.6(ii)). E is open: let $v \in E$ and $\rho > 0$ with $\overline{D(v, \rho)} \subset \Omega$. By Theorem 15.6, on $D(v, \rho)$, $f(z) = \sum_n \frac{f^{(n)}(v)}{n!}(z - v)^n = 0$: hence $f \equiv 0$ on $D(v, \rho)$, and with it all its derivatives, i.e. $D(v, \rho) \subseteq E$. **Conclusion:** E is nonempty (it contains w by (c)), open

and closed in Ω , which is connected; hence $E = \Omega$ and in particular $f = f^{(0)} \equiv 0$. $\square$

Corollary 15.3: Two functions that agree too much. Let f, h be holomorphic on a connected open set Ω and let $S = \{z \in \Omega : f(z) = h(z)\}$. If S has an accumulation point in Ω , then $f = h$ on the whole of Ω . In particular, if f and h agree on a segment, on an arc of a circle, or on a convergent sequence in Ω , they agree everywhere.

Proof. The function $f - h$ is holomorphic on Ω and $S = Z(f - h)$ has an accumulation point in Ω ; by Theorem 15.10, (b) $\Rightarrow$ (a), we get $f - h \equiv 0$. A segment, an arc of a circle, and a sequence converging to a point of Ω all have an accumulation point in Ω . $\square$

Corollary 15.4: Zeros are isolated. If f is holomorphic on a connected open set Ω and is not identically zero, then $Z(f)$ has no accumulation points in Ω : every zero is isolated and has a finite order $m \geq 1$. Consequently $Z(f) \cap K$ is finite for every compact set $K \subseteq \Omega$.

Proof. The first claim is the negation of (b) in Theorem 15.10; the finiteness of the order is Theorem 15.9 (applicable because f is not identically zero on any neighborhood, by the identity principle). For the second: if $Z(f) \cap K$ were infinite it would contain a sequence of distinct points, which by compactness of K would have a subsequence converging to a point of $K \subseteq \Omega$; that point would be an accumulation point of $Z(f)$, which is excluded. $\square$

Lemma 15.7: Mean value property on a circle. Let f be holomorphic on an open set containing $\overline{D(w, \rho)}$. Then

$$f(w) = \frac{1}{2\pi} \int_0^{2\pi} f(w + \rho e^{i\theta}) d\theta.$$

$$\text{In particular } |f(w)| \leq \frac{1}{2\pi} \int_0^{2\pi} |f(w + \rho e^{i\theta})| d\theta.$$

Proof. Step 1 — applying Cauchy's formula at the center. By Theorem 15.3 with $z = z_0 = w$ and $r = \rho$,

$$f(w) = \frac{1}{2\pi i} \oint_{|\zeta - w| = \rho} \frac{f(\zeta)}{\zeta - w} d\zeta.$$

Step 2 — parametrizing. With $\zeta = w + \rho e^{i\theta}$ we have $\zeta - w = \rho e^{i\theta}$ and $d\zeta = i\rho e^{i\theta} d\theta$, hence

$$f(w) = \frac{1}{2\pi i} \int_0^{2\pi} \frac{f(w + \rho e^{i\theta})}{\rho e^{i\theta}} i\rho e^{i\theta} d\theta = \frac{1}{2\pi} \int_0^{2\pi} f(w + \rho e^{i\theta}) d\theta.$$

Step 3 — the inequality. It follows from Step 2 of Lemma 15.2 applied to the integral over $[0, 2\pi]$: the modulus of an integral does not exceed the integral of the modulus. $\square$

Lemma 15.8: Constant modulus implies a constant function. Let f be holomorphic on a connected open set Ω and let $|f|$ be constant on Ω . Then f is constant.

Proof. Step 1 — the trivial case. Let $|f| \equiv c \geq 0$. If $c = 0$ then $f \equiv 0$ and it is constant.

Step 2 — $c > 0$: the conjugate is holomorphic. If $c > 0$, f never vanishes, and from $f\bar{f} = |f|^2 = c^2$ it follows that

$$\bar{f} = \frac{c^2}{f},$$

which is holomorphic on Ω (quotient of holomorphic functions with nowhere-vanishing denominator).

Step 3 — real and imaginary parts. The functions

$$2u = f + \bar{f} = f + \frac{c^2}{f}, \quad 2iv = f - \bar{f} = f - \frac{c^2}{f}$$

are both holomorphic on Ω . The first takes only real values (it is $2 \operatorname{Re} f$), the second only purely imaginary values, hence $2v$ is holomorphic and real-valued. By Lemma 15.1 (last statement), u and v are constant on the connected set Ω .

Step 4 — conclusion. $f = u + iv$ is constant. $\square$

Theorem 15.11: Maximum modulus principle, strong form. Let $\Omega \subseteq \mathbb{C}$ be open and connected and f holomorphic on Ω . If there is $w \in \Omega$ such that

$$|f(z)| \leq |f(w)| \quad \text{for every } z \text{ in a neighborhood of } w$$

(i.e. if $|f|$ has a local maximum at w), then f is constant on Ω . Equivalently: if f is not constant, $|f|$ has no local maximum in Ω .

Proof. **Step 1 — the modulus is constant on a circle.** Let $\delta > 0$ be such that $\overline{D(w, \delta)} \subset \Omega$ and $|f(z)| \leq M := |f(w)|$ for $|z - w| \leq \delta$. Let $0 < \rho \leq \delta$. By Lemma 15.7,

$$M = |f(w)| \leq \frac{1}{2\pi} \int_0^{2\pi} |f(w + \rho e^{i\theta})| d\theta \leq \frac{1}{2\pi} \int_0^{2\pi} M d\theta = M.$$

The two inequalities are therefore equalities, and in particular

$$\int_0^{2\pi} (M - |f(w + \rho e^{i\theta})|) d\theta = 0.$$

The integrand is continuous in θ and nonnegative: if it were strictly positive at a point θ_0 , it would be so on a whole interval about θ_0 and the integral would be strictly positive. Hence $|f(w + \rho e^{i\theta})| = M$ for every θ .

Step 2 — the modulus is constant on a disk. Step 1 holds for every $\rho \in (0, \delta]$, and $|f(w)| = M$: hence $|f| \equiv M$ on the whole of $D(w, \delta)$.

Step 3 — from constant modulus to a constant function. $D(w, \delta)$ is open and connected; by Lemma 15.8, f is constant on $D(w, \delta)$, i.e. $f \equiv f(w)$ there.

Step 4 — it propagates to all of Ω . The function $f - f(w)$ is holomorphic on the connected set Ω and vanishes on $D(w, \delta)$, which has accumulation points in Ω ; by Theorem 15.10 it is identically zero, i.e. $f \equiv f(w)$ on Ω . $\square$

Corollary 15.5: The maximum lies on the boundary. Let $\Omega \subseteq \mathbb{C}$ be open, connected, bounded, and nonempty, and let f be continuous on $\overline{\Omega}$ and holomorphic on Ω . Then

$$\max_{z \in \overline{\Omega}} |f(z)| = \max_{z \in \partial\Omega} |f(z)|.$$

Proof. **Step 1 — existence of the maximum.** $\overline{\Omega}$ is closed and bounded, hence compact, and $|f|$ is continuous on it: there is $p \in \overline{\Omega}$ with $|f(p)| = \max_{\overline{\Omega}} |f|$. The boundary $\partial\Omega$ is nonempty (otherwise Ω would be open and closed in the connected set $\mathbb{C}$, hence $\Omega = \mathbb{C}$, which is not bounded) and compact, so $\max_{\partial\Omega} |f|$ also exists.

Step 2 — if the maximum is interior. If $p \in \partial\Omega$ there is nothing more to prove, since $\max_{\partial\Omega} |f| \leq \max_{\overline{\Omega}} |f| = |f(p)|$ and the other inequality is obvious. So let $p \in \Omega$. Then $|f|$ has a local maximum at p (indeed a global one on $\overline{\Omega}$), and by Theorem 15.11, f is constant on Ω ; by continuity f is constant on $\overline{\Omega}$, and then $|f|$ takes the same value on $\partial\Omega$, which is nonempty.

| In both cases the two maxima coincide. □

Corollary 15.6: Minimum modulus principle. *Let $\Omega \subseteq \mathbb{C}$ be open and connected, f holomorphic on Ω and never zero. If $|f|$ has a local minimum at $w \in \Omega$, then f is constant. If moreover Ω is bounded, f is continuous on $\overline{\Omega}$, holomorphic on Ω , and $f(z) \neq 0$ for every $z \in \overline{\Omega}$, then*

$$\min_{z \in \overline{\Omega}} |f(z)| = \min_{z \in \partial\Omega} |f(z)|.$$

The hypothesis “never zero” cannot be dropped: $f(z) = z$ on the unit disk has an interior local minimum of the modulus at $z = 0$, where it equals 0, and is not constant.

Proof. Step 1 — the reciprocal function. Since f does not vanish on Ω , the function $h = 1/f$ is holomorphic on Ω and $|h| = 1/|f|$.

Step 2 — minimum of $|f|$ = maximum of $|h|$. If $|f|$ has a local minimum at w , i.e. $|f(z)| \geq |f(w)| > 0$ in a neighborhood, then $|h(z)| \leq |h(w)|$ in the same neighborhood: $|h|$ has a local maximum at w . By Theorem 15.11, h is constant on Ω , and hence so is $f = 1/h$.

Step 3 — the boundary version. Under the hypotheses of the second part, $h = 1/f$ is continuous on $\overline{\Omega}$ (quotient of continuous functions with nowhere-vanishing denominator on a compact set) and holomorphic on Ω ; Corollary 15.5 applied to h gives $\max_{\overline{\Omega}} |h| = \max_{\partial\Omega} |h|$, i.e., passing to reciprocals, $\min_{\overline{\Omega}} |f| = \min_{\partial\Omega} |f|$.

Step 4 — the counterexample. For $f(z) = z$ on $\mathbb{D}$ we have $|f(0)| = 0 \leq |f(z)|$ for every z : a local minimum at 0, and f is not constant. The hypothesis violated is exactly “ f never zero”. □

Remark 15.15: Why there are no interior maxima. *The proof of Theorem 15.11 reads as follows: the value at a point is the average of the values on every circle about it (Lemma 15.7); an average cannot exceed the maximum of the averaged values, and equals it only if they are all equal. This is the same mechanism that governs harmonic functions and the Poisson kernel (Chapter 16), and it is no coincidence: the real part of a holomorphic function is harmonic, and Lemma 15.7 is the mean value property of harmonic functions written for a complex-valued function.*

15.6. Schwarz’s lemma and the automorphisms of the disk

The maximum modulus principle, applied not to f but to the auxiliary function $f(z)/z$, produces a statement of surprising precision: a holomorphic function that maps the unit disk into itself and fixes the center cannot “push” any point farther from the origin, and if it fails to bring even a single point closer, then it is a rotation. From this one obtains the *complete* description of the holomorphic bijections of the disk onto itself.

Lemma 15.9: Schwarz’s lemma, with the equality case. *Let $f : \mathbb{D} \rightarrow \mathbb{D}$ be holomorphic on the unit disk $\mathbb{D} = D(0, 1)$, with values in $\mathbb{D}$, and $f(0) = 0$. Then*

$$|f(z)| \leq |z| \quad \text{for every } z \in \mathbb{D}, \quad \text{and} \quad |f'(0)| \leq 1.$$

Moreover, if one of the two equalities

$$|f(z_0)| = |z_0| \quad \text{for a single } z_0 \in \mathbb{D} \setminus \{0\}, \quad \text{or} \quad |f'(0)| = 1,$$

holds, then there is $\lambda \in \mathbb{C}$ with $|\lambda| = 1$ such that $f(z) = \lambda z$ for every $z \in \mathbb{D}$; and in that case both equalities hold for every z .

Proof. Step 1 — the series expansion on the whole of $\mathbb{D}$. For every $\rho < 1$ we have $\overline{D(0, \rho)} \subset \mathbb{D}$, so Theorem 15.6 gives $f(z) = \sum_{n \geq 0} a_n z^n$ on $D(0, \rho)$ with $a_n = f^{(n)}(0)/n!$ independent of ρ . Letting ρ range over $(0, 1)$ gives the same series on the whole of $\mathbb{D}$. From $f(0) = 0$ it follows that $a_0 = 0$.

Step 2 — the auxiliary function $g = f(z)/z$. Set

$$g(z) = \sum_{k=0}^{\infty} a_{k+1} z^k.$$

As in Step 3 of Theorem 15.9, the series converges for every $|z| < 1$ (for $z \neq 0$ it equals $f(z)/z$, a quotient of a series convergent at z), hence g is holomorphic on $\mathbb{D}$ and

$$g(z) = \frac{f(z)}{z} \quad (z \neq 0), \quad g(0) = a_1 = f'(0).$$

Step 3 — estimate on the circle of radius r . Let $0 < r < 1$. For $|z| = r$ we have $|f(z)| < 1$ (because f takes values in $\mathbb{D}$), hence

$$|g(z)| = \frac{|f(z)|}{r} < \frac{1}{r}.$$

g is continuous on $\overline{D(0, r)}$ and holomorphic on $D(0, r)$, which is open, connected, and bounded: by Corollary 15.5,

$$\max_{|z| \leq r} |g(z)| = \max_{|z|=r} |g(z)| \leq \frac{1}{r}.$$

Step 4 — letting r tend to 1. Fix $z \in \mathbb{D}$. For every r with $|z| < r < 1$, Step 3 gives $|g(z)| \leq 1/r$. The left-hand side does not depend on r ; letting $r \rightarrow 1^-$ gives $|g(z)| \leq 1$.

Step 5 — the two inequalities. For $z \neq 0$, $|f(z)| = |z| |g(z)| \leq |z|$; for $z = 0$, $f(0) = 0 = |0|$ holds. And $|f'(0)| = |g(0)| \leq 1$.

Step 6 — the equality case. Suppose $|f(z_0)| = |z_0|$ with $z_0 \in \mathbb{D}$, $z_0 \neq 0$: then $|g(z_0)| = |f(z_0)|/|z_0| = 1$. Or suppose $|f'(0)| = 1$: then $|g(0)| = 1$. In either case there is a point $w_0 \in \mathbb{D}$ with $|g(w_0)| = 1$; since $|g| \leq 1$ on the whole of $\mathbb{D}$ (Step 4), $|g|$ has at w_0 a maximum (global, hence also local) on $\mathbb{D}$, which is open and connected. By Theorem 15.11, g is constant: $g \equiv \lambda$ with $|\lambda| = |g(w_0)| = 1$. Hence $f(z) = zg(z) = \lambda z$ for every z , and then $|f(z)| = |z|$ for every z and $|f'(0)| = |\lambda| = 1$. $\square$

Definition 15.4: Blaschke factor. For $a \in \mathbb{D}$, the **Blaschke factor** of parameter a is the transformation

$$\varphi_a(z) = \frac{z - a}{1 - \bar{a}z}.$$

It is a Möbius transformation in the sense of Definition 6.4, associated with the matrix $\begin{pmatrix} 1 & -a \\ -\bar{a} & 1 \end{pmatrix}$ of determinant $1 - |a|^2 \neq 0$; its only pole is $z = 1/\bar{a}$ (if $a \neq 0$), of modulus $1/|a| > 1$, so φ_a is holomorphic on an open set containing $\overline{\mathbb{D}}$. For $a = 0$, $\varphi_0 = \text{id}$.

Lemma 15.10: Fundamental identity and properties of the Blaschke factor. Let $a \in \mathbb{D}$. Then:

(i) for every $z \in \mathbb{C}$ with $\bar{a}z \neq 1$ the **fundamental identity** holds:

$$|1 - \bar{a}z|^2 - |z - a|^2 = (1 - |a|^2)(1 - |z|^2), \quad \text{i.e.} \quad 1 - |\varphi_a(z)|^2 = \frac{(1 - |a|^2)(1 - |z|^2)}{|1 - \bar{a}z|^2};$$

(ii) φ_a maps $\mathbb{T}$ into $\mathbb{T}$, $\mathbb{D}$ into $\mathbb{D}$, and the exterior of the disk into the exterior;

- (iii) $\varphi_{-a} \circ \varphi_a = \varphi_a \circ \varphi_{-a} = \text{id}$; in particular $\varphi_a : \mathbb{D} \rightarrow \mathbb{D}$ is bijective with inverse φ_{-a} , and both φ_a and its inverse are holomorphic on $\mathbb{D}$;
(iv) $\varphi_a(a) = 0$, $\varphi_a(0) = -a$, and

$$\varphi'_a(z) = \frac{1 - |a|^2}{(1 - \bar{a}z)^2}, \quad \varphi'_a(0) = 1 - |a|^2, \quad \varphi'_a(a) = \frac{1}{1 - |a|^2}.$$

Proof. Step 1 — identity (i). Using $|w|^2 = w\bar{w}$ and $\overline{1 - \bar{a}z} = 1 - a\bar{z}$:

$$|1 - \bar{a}z|^2 = (1 - \bar{a}z)(1 - a\bar{z}) = 1 - a\bar{z} - \bar{a}z + |a|^2|z|^2,$$

$$|z - a|^2 = (z - a)(\bar{z} - \bar{a}) = |z|^2 - \bar{a}z - a\bar{z} + |a|^2.$$

Subtracting, the terms $-a\bar{z}$ and $-\bar{a}z$ cancel and what remains is

$$|1 - \bar{a}z|^2 - |z - a|^2 = 1 + |a|^2|z|^2 - |z|^2 - |a|^2 = (1 - |z|^2) - |a|^2(1 - |z|^2) = (1 - |a|^2)(1 - |z|^2).$$

Dividing by $|1 - \bar{a}z|^2 > 0$ gives the second form, since $|\varphi_a(z)|^2 = |z - a|^2 / |1 - \bar{a}z|^2$.

Step 2 — (ii). Since $|a| < 1$, the factor $1 - |a|^2$ is strictly positive. By (i), the sign of $1 - |\varphi_a(z)|^2$ is that of $1 - |z|^2$: hence $|z| < 1 \Rightarrow |\varphi_a(z)| < 1$, $|z| = 1 \Rightarrow |\varphi_a(z)| = 1$, $|z| > 1$ (and $\bar{a}z \neq 1$) $\Rightarrow |\varphi_a(z)| > 1$.

Step 3 — (iii). A direct computation: for z with $\bar{a}z \neq 1$,

$$\varphi_{-a}(\varphi_a(z)) = \frac{\frac{z-a}{1-\bar{a}z} + a}{1 + \bar{a}\frac{z-a}{1-\bar{a}z}} = \frac{(z-a) + a(1-\bar{a}z)}{(1-\bar{a}z) + \bar{a}(z-a)} = \frac{z-a+a-|a|^2z}{1-\bar{a}z+\bar{a}z-|a|^2} = \frac{z(1-|a|^2)}{1-|a|^2} = z,$$

where numerator and denominator were multiplied by $1 - \bar{a}z \neq 0$. Swapping a with $-a$ gives the other composition. By (ii), both maps send $\mathbb{D}$ into $\mathbb{D}$, hence the restriction of φ_a to $\mathbb{D}$ is a bijection of $\mathbb{D}$ with inverse $\varphi_{-a}|_{\mathbb{D}}$; both are holomorphic on $\mathbb{D}$ because their poles $1/\bar{a}$ and $-1/\bar{a}$ have modulus > 1 .

Step 4 — (iv). $\varphi_a(a) = \frac{a-a}{1-|a|^2} = 0$ and $\varphi_a(0) = \frac{-a}{1} = -a$. For the derivative, by the quotient rule,

$$\varphi'_a(z) = \frac{1 \cdot (1 - \bar{a}z) - (z - a)(-\bar{a})}{(1 - \bar{a}z)^2} = \frac{1 - \bar{a}z + \bar{a}z - |a|^2}{(1 - \bar{a}z)^2} = \frac{1 - |a|^2}{(1 - \bar{a}z)^2}.$$

Evaluating at $z = 0$ gives $1 - |a|^2$; evaluating at $z = a$, the denominator equals $(1 - |a|^2)^2$ and the quotient $1/(1 - |a|^2)$. $\square$

Remark 15.16: What is inherited from Chapter 6. Lemma 15.10 was proved directly, with identity (i), and uses nothing from Chapter 6. It is nonetheless useful to know that φ_a fits fully into that picture: it is a Möbius transformation (Definition 6.4), hence a bijection of $\hat{\mathbb{C}}$ belonging to the Möbius group (Proposition 6.7), and it sends generalized circles to generalized circles (Theorem 6.6) — which gives a second proof of point (ii): $\varphi_a(\mathbb{T})$ is a generalized circle contained in $\mathbb{T}$ by Step 2, and a generalized circle contained in a circle coincides with it; then φ_a , being a homeomorphism of $\hat{\mathbb{C}}$, permutes the two connected components of $\hat{\mathbb{C}} \setminus \mathbb{T}$, and since $\varphi_a(a) = 0 \in \mathbb{D}$ it sends $\mathbb{D}$ into $\mathbb{D}$. The composition $\varphi_{-a} \circ \varphi_a = \text{id}$ can also be read as a product of matrices: $\begin{pmatrix} 1 & a \\ \bar{a} & 1 \end{pmatrix} \begin{pmatrix} 1 & -a \\ -\bar{a} & 1 \end{pmatrix} = (1 - |a|^2) \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$, and scalar matrices are the kernel of the homomorphism Ψ of Proposition 6.7.

Definition 15.5: Automorphism of the disk. An **automorphism** of the unit disk is a function $f : \mathbb{D} \rightarrow \mathbb{D}$ that is holomorphic, bijective, and whose inverse f^{-1} is holomorphic. The set of automorphisms is denoted $\text{Aut}(\mathbb{D})$: under composition it is a group (the composition of holomorphic bijections with holomorphic inverse is again such a map, the identity belongs to it, and the inverse of an automorphism is an automorphism by definition).

Theorem 15.12: The automorphisms of the disk are exactly the rotated Blaschke factors. A function $f : \mathbb{D} \rightarrow \mathbb{D}$ is an automorphism of the disk if and only if there exist $\theta \in \mathbb{R}$ and $a \in \mathbb{D}$ such that

$$f(z) = e^{i\theta} \varphi_a(z) = e^{i\theta} \frac{z - a}{1 - \bar{a}z} \quad \text{for every } z \in \mathbb{D}.$$

Moreover a is uniquely determined by f (it is $a = f^{-1}(0)$) and θ is determined modulo 2π .

Proof. **Step 1 — every map of that form is an automorphism.** The rotation $r_\theta(w) = e^{i\theta}w$ is holomorphic, sends $\mathbb{D}$ into $\mathbb{D}$ (preserving the modulus), and is bijective with inverse $r_{-\theta}$, also holomorphic: it is an automorphism. By Lemma 15.10(ii)–(iii), so is φ_a . The composition $r_\theta \circ \varphi_a$ is therefore an automorphism (Definition 15.5).

Step 2 — reduction to the case $f(0) = 0$. Let $f \in \text{Aut}(\mathbb{D})$ and set $a = f^{-1}(0) \in \mathbb{D}$. Consider

$$g = f \circ \varphi_{-a} : \mathbb{D} \rightarrow \mathbb{D}.$$

This is an automorphism (composition of automorphisms) and $g(0) = f(\varphi_{-a}(0)) = f(a) = 0$, because $\varphi_{-a}(0) = \frac{0+a}{1+0} = a$ by Lemma 15.10(iv) applied to $-a$.

Step 3 — Schwarz in both directions. g is holomorphic from $\mathbb{D}$ to $\mathbb{D}$ with $g(0) = 0$: by Lemma 15.9, $|g(z)| \leq |z|$ for every $z \in \mathbb{D}$. Also g^{-1} is holomorphic from $\mathbb{D}$ to $\mathbb{D}$ with $g^{-1}(0) = 0$ (because $g(0) = 0$ and g is bijective): hence $|g^{-1}(w)| \leq |w|$ for every $w \in \mathbb{D}$. Setting $w = g(z)$ in the second inequality,

$$|z| = |g^{-1}(g(z))| \leq |g(z)|.$$

Together with the first, $|g(z)| = |z|$ for every $z \in \mathbb{D}$.

Step 4 — the equality case. Choosing any $z_0 \in \mathbb{D} \setminus \{0\}$ gives $|g(z_0)| = |z_0|$: by the equality case of Lemma 15.9 there is λ with $|\lambda| = 1$ and $g(z) = \lambda z$. Writing $\lambda = e^{i\theta}$ (possible because every number of modulus 1 is an imaginary exponential, Volume II, Chapter 3),

$$g = r_\theta.$$

Step 5 — reassembling. From $g = f \circ \varphi_{-a}$ and $\varphi_{-a} \circ \varphi_a = \text{id}$ (Lemma 15.10(iii)) it follows that

$$f = f \circ \varphi_{-a} \circ \varphi_a = g \circ \varphi_a = r_\theta \circ \varphi_a, \quad \text{i.e.} \quad f(z) = e^{i\theta} \frac{z - a}{1 - \bar{a}z}.$$

Step 6 — uniqueness. If $e^{i\theta} \varphi_a = e^{i\theta'} \varphi_{a'}$ on $\mathbb{D}$, evaluating at $z = a$ gives $0 = e^{i\theta'} \varphi_{a'}(a)$, hence $\varphi_{a'}(a) = 0$, i.e. $a = a'$ (the only zero of $\varphi_{a'}$ is a'). Then $e^{i\theta} \varphi_a = e^{i\theta'} \varphi_a$, and evaluating at a point where $\varphi_a \neq 0$ (for instance $z = 0$, where it equals $-a$, if $a \neq 0$; or $z = \frac{1}{2}$ if $a = 0$), one gets $e^{i\theta} = e^{i\theta'}$, i.e. $\theta \equiv \theta' \pmod{2\pi}$. $\square$

Corollary 15.7: The automorphisms fixing the center are the rotations. If $f \in \text{Aut}(\mathbb{D})$ and $f(0) = 0$, then $f(z) = e^{i\theta}z$ for some $\theta \in \mathbb{R}$. The subgroup of $\text{Aut}(\mathbb{D})$ of automorphisms fixing 0 is therefore isomorphic to the group $\mathbb{T}$ of Chapter 6 (Definition 6.1).

Proof. By Theorem 15.12, $f = e^{i\theta} \varphi_a$ with $a = f^{-1}(0)$. But $f(0) = 0$ implies $f^{-1}(0) = 0$, i.e. $a = 0$, and $\varphi_0 = \text{id}$: hence $f(z) = e^{i\theta} z$. The map $e^{i\theta} \mapsto r_\theta$ is a group isomorphism from $\mathbb{T}$ onto the subgroup in question: it is surjective by what was just shown, it is a homomorphism because $r_\theta \circ r_{\theta'} = r_{\theta+\theta'}$, and it is injective because $r_\theta = \text{id}$ forces $e^{i\theta} = 1$ (evaluate at $z = \frac{1}{2}$). $\square$

Figure 15.2: The Blaschke factor $\varphi_{1/2}(z) = \frac{z - \frac{1}{2}}{1 - \frac{1}{2}z}$. Coordinates computed by hand: $\varphi_{1/2}(\frac{1}{2}) = 0$; $\varphi_{1/2}(0) = \frac{-1/2}{1} = -\frac{1}{2}$; $\varphi_{1/2}(\frac{4}{5}) = \frac{4/5 - 1/2}{1 - 2/5} = \frac{3/10}{3/5} = \frac{1}{2}$; $\varphi_{1/2}(i) = \frac{i - \frac{1}{2}}{1 - \frac{i}{2}} = \frac{(i - \frac{1}{2})(1 + \frac{i}{2})}{1 + \frac{1}{4}} = \frac{-1 + \frac{3}{4}i}{5/4} = -\frac{4}{5} + \frac{3}{5}i$, of modulus $\sqrt{\frac{16}{25} + \frac{9}{25}} = 1$, consistent with Lemma 15.10(ii). $\checkmark$ The point i stays on the boundary, interior points stay interior, and a goes to the center.

Remark 15.17: Panorama: the Poincaré metric and the Schwarz–Pick lemma.

Theorem 15.12 says that $\text{Aut}(\mathbb{D})$ acts transitively on $\mathbb{D}$ (given a, b there is an automorphism sending a to b : it suffices to compose φ_a with φ_{-b}) and that the stabilizer of every point is a circle of rotations (Corollary 15.7). This is the starting point of the hyperbolic geometry of the disk: the Poincaré metric $ds = \frac{2|dz|}{1 - |z|^2}$ is, up to a constant, the unique Riemannian metric on $\mathbb{D}$ invariant under $\text{Aut}(\mathbb{D})$, and the Schwarz–Pick lemma states that every holomorphic $f : \mathbb{D} \rightarrow \mathbb{D}$ does not increase Poincaré distances, with equality if and only if $f \in \text{Aut}(\mathbb{D})$. These statements are not proved here and are given as a **panorama**: the source is Conway, *Functions of One Complex Variable I*, Chapter VI, §2 (“Schwarz’s Lemma”), where the equality case of Lemma 15.9 is used exactly as here.

15.7. Classification of isolated singularities

Definition 15.3 introduced isolated singularities without distinguishing their types. The Laurent expansion (Theorem 15.4) allows one to do so cleanly: everything depends on how many coefficients of the *principal part* are nonzero — none, finitely many, or infinitely many.

Definition 15.6: Removable singularity, pole, essential singularity. Let z_0 be an isolated singularity of f (Definition 15.3) and let $f(z) = \sum_{n \in \mathbb{Z}} a_n(z - z_0)^n$ be its Laurent expansion on the annulus $0 < |z - z_0| < r$ (Theorem 15.4). One says that z_0 is:

- a **removable singularity** if $a_n = 0$ for every $n < 0$;
- a **pole of order** $k \geq 1$ if $a_{-k} \neq 0$ and $a_n = 0$ for every $n < -k$ (for $k = 1$ one says *simple pole*, for $k = 2$ *double pole*);

- an **essential singularity** if $a_n \neq 0$ for infinitely many indices $n < 0$.

The three cases are mutually exclusive and exhaust all possibilities, because the set $\{n < 0 : a_n \neq 0\}$ is either empty, finite and nonempty, or infinite.

Theorem 15.13: Riemann's theorem on removable singularities. Let f be holomorphic on the annulus $A = \{0 < |z - z_0| < r\}$, and suppose that f is bounded in a punctured neighborhood of z_0 , i.e. that there exist $M \geq 0$ and $\rho_0 \in (0, r)$ with $|f(z)| \leq M$ for $0 < |z - z_0| \leq \rho_0$. Then z_0 is a removable singularity and f extends uniquely to a function holomorphic on the whole disk $D(z_0, r)$.

Proof. Step 1 — the negative coefficients tend to zero. By Theorem 15.4 (with $r_1 = 0$, $r_2 = r$), for every $\rho \in (0, r)$

$$a_n = \frac{1}{2\pi i} \oint_{|\zeta - z_0| = \rho} \frac{f(\zeta)}{(\zeta - z_0)^{n+1}} d\zeta,$$

and the value does not depend on ρ . Let $0 < \rho \leq \rho_0$. On the circle we have $|f| \leq M$ and $|\zeta - z_0|^{n+1} = \rho^{n+1}$, hence by the ML estimate (Lemma 15.2), with length $2\pi\rho$,

$$|a_n| \leq \frac{1}{2\pi} \cdot \frac{M}{\rho^{n+1}} \cdot 2\pi\rho = \frac{M}{\rho^n} = M\rho^{|n|} \quad \text{for } n < 0.$$

Step 2 — letting ρ tend to zero. For $n < 0$ we have $|n| \geq 1$ and $M\rho^{|n|} \rightarrow 0$ as $\rho \rightarrow 0^+$, while a_n does not depend on ρ : hence $a_n = 0$ for every $n < 0$. The singularity is removable.

Step 3 — the extension. What remains is $f(z) = \sum_{n \geq 0} a_n(z - z_0)^n$ for $0 < |z - z_0| < r$. A power series that converges at every point of a punctured disk also converges at the center (where it equals a_0) and has radius of convergence $\geq r$: it defines a function $\tilde{f}$ holomorphic on $D(z_0, r)$ that agrees with f away from the center. Uniqueness of the extension follows from continuity: two continuous extensions that agree on the punctured disk also agree at z_0 , which is an accumulation point of it. $\square$

Theorem 15.14: Characterization of poles. Let z_0 be an isolated singularity of f , holomorphic on $\{0 < |z - z_0| < r\}$, and let $k \geq 1$ be an integer. The following are equivalent:

(a) z_0 is a pole of order k ;

(b) there exists g holomorphic on $D(z_0, r)$ with $g(z_0) \neq 0$ and $f(z) = \frac{g(z)}{(z - z_0)^k}$ for $0 < |z - z_0| < r$;

(c) the limit $\lim_{z \rightarrow z_0} (z - z_0)^k f(z)$ exists, is finite, and is nonzero.

Moreover z_0 is a pole (of some order) if and only if $\lim_{z \rightarrow z_0} |f(z)| = +\infty$.

Proof. Step 1 — (a) $\Rightarrow$ (b). From the Laurent expansion with $a_n = 0$ for $n < -k$ and $a_{-k} \neq 0$:

$$(z - z_0)^k f(z) = \sum_{n \geq -k} a_n (z - z_0)^{n+k} = \sum_{m \geq 0} a_{m-k} (z - z_0)^m =: g(z),$$

a power series convergent for $0 < |z - z_0| < r$ and hence, as in Step 3 of Theorem 15.13, on the whole of $D(z_0, r)$. It defines g holomorphic with $g(z_0) = a_{-k} \neq 0$.

Step 2 — (b) $\Rightarrow$ (c). As $z \rightarrow z_0$, $(z - z_0)^k f(z) = g(z) \rightarrow g(z_0) \neq 0$, finite, by continuity of g .

Step 3 — (c) $\Rightarrow$ (a). Let $L = \lim_{z \rightarrow z_0} (z - z_0)^k f(z) \neq 0$, finite, and set $h(z) = (z - z_0)^k f(z)$ for $0 < |z - z_0| < r$. Having a finite limit at z_0 , h is bounded in a punctured neighborhood; by Theorem 15.13 it extends to a function holomorphic on $D(z_0, r)$ with $h(z_0) = L \neq 0$.

Expanding $h(z) = \sum_{m \geq 0} b_m(z - z_0)^m$ (Theorem 15.6) with $b_0 = L \neq 0$, one gets for $0 < |z - z_0|$,

$$f(z) = \frac{h(z)}{(z - z_0)^k} = \sum_{m \geq 0} b_m(z - z_0)^{m-k} = \sum_{n \geq -k} b_{n+k}(z - z_0)^n.$$

By uniqueness of the Laurent expansion (Theorem 15.4, Step 5), we get $a_n = b_{n+k}$, hence $a_n = 0$ for $n < -k$ and $a_{-k} = b_0 = L \neq 0$: a pole of order k .

Step 4 — pole $\Rightarrow$ infinite modulus. If z_0 is a pole of order k , by (b) we have $f = g/(z - z_0)^k$ with g continuous and $g(z_0) \neq 0$; there is $\delta > 0$ with $|g(z)| \geq |g(z_0)|/2 > 0$ for $|z - z_0| < \delta$, hence

$$|f(z)| \geq \frac{|g(z_0)|}{2|z - z_0|^k} \xrightarrow{z \rightarrow z_0} +\infty.$$

Step 5 — infinite modulus $\Rightarrow$ pole. If $|f(z)| \rightarrow +\infty$, there is $\delta \in (0, r)$ such that $|f(z)| \geq 1$ for $0 < |z - z_0| < \delta$; in particular f does not vanish there, and $u = 1/f$ is holomorphic on $\{0 < |z - z_0| < \delta\}$ with $|u| \leq 1$. By Theorem 15.13, u extends holomorphically to $D(z_0, \delta)$, and $u(z_0) = \lim_{z \rightarrow z_0} 1/f(z) = 0$. The function u is not identically zero (it equals $1/f \neq 0$ on the punctured disk), so by Theorem 15.9 there exist $k \geq 1$, $\rho' > 0$, and v holomorphic on $D(z_0, \rho')$ with $v(z_0) \neq 0$ and $u(z) = (z - z_0)^k v(z)$. Shrinking ρ' one may assume v never zero (by continuity), so that

$$f(z) = \frac{1}{u(z)} = \frac{1/v(z)}{(z - z_0)^k} \quad \text{for } 0 < |z - z_0| < \rho',$$

with $1/v$ holomorphic and nonzero at z_0 : this is condition (b), hence z_0 is a pole of order k . $\square$

Proposition 15.2: The formulas for the residue at a pole. Let ξ be a pole of order $k \geq 1$ of f . Then:

- (i) $\text{Res}(f, \xi) = \frac{1}{(k-1)!} \lim_{z \rightarrow \xi} \frac{d^{k-1}}{dz^{k-1}} [(z - \xi)^k f(z)]$;
- (ii) in particular, if the pole is simple ($k = 1$), $\text{Res}(f, \xi) = \lim_{z \rightarrow \xi} (z - \xi)f(z)$;
- (iii) if $f = p/q$ with p, q holomorphic in a neighborhood of ξ , $p(\xi) \neq 0$, $q(\xi) = 0$ and $q'(\xi) \neq 0$, then ξ is a simple pole and $\text{Res}(f, \xi) = \frac{p(\xi)}{q'(\xi)}$.

Proof. **Step 1 — (i).** By Theorem 15.14, Step 1, the function $g(z) = (z - \xi)^k f(z)$ extends holomorphically to a disk $D(\xi, r)$, where $g(z) = \sum_{m \geq 0} a_{m-k}(z - \xi)^m$, with a_n the Laurent coefficients of f . A power series is differentiated term by term (Theorem 15.6, Step 3) and the m -th coefficient equals $g^{(m)}(\xi)/m!$: taking $m = k - 1$,

$$a_{-1} = a_{(k-1)-k} = \frac{g^{(k-1)}(\xi)}{(k-1)!}.$$

Since $g^{(k-1)}$ is continuous at ξ (Theorem 15.6(ii)), the limit as $z \rightarrow \xi$ of the $(k-1)$ -th derivative of $(z - \xi)^k f(z)$ equals $g^{(k-1)}(\xi)$, and $\text{Res}(f, \xi) = a_{-1}$ by Definition 15.3.

Step 2 — (ii). This is (i) with $k = 1$: the 0-th derivative is the function itself and $0! = 1$, hence $\text{Res}(f, \xi) = \lim_{z \rightarrow \xi} (z - \xi)f(z)$.

Step 3 — (iii). From $q(\xi) = 0$ and $q'(\xi) \neq 0$ it follows, by Theorem 15.9, that ξ is a zero of q of order 1 (the order is the first index with a nonzero Taylor coefficient, and the coefficient of index 1 is $q'(\xi) \neq 0$): hence $q(z) = (z - \xi)q_1(z)$ with q_1 holomorphic and $q_1(\xi) = q'(\xi) \neq 0$. Then, for z near ξ and $z \neq \xi$,

$$(z - \xi)f(z) = (z - \xi) \frac{p(z)}{(z - \xi)q_1(z)} = \frac{p(z)}{q_1(z)} \xrightarrow{z \rightarrow \xi} \frac{p(\xi)}{q'(\xi)} \neq 0,$$

a finite, nonzero limit: by Theorem 15.14(c) with $k = 1$, ξ is a simple pole, and by (ii) the residue is exactly $p(\xi)/q'(\xi)$. $\square$

Theorem 15.15: Casorati–Weierstrass theorem. *Let z_0 be an essential singularity of f , holomorphic on $\{0 < |z - z_0| < r\}$. Then for every $\delta \in (0, r)$ the image $f(\{0 < |z - z_0| < \delta\})$ is dense in $\mathbb{C}$: for every $w_0 \in \mathbb{C}$ and every $\varepsilon > 0$ there is z with $0 < |z - z_0| < \delta$ and $|f(z) - w_0| < \varepsilon$.*

Proof. Step 1 — by contradiction. Suppose there exist $w_0 \in \mathbb{C}$, $\varepsilon > 0$ and $\delta \in (0, r)$ such that $|f(z) - w_0| \geq \varepsilon$ for every z with $0 < |z - z_0| < \delta$. Then $f - w_0$ does not vanish on that punctured disk and

$$h(z) = \frac{1}{f(z) - w_0}$$

is holomorphic there, with $|h(z)| \leq 1/\varepsilon$: it is bounded. By Theorem 15.13, h extends holomorphically to $D(z_0, \delta)$; let $c = h(z_0)$.

Step 2 — the case $c \neq 0$. By continuity h is nonzero on a whole disk $D(z_0, \delta')$, so $f - w_0 = 1/h$ is holomorphic on $D(z_0, \delta')$ and in particular bounded in a punctured neighborhood of z_0 . By Theorem 15.13 applied to f , the singularity would be removable: a contradiction, because z_0 is essential (Definition 15.6, the three cases being mutually exclusive).

Step 3 — the case $c = 0$. h is not identically zero, because it equals $1/(f - w_0) \neq 0$ on the punctured disk. By Theorem 15.9 there exist $k \geq 1$ and v holomorphic with $v(z_0) \neq 0$ and $h(z) = (z - z_0)^k v(z)$ on a disk $D(z_0, \delta'')$; shrinking the radius one may assume v never zero. Then

$$f(z) - w_0 = \frac{1}{h(z)} = \frac{1/v(z)}{(z - z_0)^k},$$

i.e. $f - w_0$ has a pole of order k at z_0 (Theorem 15.14(b)); and since f and $f - w_0$ differ by a constant, which does not alter the principal part of the Laurent expansion, f too would have a pole at z_0 : again a contradiction.

Step 4 — conclusion. Both cases are impossible, so the assumption for contradiction of Step 1 is false: the image is dense. $\square$

Remark 15.18: Panorama: Picard’s great theorem. *Theorem 15.15 says that near an essential singularity the function comes arbitrarily close to every complex value. Picard’s great theorem says much more: in every punctured neighborhood of an essential singularity the function attains every complex value, infinitely many times, with at most one exception. For $f(z) = e^{1/z}$ at $z_0 = 0$ the exception is $w = 0$, which $e^{1/z}$ never attains. This theorem is not proved here and is given as a **panorama**: the proof requires the modular function or Schottky’s theorem, and is found in Conway, Functions of One Complex Variable I, Chapter XII (“The Range of an Analytic Function”), and in Ahlfors, Chapter 8. What is proved here, Casorati–Weierstrass, is its elementary part and suffices for all uses in this treatise.*

Definition 15.7: Meromorphic function. Let $\Omega \subseteq \mathbb{C}$ be open. A function f is called **meromorphic** on Ω if there exists a set $P \subseteq \Omega$ with no accumulation points in Ω , such that f is holomorphic on $\Omega \setminus P$ and every point of P is a pole of f . The set P is the set of poles. By Corollary 15.4, $P \cap K$ is finite for every compact set $K \subseteq \Omega$: on a compact set the poles are finite in number.

Example 15.3: The three types, seen on three functions. All three functions have an isolated singularity at $z_0 = 0$.

(1) $f_1(z) = \frac{\sin z}{z}$: **removable**. From $\sin z = \sum_{j \geq 0} \frac{(-1)^j}{(2j+1)!} z^{2j+1}$ (Taylor series of the exponential combined as $\frac{e^{iz} - e^{-iz}}{2i}$), it follows that $f_1(z) = \sum_{j \geq 0} \frac{(-1)^j}{(2j+1)!} z^{2j} = 1 - \frac{z^2}{6} + \frac{z^4}{120} - \dots$: no negative powers. The extension gives $f_1(0) = 1$. Independent check: $|f_1(z)| \leq \frac{|\sin z|}{|z|}$ is bounded near 0, so Theorem 15.13 gives the same conclusion.

(2) $f_2(z) = \frac{e^z}{z^3}$: **pole of order 3**. From $e^z = \sum_{m \geq 0} z^m/m!$,

$$f_2(z) = \frac{1}{z^3} + \frac{1}{z^2} + \frac{1}{2z} + \frac{1}{6} + \frac{z}{24} + \dots,$$

a principal part with three terms, $a_{-3} = 1 \neq 0$: pole of order 3 and $\text{Res}(f_2, 0) = a_{-1} = \frac{1}{2}$. Independent check with Proposition 15.2(i), $k = 3$: $\frac{1}{2!} \lim_{z \rightarrow 0} \frac{d^2}{dz^2} [z^3 f_2(z)] = \frac{1}{2} \lim_{z \rightarrow 0} \frac{d^2}{dz^2} e^z = \frac{1}{2} e^0 = \frac{1}{2}$. ✓

(3) $f_3(z) = e^{1/z}$: **essential**. Substituting $w = 1/z$ into the series of the exponential, $f_3(z) = \sum_{m \geq 0} \frac{1}{m!} z^{-m}$: infinitely many nonzero negative coefficients. The residue is $a_{-1} = \frac{1}{1!} = 1$. Consistently with Theorem 15.15, approaching 0 along the positive real axis $f_3 \rightarrow +\infty$, along the negative real axis $f_3 \rightarrow 0$, and along the imaginary axis $f_3(it) = e^{-i/t}$ stays on the unit circle: no limit, and the image of every punctured neighborhood is dense.

15.8. Winding number, the argument principle, and Rouché's theorem

In Theorem 15.5 the factor $2\pi i$ appears before each residue because the contour is a circle traversed *once*. If the path winds n times, the factor becomes $2\pi in$: that integer is the *winding number*, and it is the same topological invariant built in Chapter 12 as the number of turns of a loop.

Definition 15.8: Winding number of a loop. Let $\gamma : [a, b] \rightarrow \mathbb{C}$ be a piecewise regular loop and $z_0 \in \mathbb{C} \setminus \gamma^*$. The **winding number** (or *turning number*) of γ about z_0 is the number

$$\text{Ind}_\gamma(z_0) = \frac{1}{2\pi i} \oint_\gamma \frac{dz}{z - z_0}.$$

The integral makes sense because $z \mapsto 1/(z - z_0)$ is continuous on γ^* , which does not contain z_0 .

Theorem 15.16: The index is an integer. Let γ be a piecewise regular loop and $z_0 \notin \gamma^*$. Then $\text{Ind}_\gamma(z_0) \in \mathbb{Z}$.

Proof. Step 1 — reparametrization and an auxiliary function. Up to the affine substitution $t \mapsto a + t(b - a)$, which does not change the integral (Definition 15.2), one may assume $\gamma : [0, 1] \rightarrow \mathbb{C}$ with $\gamma(0) = \gamma(1)$. The function $t \mapsto \frac{\gamma'(t)}{\gamma(t) - z_0}$ is piecewise continuous and bounded on $[0, 1]$: continuous where γ is of class C^1 , and with denominator of modulus $\geq \text{dist}(z_0, \gamma^*) > 0$ everywhere (the distance is positive because γ^* is compact and $z_0 \notin \gamma^*$). Set

$$h(t) = \int_0^t \frac{\gamma'(u)}{\gamma(u) - z_0} du,$$

which is continuous on $[0, 1]$, with $h(0) = 0$ and $h(1) = \oint_{\gamma} \frac{dz}{z - z_0}$, and differentiable with $h'(t) = \frac{\gamma'(t)}{\gamma(t) - z_0}$ at every point except at most the finitely many where γ' jumps (fundamental theorem of calculus).

Step 2 — a constant function. Set $\varphi(t) = (\gamma(t) - z_0)e^{-h(t)}$. It is continuous on $[0, 1]$ and differentiable away from the exceptional points, with

$$\varphi'(t) = \gamma'(t)e^{-h(t)} - (\gamma(t) - z_0)h'(t)e^{-h(t)} = \gamma'(t)e^{-h(t)} - (\gamma(t) - z_0)\frac{\gamma'(t)}{\gamma(t) - z_0}e^{-h(t)} = 0.$$

A function continuous on $[0, 1]$ with vanishing derivative except at finitely many points is constant: it is constant on each of the closed subintervals determined by the exceptional points (Lagrange's theorem applied to real and imaginary parts), and the values glue together by continuity at the endpoints. Hence $\varphi(1) = \varphi(0)$.

Step 3 — conclusion. Since $\gamma(1) = \gamma(0)$ and $h(0) = 0$,

$$(\gamma(0) - z_0)e^{-h(1)} = \gamma(0) - z_0,$$

and $\gamma(0) - z_0 \neq 0$: hence $e^{-h(1)} = 1$, i.e. $e^{h(1)} = 1$. Writing $h(1) = \sigma + i\tau$ with σ, τ real, from $1 = |e^{h(1)}| = e^{\sigma}$ it follows that $\sigma = 0$; and from $e^{i\tau} = 1$ it follows that $\tau \in 2\pi\mathbb{Z}$. Therefore $\text{Ind}_{\gamma}(z_0) = h(1)/(2\pi i) = \tau/(2\pi) \in \mathbb{Z}$. $\square$

Remark 15.19: The index is the winding number, and it is a degree. The proof just given retraces, for loops that are only piecewise regular, that of Theorem 12.6 of Chapter 12, which for loops of class C^1 establishes the equality

$$\text{Ind}_{\gamma}(z_0) = \frac{1}{2\pi i} \oint_{\gamma} \frac{dz}{z - z_0} = w(\gamma - z_0),$$

where w is the topological winding number of Definition 12.6, defined via the lifting of the exponential and invariant under homotopy (Theorem 12.5). In particular the index of the unit circle traversed n times, i.e. of the loop $t \mapsto e^{2\pi i n t}$, equals n : it is the degree of the map $z \mapsto z^n$ in the sense of Definition 12.8, and the classification of maps $S^1 \rightarrow S^1$ by degree (Theorem 12.8) says that this integer determines the loop up to homotopy. This is the bridge between the analytic computation of this chapter and the topology of Chapter 12: the integer coefficient multiplying the residues is not a computational trick, it is an invariant.

Proposition 15.3: Index of a circle. Let γ be the circle $|\zeta - z_0| = r$ traversed once counterclockwise. Then

$$\text{Ind}_{\gamma}(z) = \begin{cases} 1, & |z - z_0| < r, \\ 0, & |z - z_0| > r. \end{cases}$$

Proof. The interior case is Step 3 of the Alternative proof of Theorem 15.3: the geometric expansion of $1/(\zeta - z)$ in powers of $(z - z_0)/(\zeta - z_0)$ converges uniformly on the circle and, integrated term by term with Lemma 15.5, leaves only the term $2\pi i$; dividing by $2\pi i$ gives 1. The exterior case is Observation 15.7: the expansion in the reciprocal variable produces only exponents ≥ 0 , all with vanishing integral, and the index equals 0. $\square$

Proposition 15.4: Index of the D-shaped contour. Let $R > 1$ and let γ_R be the loop obtained by first traversing the segment $[-R, R]$ of the real axis, from $-R$ to R , and then

the arc $\alpha_R(\theta) = Re^{i\theta}$, $\theta \in [0, \pi]$. Then

$$\text{Ind}_{\gamma_R}(i) = 1, \quad \text{Ind}_{\gamma_R}(-i) = 0.$$

Proof. Step 1 — the contribution of the segment. With $z = x$ real and $\frac{1}{x \mp i} = \frac{x \pm i}{x^2 + 1}$,

$$\int_{-R}^R \frac{dx}{x - i} = \int_{-R}^R \frac{x dx}{x^2 + 1} + i \int_{-R}^R \frac{dx}{x^2 + 1} = 0 + 2i \arctan R,$$

because the first integrand is odd on a symmetric interval and $\int_{-R}^R \frac{dx}{x^2 + 1} = 2 \arctan R$. Similarly $\int_{-R}^R \frac{dx}{x + i} = -2i \arctan R$.

Step 2 — the contribution of the arc: expanding the kernel. Let $c = \pm i$, with $|c| = 1 < R$. For $|z| = R$ we have $|c/z| = 1/R < 1$, hence

$$\frac{1}{z - c} = \frac{1}{z} \cdot \frac{1}{1 - c/z} = \sum_{n=0}^{\infty} \frac{c^n}{z^{n+1}},$$

a series uniformly convergent on $|z| = R$ because the modulus of the n -th term equals R^{-n-1} and $\sum_n R^{-n-1} < \infty$. One can integrate term by term over the arc.

Step 3 — the integrals of the powers over the arc. With $z = Re^{i\theta}$, $dz = iRe^{i\theta} d\theta$ and $\theta \in [0, \pi]$:

$$\int_{\alpha_R} \frac{dz}{z^{n+1}} = \int_0^\pi R^{-n-1} e^{-i(n+1)\theta} iRe^{i\theta} d\theta = iR^{-n} \int_0^\pi e^{-in\theta} d\theta.$$

For $n = 0$ the integral equals π and the contribution is $i\pi$. For $n \geq 1$,

$$\int_0^\pi e^{-in\theta} d\theta = \left[\frac{e^{-in\theta}}{-in} \right]_0^\pi = \frac{e^{-in\pi} - 1}{-in} = \frac{(-1)^n - 1}{-in},$$

so the contribution is $iR^{-n} \cdot \frac{(-1)^n - 1}{-in} = R^{-n} \frac{1 - (-1)^n}{n}$, which is zero for n even and equals $\frac{2}{nR^n}$ for n odd.

Step 4 — summing the series. Setting $n = 2k + 1$ and using $c^{2k+1} = c(c^2)^k = c(-1)^k$ (because $c^2 = (\pm i)^2 = -1$),

$$\int_{\alpha_R} \frac{dz}{z - c} = i\pi + \sum_{k=0}^{\infty} c(-1)^k \cdot \frac{2}{(2k+1)R^{2k+1}} = i\pi + 2c \sum_{k=0}^{\infty} \frac{(-1)^k}{2k+1} \left(\frac{1}{R}\right)^{2k+1} = i\pi + 2c \arctan \frac{1}{R},$$

where the Gregory–Leibniz series $\arctan x = \sum_{k \geq 0} \frac{(-1)^k}{2k+1} x^{2k+1}$ was used, valid for $|x| \leq 1$ and here applied to $x = 1/R \in (0, 1)$.

Step 5 — the arctangent identity. For $R > 0$, $\arctan R + \arctan \frac{1}{R} = \frac{\pi}{2}$: the derivative with respect to R of the sum is $\frac{1}{1+R^2} + \frac{-1/R^2}{1+1/R^2} = \frac{1}{1+R^2} - \frac{1}{R^2+1} = 0$, so the sum is constant on $(0, +\infty)$, and at $R = 1$ it equals $\frac{\pi}{4} + \frac{\pi}{4} = \frac{\pi}{2}$.

Step 6 — the two indices. For $c = i$ (Steps 1 and 4):

$$\oint_{\gamma_R} \frac{dz}{z - i} = 2i \arctan R + i\pi + 2i \arctan \frac{1}{R} = i \left(2 \cdot \frac{\pi}{2} + \pi \right) = 2\pi i,$$

hence $\text{Ind}_{\gamma_R}(i) = 1$. For $c = -i$:

$$\oint_{\gamma_R} \frac{dz}{z + i} = -2i \arctan R + i\pi - 2i \arctan \frac{1}{R} = i \left(\pi - 2 \cdot \frac{\pi}{2} \right) = 0,$$

hence $\text{Ind}_{\gamma_R}(-i) = 0$. Both values are integers, consistently with Theorem 15.16. ✓ □

Figure 15.3: The D -shaped contour of Proposition 15.4: segment $[-R, R]$ plus semicircle α_R of radius $R > 1$, traversed counterclockwise. The point i (ordinate 1) is enclosed, the point $-i$ is outside. In the drawing $R = 3$ and the vertex of the arc is $(0, 3)$; the point $-i$ is drawn at $(0, -0.5)$ so as not to fall outside the figure, but in the complex plane it has ordinate -1 : in either case it lies in the lower half-plane, which the contour never touches.

Lemma 15.11: The principal logarithm and loops in the slit plane. Let $\Omega_+ = \mathbb{C} \setminus (-\infty, 0]$ be the plane with the nonpositive real half-line removed. For $w = x + iy \in \Omega_+$, set

$$\operatorname{Arg} w = 2 \arctan \frac{y}{|w| + x} \in (-\pi, \pi), \quad \operatorname{Log} w = \ln |w| + i \operatorname{Arg} w.$$

Then Log is holomorphic on Ω_+ with $\operatorname{Log}'(w) = 1/w$, and consequently

$$\oint_{\eta} \frac{dw}{w} = 0$$

for every piecewise regular loop η contained in Ω_+ .

Proof. Step 1 — the formula is well-defined and continuous. For $w \in \Omega_+$ we have $|w| + x > 0$: indeed $|w| \geq |x| \geq -x$ with equality only if $y = 0$ and $x \leq 0$, a case that is excluded. Hence the formula for Arg defines a continuous function on Ω_+ with values in $(-\pi, \pi)$, and Log is continuous.

Step 2 — Log inverts the exponential. Setting $\theta = \operatorname{Arg} w$, from the bisection formula $\tan \frac{\theta}{2} = \frac{\sin \theta}{1 + \cos \theta}$ and from $\cos \theta = x/|w|$, $\sin \theta = y/|w|$ (polar form, Volume II, Chapter 3), it follows that

$$\tan \frac{\theta}{2} = \frac{y/|w|}{1 + x/|w|} = \frac{y}{|w| + x},$$

i.e. θ is exactly the argument of w in $(-\pi, \pi)$, and $e^{\operatorname{Log} w} = e^{\ln |w|} e^{i\theta} = |w|(\cos \theta + i \sin \theta) = w$. Moreover Log is injective, because the modulus composed with the argument already is: from $\operatorname{Log} w_1 = \operatorname{Log} w_2$ it follows that $w_1 = e^{\operatorname{Log} w_1} = e^{\operatorname{Log} w_2} = w_2$.

Step 3 — differentiability. Let $w_0 \in \Omega_+$ and $w \rightarrow w_0$ in Ω_+ , $w \neq w_0$. Setting $u = \operatorname{Log} w$ and $u_0 = \operatorname{Log} w_0$, we have $u \rightarrow u_0$ by continuity (Step 1) and $u \neq u_0$ by injectivity (Step 2). Then

$$\frac{\operatorname{Log} w - \operatorname{Log} w_0}{w - w_0} = \frac{u - u_0}{e^u - e^{u_0}} = \left(\frac{e^u - e^{u_0}}{u - u_0} \right)^{-1} \xrightarrow{w \rightarrow w_0} \frac{1}{e^{u_0}} = \frac{1}{w_0},$$

because the difference quotient of the exponential tends to $e^{u_0} \neq 0$ (the exponential function is holomorphic with derivative itself, being the sum of the power series $\sum z^m/m!$). Hence Log is holomorphic with derivative $1/w$, which is continuous on Ω_+ .

Step 4 — loops. By Lemma 15.3 applied to $F = \operatorname{Log}$, $g = 1/w$ on Ω_+ , we get $\oint_{\eta} dw/w = 0$ for every loop η in Ω_+ . $\square$

Theorem 15.17: Residue theorem on a convex open set. Let $\Omega \subseteq \mathbb{C}$ be open and convex, let $\xi_1, \dots, \xi_p \in \Omega$ be distinct points, and let f be holomorphic on $\Omega \setminus \{\xi_1, \dots, \xi_p\}$. Then for every piecewise regular loop γ contained in $\Omega \setminus \{\xi_1, \dots, \xi_p\}$,

$$\frac{1}{2\pi i} \oint_{\gamma} f(z) dz = \sum_{j=1}^p \text{Ind}_{\gamma}(\xi_j) \text{Res}(f, \xi_j).$$

Proof. **Step 1 — the principal parts are entire functions away from their pole.** For each j choose $\delta_j > 0$ such that $D(\xi_j, \delta_j) \subseteq \Omega$ and $\xi_l \notin D(\xi_j, \delta_j)$ for $l \neq j$. On the annulus $0 < |z - \xi_j| < \delta_j$ we have the Laurent expansion $f(z) = \sum_{n \in \mathbb{Z}} a_n^{(j)} (z - \xi_j)^n$ (Theorem 15.4). Set

$$P_j(z) = \sum_{m=1}^{\infty} a_{-m}^{(j)} (z - \xi_j)^{-m}.$$

In the variable $w = 1/(z - \xi_j)$ this is the power series $\sum_{m \geq 1} a_{-m}^{(j)} w^m$, which converges for $0 < |z - \xi_j| < \delta_j$, i.e. for $|w| > 1/\delta_j$: it converges, therefore, at points of arbitrarily large modulus, and since the set of convergence of a power series is a disk (if it converges at w_1 it converges absolutely for $|w| < |w_1|$), its radius of convergence is $+\infty$. Hence P_j is defined and holomorphic on $\mathbb{C} \setminus \{\xi_j\}$, with uniform convergence on every set $\{|z - \xi_j| \geq s\}$, $s > 0$.

Step 2 — the difference is holomorphic on the whole of Ω . Set $g = f - \sum_{j=1}^p P_j$ on $\Omega \setminus \{\xi_1, \dots, \xi_p\}$. Near ξ_j , for $0 < |z - \xi_j| < \delta_j$,

$$f(z) - P_j(z) = \sum_{n \geq 0} a_n^{(j)} (z - \xi_j)^n,$$

a convergent power series, which extends to a function holomorphic on $D(\xi_j, \delta_j)$; the other P_l ($l \neq j$) are holomorphic in a neighborhood of ξ_j by Step 1. Hence g extends to a function $\tilde{g}$ holomorphic on the whole of Ω .

Step 3 — Cauchy on the convex set. Ω is open and convex and $\tilde{g}$ is holomorphic there: by Corollary 15.1, $\oint_{\gamma} \tilde{g} = 0$. Since γ avoids the points ξ_j , on γ^* we have $\tilde{g} = f - \sum_j P_j$, and hence

$$\oint_{\gamma} f(z) dz = \sum_{j=1}^p \oint_{\gamma} P_j(z) dz.$$

Step 4 — the integral of a principal part. Let $s_j = \text{dist}(\xi_j, \gamma^*) > 0$. On γ^* the series defining P_j converges uniformly (Step 1), hence it can be integrated term by term:

$$\oint_{\gamma} P_j(z) dz = \sum_{m=1}^{\infty} a_{-m}^{(j)} \oint_{\gamma} (z - \xi_j)^{-m} dz.$$

For $m \geq 2$ the function $(z - \xi_j)^{-m}$ is the derivative of $\frac{(z - \xi_j)^{1-m}}{1-m}$, holomorphic on $\mathbb{C} \setminus \{\xi_j\}$ with continuous derivative; since γ is a loop in $\mathbb{C} \setminus \{\xi_j\}$, Lemma 15.3 gives a vanishing integral. For $m = 1$, by Definition 15.8, $\oint_{\gamma} \frac{dz}{z - \xi_j} = 2\pi i \text{Ind}_{\gamma}(\xi_j)$. Hence

$$\oint_{\gamma} P_j(z) dz = 2\pi i a_{-1}^{(j)} \text{Ind}_{\gamma}(\xi_j) = 2\pi i \text{Res}(f, \xi_j) \text{Ind}_{\gamma}(\xi_j),$$

having used Definition 15.3. Summing over j and dividing by $2\pi i$ gives the claim. $\square$

Theorem 15.18: Argument principle. Let $\Omega \subseteq \mathbb{C}$ be open and convex and let f be meromorphic on Ω (Definition 15.7), not identically zero, with a finite number of zeros $\alpha_1, \dots, \alpha_M$ of multiplicities $m_1, \dots, m_M$ and a finite number of poles $\beta_1, \dots, \beta_N$ of orders $k_1, \dots, k_N$. Let γ be a piecewise regular loop in Ω passing through no zero and no pole. Then

$$\frac{1}{2\pi i} \oint_{\gamma} \frac{f'(z)}{f(z)} dz = \sum_{j=1}^M m_j \operatorname{Ind}_{\gamma}(\alpha_j) - \sum_{l=1}^N k_l \operatorname{Ind}_{\gamma}(\beta_l).$$

Proof. **Step 1 — f'/f and its poles.** The function f'/f is holomorphic on Ω minus the zeros and poles of f , which are finite in number.

Step 2 — at a zero. Let α be a zero of multiplicity m . By Theorem 15.9 there is g holomorphic on a disk $D(\alpha, \rho)$, with $g(\alpha) \neq 0$, such that $f(z) = (z - \alpha)^m g(z)$; shrinking ρ one may assume g never zero. Differentiating (product rule), $f'(z) = m(z - \alpha)^{m-1} g(z) + (z - \alpha)^m g'(z)$, so for $z \neq \alpha$

$$\frac{f'(z)}{f(z)} = \frac{m(z - \alpha)^{m-1} g + (z - \alpha)^m g'}{(z - \alpha)^m g} = \frac{m}{z - \alpha} + \frac{g'(z)}{g(z)}.$$

The second term is holomorphic on $D(\alpha, \rho)$; the first is the principal part. Hence α is a simple pole of f'/f with $\operatorname{Res}(f'/f, \alpha) = m$ (Definition 15.3, read off the Laurent expansion: the principal part is $m(z - \alpha)^{-1}$).

Step 3 — at a pole. Let β be a pole of order k . By Theorem 15.14(b) there is h holomorphic on $D(\beta, \rho)$ with $h(\beta) \neq 0$ and $f(z) = h(z)(z - \beta)^{-k}$; shrinking ρ , h is never zero. Differentiating, $f'(z) = h'(z)(z - \beta)^{-k} - k h(z)(z - \beta)^{-k-1}$, hence

$$\frac{f'(z)}{f(z)} = \frac{h'(z)}{h(z)} - \frac{k}{z - \beta},$$

and β is a simple pole of f'/f with residue $-k$.

Step 4 — the residue theorem. Applying Theorem 15.17 to the function f'/f on Ω , with isolated singularities $\alpha_1, \dots, \alpha_M, \beta_1, \dots, \beta_N$ and with the loop γ avoiding all of them,

$$\frac{1}{2\pi i} \oint_{\gamma} \frac{f'}{f} = \sum_j \operatorname{Ind}_{\gamma}(\alpha_j) m_j + \sum_l \operatorname{Ind}_{\gamma}(\beta_l) (-k_l),$$

which is the claim. □

Corollary 15.8: Argument principle on a circle: zeros minus poles. Let f be meromorphic on an open set A containing $\overline{D}(z_0, r)$, with no zeros and no poles on the circle $|z - z_0| = r$. Let Z and P be the number of zeros and the number of poles of f interior to the circle, each counted with its own multiplicity (order). Then

$$\frac{1}{2\pi i} \oint_{|z-z_0|=r} \frac{f'(z)}{f(z)} dz = Z - P.$$

Proof. **Step 1 — a convex set with compact closure in A .** As in Step 1 of the Alternative proof of Theorem 15.3, one finds $R > r$ with $\overline{D}(z_0, R) \subset A$; set $R'' = \frac{r+R}{2}$ and $\Omega = D(z_0, R'')$, an open convex set with $\overline{\Omega} \subset A$ compact.

Step 2 — finiteness. The poles of f in $\overline{\Omega}$ are finite in number because the set of poles has no accumulation points in A (Definition 15.7) and $\overline{\Omega} \subset A$ is compact. As for the zeros: $\Omega = D(z_0, R'')$ is connected and f , being holomorphic and not identically zero on Ω minus its finitely many poles (it is nonzero on the circle $|z - z_0| = r$ by hypothesis), has finitely many

zeros in $\bar{\Omega}$ by Corollary 15.4. Hence the hypotheses of Theorem 15.18 are satisfied on Ω .

Step 3 — the indices. By Proposition 15.3, the index of the circle equals 1 at points with $|z - z_0| < r$ and 0 at points with $|z - z_0| > r$; on the circle there are neither zeros nor poles by hypothesis. Hence in the formula of Theorem 15.18 exactly the interior zeros and poles survive, with coefficient 1, giving $Z - P$. $\square$

Remark 15.20: Why it is called the “argument principle”. If γ is a loop avoiding zeros and poles, the image path $\eta = f \circ \gamma$ is a piecewise regular loop in $\mathbb{C} \setminus \{0\}$, with $\eta'(t) = f'(\gamma(t))\gamma'(t)$ (chain rule). Hence

$$\oint_{\gamma} \frac{f'(z)}{f(z)} dz = \int_a^b \frac{f'(\gamma(t))\gamma'(t)}{f(\gamma(t))} dt = \int_a^b \frac{\eta'(t)}{\eta(t)} dt = \oint_{\eta} \frac{dw}{w} = 2\pi i \operatorname{Ind}_{\eta}(0).$$

The left-hand side counts zeros minus poles; the right-hand side counts the turns that the image $f \circ \gamma$ makes about the origin, i.e. how many times the argument of $f(z)$ completes a full turn while z traces γ . In the language of Chapter 12 it is the degree of the loop $\eta/|\eta| : S^1 \rightarrow S^1$ (Definition 12.8).

Theorem 15.19: Rouché’s theorem. Let f and g be holomorphic on an open set containing $\overline{D(z_0, r)}$, and suppose

$$|f(z) - g(z)| < |f(z)| \quad \text{for every } z \text{ with } |z - z_0| = r.$$

Then f and g have the same number of zeros in $D(z_0, r)$, counted with multiplicity.

Proof. **Step 1 — neither f nor g vanishes on the circle.** On the circle, $|f(z)| > |f(z) - g(z)| \geq 0$ gives $f(z) \neq 0$; and $|g(z)| \geq |f(z)| - |f(z) - g(z)| > 0$ gives $g(z) \neq 0$.

Step 2 — the quotient lies in a disk not containing 0. By continuity, there is an open neighborhood U of the circle, contained in the original open set, on which f does not vanish; on U the function $h = g/f$ is holomorphic. For $|z - z_0| = r$,

$$|h(z) - 1| = \left| \frac{g(z) - f(z)}{f(z)} \right| = \frac{|f(z) - g(z)|}{|f(z)|} < 1,$$

hence $h(z) \in D(1, 1)$. Every $w \in D(1, 1)$ has $\operatorname{Re} w > 0$ (from $|w - 1| < 1$ it follows that $(\operatorname{Re} w - 1)^2 < 1$, i.e. $0 < \operatorname{Re} w < 2$), so $D(1, 1) \subset \Omega_+ = \mathbb{C} \setminus (-\infty, 0]$.

Step 3 — the image loop has zero index. Let γ be the circle $|z - z_0| = r$ and $\eta = h \circ \gamma$: it is a piecewise regular loop contained in $D(1, 1) \subset \Omega_+$. By Lemma 15.11, $\oint_{\eta} \frac{dw}{w} = 0$; and by the computation of Observation 15.20 (chain rule),

$$\oint_{\gamma} \frac{h'(z)}{h(z)} dz = \oint_{\eta} \frac{dw}{w} = 0.$$

Step 4 — separating the quotient. On U , where f and g do not vanish (shrinking U by continuity so that $g \neq 0$ too, by Step 1),

$$\frac{h'}{h} = \frac{(g/f)'}{g/f} = \frac{\frac{g'f - gf'}{f^2}}{\frac{g}{f}} = \frac{g'f - gf'}{fg} = \frac{g'}{g} - \frac{f'}{f}.$$

Integrating over $\gamma \subset U$ and using Step 3,

$$\oint_{\gamma} \frac{g'}{g} dz - \oint_{\gamma} \frac{f'}{f} dz = 0.$$

Step 5 — the argument principle. f and g are holomorphic, hence have no poles; by Corollary 15.8 applied to each, $\frac{1}{2\pi i} \oint_{\gamma} \frac{f'}{f} = Z_f$ and $\frac{1}{2\pi i} \oint_{\gamma} \frac{g'}{g} = Z_g$, the numbers of interior zeros with multiplicity. Step 4 gives $Z_g = Z_f$. $\square$

Corollary 15.9: Fundamental theorem of algebra, by the second route. Let $P(z) = c_n z^n + \cdots + c_0$ with $n \geq 1$ and $c_n \neq 0$. Setting

$$R = 1 + \frac{1}{|c_n|} \sum_{k=0}^{n-1} |c_k|,$$

the polynomial P has exactly n zeros in $D(0, R)$, counted with multiplicity, and none elsewhere in $\mathbb{C}$.

Proof. **Step 1 — the comparison on the circle $|z| = R$.** Take $f(z) = c_n z^n$ and $g = P$. Since $R \geq 1$, for $|z| = R$ and $0 \leq k \leq n-1$ we have $R^k \leq R^{n-1}$, hence

$$|f(z) - g(z)| = \left| \sum_{k=0}^{n-1} c_k z^k \right| \leq \sum_{k=0}^{n-1} |c_k| R^k \leq R^{n-1} \sum_{k=0}^{n-1} |c_k| = R^n \cdot \frac{1}{R} \sum_{k=0}^{n-1} |c_k|.$$

From $R > \frac{1}{|c_n|} \sum_{k < n} |c_k|$ it follows that $\frac{1}{R} \sum_{k < n} |c_k| < |c_n|$, hence $|f(z) - g(z)| < |c_n| R^n = |f(z)|$ on the circle.

Step 2 — Rouché. By Theorem 15.19, P and $c_n z^n$ have the same number of zeros in $D(0, R)$. The function $c_n z^n$ has the single zero $z = 0$, of multiplicity n (the first nonzero Taylor coefficient is the one of index n , Theorem 15.9): hence P has exactly n zeros in $D(0, R)$.

Step 3 — there are no others. For $|z| \geq R$, Step 1 gives $|P(z)| \geq |f(z)| - |f(z) - g(z)| > 0$: outside the disk P does not vanish. Since P has degree n and, by Corollary 15.2, factors into n linear factors, its zeros are exactly n , counted with multiplicity, all in $D(0, R)$. $\square$

15.9. Three real integrals computed with residues

The residue theorem turns the computation of certain real integrals into an algebraic computation: one chooses a closed contour, identifies the singularities it encloses, and sums the residues. Three such computations are carried out here — two over $\mathbb{R}$, one over $[0, 2\pi]$ — each checked by a *second, independent method* (a real substitution, a Weierstrass substitution, Fourier inversion) and by a numerical quadrature performed in double precision.

Example 15.4: First integral: $\int_{-\infty}^{+\infty} \frac{dx}{(x^2+1)^2}$. **Statement.** Compute $I_1 = \int_{-\infty}^{+\infty} \frac{dx}{(x^2+1)^2}$.

Step 1 — the integral converges. The integrand is positive, continuous, and $\leq 1/x^4$ for $|x| \geq 1$: the improper integral converges absolutely, and $I_1 = \lim_{R \rightarrow +\infty} \int_{-R}^R$.

Step 2 — the contour and the convex set. Let $R > 1$, let γ_R be the D -shaped contour of Proposition 15.4, and let

$$\Omega_R = D(0, R+1) \cap \left\{ z \in \mathbb{C} : \operatorname{Im} z > -\frac{1}{2} \right\},$$

the intersection of an open disk and an open half-plane: it is open and convex. It contains the support of γ_R (the segment has imaginary part 0, the arc has imaginary part ≥ 0 , and all points have modulus $\leq R < R+1$) and contains i , while it does *not* contain $-i$, which has imaginary part $-1 < -\frac{1}{2}$.

Step 3 — the function and its only singularity in Ω_R . Set $f(z) = \frac{1}{(z^2 + 1)^2} = \frac{1}{(z - i)^2(z + i)^2}$. Its only singularities are $\pm i$; in Ω_R only $z = i$ remains, a pole of order 2 (the factor $(z - i)^{-2}$ with $1/(z + i)^2$ holomorphic and nonzero at i : Theorem 15.14(b) with $k = 2$).

Step 4 — the residue. By Proposition 15.2(i) with $k = 2$,

$$\operatorname{Res}(f, i) = \frac{1}{1!} \lim_{z \rightarrow i} \frac{d}{dz} [(z - i)^2 f(z)] = \lim_{z \rightarrow i} \frac{d}{dz} \frac{1}{(z + i)^2} = \lim_{z \rightarrow i} \frac{-2}{(z + i)^3} = \frac{-2}{(2i)^3}.$$

Since $(2i)^3 = 8i^3 = -8i$, we get $\operatorname{Res}(f, i) = \frac{-2}{-8i} = \frac{1}{4i} = -\frac{i}{4}$.

Step 5 — the residue theorem. By Theorem 15.17 on Ω_R , with the only singularity i and $\operatorname{Ind}_{\gamma_R}(i) = 1$ (Proposition 15.4),

$$\oint_{\gamma_R} f(z) dz = 2\pi i \cdot 1 \cdot \frac{1}{4i} = \frac{\pi}{2}.$$

Step 6 — the arc vanishes. For $|z| = R > 1$ we have $|z^2 + 1| \geq |z|^2 - 1 = R^2 - 1$, hence $|f(z)| \leq \frac{1}{(R^2 - 1)^2}$; the arc α_R has length πR , and by the ML estimate (Lemma 15.2)

$$\left| \int_{\alpha_R} f(z) dz \right| \leq \frac{\pi R}{(R^2 - 1)^2} \xrightarrow{R \rightarrow +\infty} 0.$$

Step 7 — conclusion. Since $\oint_{\gamma_R} f = \int_{-R}^R f(x) dx + \int_{\alpha_R} f$, letting $R \rightarrow +\infty$ gives

$$I_1 = \frac{\pi}{2} = 1.5707963$$

Second, independent method: the substitution $x = \tan t$. With $x = \tan t$, $t \in (-\frac{\pi}{2}, \frac{\pi}{2})$, we have $dx = \frac{dt}{\cos^2 t}$ and $1 + x^2 = \frac{1}{\cos^2 t}$, hence $(1 + x^2)^2 = \frac{1}{\cos^4 t}$ and

$$I_1 = \int_{-\pi/2}^{\pi/2} \cos^4 t \cdot \frac{dt}{\cos^2 t} = \int_{-\pi/2}^{\pi/2} \cos^2 t dt = \int_{-\pi/2}^{\pi/2} \frac{1 + \cos 2t}{2} dt = \left[\frac{t}{2} + \frac{\sin 2t}{4} \right]_{-\pi/2}^{\pi/2} = \frac{\pi}{2}.$$

Identical. ✓

Third check, numerical. Composite Simpson quadrature with 400,000 subintervals on $[-2000, 2000]$: 1.5707963; and $\frac{\pi}{2} = 1.5707963$. The neglected tail is bounded by $2 \int_{2000}^{\infty} x^{-4} dx = \frac{2}{3 \cdot 2000^3} = 8.3 \cdot 10^{-11}$, consistent with the observed discrepancy ($8.3 \cdot 10^{-11}$). ✓

Typical error. Including also the residue at $-i$. The D -shaped contour encloses only the upper half-plane, and Proposition 15.4 gives $\operatorname{Ind}_{\gamma_R}(-i) = 0$: the pole $-i$ does not contribute. The quickest way to notice this is that Ω_R was built specifically *not* to contain it.

Example 15.5: Second integral: $\int_0^{2\pi} \frac{d\theta}{5 - 4 \cos \theta}$. **Statement.** Compute $I_2 = \int_0^{2\pi} \frac{d\theta}{5 - 4 \cos \theta}$. The denominator is always $\geq 5 - 4 = 1 > 0$, so the integrand is continuous and the integral exists.

Step 1 — from the circle to algebra. With $z = e^{i\theta}$ we have $\cos \theta = \frac{1}{2}(z + z^{-1})$ and $dz = iz d\theta$, i.e. $d\theta = \frac{dz}{iz}$ (as in Step 1 of Example 15.1). Hence

$$5 - 4 \cos \theta = 5 - 2 \left(z + \frac{1}{z} \right) = \frac{5z - 2z^2 - 2}{z} = \frac{-(2z^2 - 5z + 2)}{z} = \frac{-(2z - 1)(z - 2)}{z},$$

having factored $2z^2 - 5z + 2 = (2z - 1)(z - 2)$ (the roots are $\frac{1}{2}$ and 2, and the product of the factors reproduces $2z^2 - 5z + 2$: direct check $(2z - 1)(z - 2) = 2z^2 - 4z - z + 2 = 2z^2 - 5z + 2$ ✓).

Step 2 — the contour integral.

$$I_2 = \oint_{\mathbb{T}} \frac{z}{-(2z - 1)(z - 2)} \cdot \frac{dz}{iz} = -\frac{1}{i} \oint_{\mathbb{T}} \frac{dz}{(2z - 1)(z - 2)} = i \oint_{\mathbb{T}} \frac{dz}{(2z - 1)(z - 2)},$$

because $-1/i = i$.

Step 3 — the poles. The function $F(z) = \frac{1}{(2z - 1)(z - 2)} = \frac{1}{2(z - \frac{1}{2})(z - 2)}$ has two simple poles, at $z = \frac{1}{2}$ and at $z = 2$. Only $\frac{1}{2}$ is interior to $\mathbb{T}$; by Proposition 15.3, $\text{Ind}_{\mathbb{T}}(\frac{1}{2}) = 1$ and $\text{Ind}_{\mathbb{T}}(2) = 0$.

Step 4 — the residue. By Proposition 15.2(ii),

$$\text{Res}\left(F, \frac{1}{2}\right) = \lim_{z \rightarrow 1/2} \left(z - \frac{1}{2}\right) F(z) = \frac{1}{2(\frac{1}{2} - 2)} = \frac{1}{2 \cdot (-\frac{3}{2})} = -\frac{1}{3}.$$

Step 5 — conclusion. Applying Theorem 15.17 with $\Omega = D(0, \frac{3}{2})$ (convex, containing $\mathbb{T}$ and $\frac{1}{2}$, not containing 2):

$$I_2 = i \cdot 2\pi i \cdot \left(-\frac{1}{3}\right) = -\frac{2\pi i^2}{3} = \boxed{\frac{2\pi}{3} = 2.0943951}$$

Second, independent method: the Weierstrass substitution. Since $\cos(2\pi - \theta) = \cos \theta$, the integrand is symmetric about $\theta = \pi$ and $I_2 = 2 \int_0^\pi \frac{d\theta}{5 - 4 \cos \theta}$. With $t = \tan \frac{\theta}{2}$ ($\theta : 0 \rightarrow \pi$ corresponds to $t : 0 \rightarrow +\infty$), $\cos \theta = \frac{1-t^2}{1+t^2}$ and $d\theta = \frac{2dt}{1+t^2}$:

$$5 - 4 \cos \theta = \frac{5(1+t^2) - 4(1-t^2)}{1+t^2} = \frac{1+9t^2}{1+t^2},$$

hence

$$\int_0^\pi \frac{d\theta}{5 - 4 \cos \theta} = \int_0^{+\infty} \frac{1+t^2}{1+9t^2} \cdot \frac{2dt}{1+t^2} = \int_0^{+\infty} \frac{2dt}{1+9t^2} = \frac{2}{3} \left[\arctan 3t \right]_0^{+\infty} = \frac{2}{3} \cdot \frac{\pi}{2} = \frac{\pi}{3},$$

and $I_2 = 2 \cdot \frac{\pi}{3} = \frac{2\pi}{3}$. Identical. ✓

Third check, with the inherited example. Writing $\frac{1}{5-4\cos\theta} = \frac{1}{4} \cdot \frac{1}{\frac{5}{4}-\cos\theta}$ and observing that $\int_0^{2\pi} \frac{d\theta}{a-\cos\theta} = \int_0^{2\pi} \frac{d\theta}{a+\cos\theta}$ (substitution $\theta \mapsto \theta + \pi$, which changes the sign of the cosine and leaves the interval unchanged by periodicity), Example 15.1 with $a = \frac{5}{4}$ gives

$$I_2 = \frac{1}{4} \cdot \frac{2\pi}{\sqrt{\frac{25}{16} - 1}} = \frac{1}{4} \cdot \frac{2\pi}{\frac{3}{4}} = \frac{2\pi}{3}. \checkmark$$

Fourth check, numerical. Composite Simpson quadrature with 200,000 subintervals on $[0, 2\pi]$: 2.0943951; and $\frac{2\pi}{3} = 2.0943951$. ✓

Typical error. Forgetting the factor $\frac{1}{iz}$ in the change of variable, or getting the sign wrong in $-1/i$. The immediate check is that I_2 must be *real and positive* (positive integrand): an imaginary result signals a sign error.

Example 15.6: Third integral: $\int_{-\infty}^{+\infty} \frac{\cos x}{x^2+1} dx$. **Statement.** Compute $I_3 = \int_{-\infty}^{+\infty} \frac{\cos x}{x^2+1} dx$.

Step 1 — convergence. $|\frac{\cos x}{x^2+1}| \leq \frac{1}{x^2+1}$, integrable on $\mathbb{R}$: the integral converges absolutely.

Step 2 — the right function. One does not integrate $\cos z/(z^2+1)$, which is unbounded on the arc ($|\cos z|$ grows like $e^{|\operatorname{Im} z|}$), but rather

$$f(z) = \frac{e^{iz}}{z^2+1},$$

whose modulus on the upper arc is controlled: for $\operatorname{Im} z \geq 0$, $|e^{iz}| = e^{-\operatorname{Im} z} \leq 1$.

Step 3 — residue. With $p(z) = e^{iz}$ and $q(z) = z^2+1$ we have $q(i) = 0$, $q'(z) = 2z$, $q'(i) = 2i \neq 0$ and $p(i) = e^{i \cdot i} = e^{-1} \neq 0$: by Proposition 15.2(iii), i is a simple pole and

$$\operatorname{Res}(f, i) = \frac{p(i)}{q'(i)} = \frac{e^{-1}}{2i}.$$

Step 4 — residue theorem. With the same convex set Ω_R and the same contour γ_R of Example 15.4 (which contains i and not $-i$), Theorem 15.17 and Proposition 15.4 give

$$\oint_{\gamma_R} f(z) dz = 2\pi i \cdot \frac{e^{-1}}{2i} = \frac{\pi}{e}.$$

Step 5 — the arc vanishes. For $|z| = R > 1$ with $\operatorname{Im} z \geq 0$,

$$|f(z)| = \frac{|e^{iz}|}{|z^2+1|} \leq \frac{1}{R^2-1},$$

and the length of the arc is πR : by Lemma 15.2, $|\int_{\alpha_R} f| \leq \frac{\pi R}{R^2-1} \rightarrow 0$.

Step 6 — taking the real part. Letting $R \rightarrow +\infty$, $\int_{-\infty}^{+\infty} \frac{e^{ix}}{x^2+1} dx = \frac{\pi}{e}$. The left-hand side has real part $\int \frac{\cos x}{x^2+1} dx$ and imaginary part $\int \frac{\sin x}{x^2+1} dx = 0$ (odd integrand, symmetric domain). The right-hand side is real. Hence

$$I_3 = \frac{\pi}{e} = 1.1557273$$

Second, independent method: Fourier inversion. Consider $h(t) = e^{-|t|}$, a continuous function integrable on $\mathbb{R}$. Its Fourier transform is computed elementarily:

$$\hat{h}(x) = \int_{-\infty}^{+\infty} e^{-|t|} e^{-ixt} dt = 2 \int_0^{+\infty} e^{-t} \cos(xt) dt,$$

(the part with $\sin$ vanishes by oddness) and

$$\int_0^{+\infty} e^{-t} \cos(xt) dt = \operatorname{Re} \int_0^{+\infty} e^{(-1+ix)t} dt = \operatorname{Re} \frac{1}{1-ix} = \operatorname{Re} \frac{1+ix}{1+x^2} = \frac{1}{1+x^2},$$

because $\int_0^T e^{(-1+ix)t} dt = \frac{e^{(-1+ix)T}-1}{-1+ix} \rightarrow \frac{-1}{-1+ix} = \frac{1}{1-ix}$ (the numerator tends to -1 because $|e^{(-1+ix)T}| = e^{-T} \rightarrow 0$). Hence $\hat{h}(x) = \frac{2}{1+x^2}$, which is integrable. By the Fourier inversion theorem (a prerequisite stated in the opening infobox),

$$e^{-|t|} = h(t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \hat{h}(x) e^{ixt} dx = \frac{1}{\pi} \int_{-\infty}^{+\infty} \frac{e^{ixt}}{1+x^2} dx = \frac{1}{\pi} \int_{-\infty}^{+\infty} \frac{\cos(xt)}{1+x^2} dx.$$

Setting $t = 1$: $e^{-1} = \frac{1}{\pi}I_3$, i.e. $I_3 = \pi/e$. Identical, and by a route that uses no residue at all. ✓

Third check, numerical. Composite Simpson quadrature with 4000000 subintervals on $[-4000, 4000]$: 1.1557273; and $\pi/e = 1.1557273$. ✓

Interpretation. The general formula just proved twice, $\int_{-\infty}^{+\infty} \frac{\cos(xt)}{1+x^2} dx = \pi e^{-|t|}$, says that the Fourier transform of the Cauchy kernel $\frac{1}{\pi(1+x^2)}$ is $e^{-|t|}$: this is the pair that governs the Poisson kernel of the half-plane in Chapter 16. The *exponential* decay of the transform is the analytic translation of the fact that $\frac{1}{1+x^2}$ extends to a function holomorphic in a strip about the real axis, of width equal to the distance of the poles $\pm i$ from the axis: 1.

Typical error. Using $\cos z$ instead of e^{iz} . On the upper arc $|\cos(Re^{i\theta})|$ is unbounded — for $z = iy$ we have $\cos(iy) = \cosh y \rightarrow +\infty$ — and the estimate of Step 5 fails. The choice of e^{iz} exploits the fact that the half-plane in which the contour closes is *the one where the exponential decays*: if the integrand were $\cos x$ multiplied by a function with poles in the lower half-plane, one would close downward with e^{-iz} .

15.10. Exercises inherited from Volume II

The exercises that follow come from Volume II, Chapter 3, and concern the topics of this chapter. They are reproduced in full, together with their solutions, which follow in the same order as the exercises.

Exercises

Exercise 15.1: N9 — An integral with a double pole. Compute

$$\oint_{|z|=3} \frac{z}{(z-1)(z-2)^2} dz$$

using Theorem 15.5, identifying the interior poles, their order, and their respective residues.

Exercise 15.2: S9 — Cauchy's estimates and Liouville's theorem. Let f be holomorphic on an open set containing $\overline{D}(z_0, r)$ and $|f| \leq M$ on $|z - z_0| = r$. Prove the **Cauchy estimates**

$$|a_n| \leq \frac{M}{r^n} \quad (n \geq 0),$$

where a_n are the coefficients of the expansion of f about z_0 , and deduce **Liouville's theorem**: a bounded entire function is constant. Observe that Cauchy's estimates are exactly those used in Chapter 2, Step 5 of the proof of the Theorem (Volume II, Chapter 2).

Exercise 15.3: S10 — The trick $\bar{z} = 1/z$ on the unit circle. Prove that on $\mathbb{T}$ one has $\bar{z} = 1/z$, and use this to show that the integral over $\mathbb{T}$ of any polynomial in the variables z and $\bar{z}$ reduces to $2\pi i$ times the coefficient of z^{-1} after the substitution. Apply the method to compute

$$\oint_{\mathbb{T}} |z-1|^2 dz.$$

Solutions

Solution. N9. *Step 1 — the poles and their order.* The function

$$f(z) = \frac{z}{(z-1)(z-2)^2}$$

has a *simple* pole at $z = 1$ and a *double* pole at $z = 2$. Both have modulus less than 3, so they are interior to the contour $|z| = 3$.

Step 2 — residue at the simple pole $z = 1$. With the *step box* formula,

$$\operatorname{Res}(f, 1) = \lim_{z \rightarrow 1} (z-1)f(z) = \lim_{z \rightarrow 1} \frac{z}{(z-2)^2} = \frac{1}{(1-2)^2} = \frac{1}{1} = 1.$$

Step 3 — residue at the double pole $z = 2$. For a pole of order $k = 2$,

$$\operatorname{Res}(f, 2) = \lim_{z \rightarrow 2} \frac{d}{dz} [(z-2)^2 f(z)] = \lim_{z \rightarrow 2} \frac{d}{dz} \left[\frac{z}{z-1} \right].$$

Differentiating by the quotient rule,

$$\frac{d}{dz} \frac{z}{z-1} = \frac{1 \cdot (z-1) - z \cdot 1}{(z-1)^2} = \frac{-1}{(z-1)^2},$$

hence

$$\operatorname{Res}(f, 2) = \frac{-1}{(2-1)^2} = -1.$$

Step 4 — the residue theorem. By Theorem 15.5,

$$\oint_{|z|=3} \frac{z dz}{(z-1)(z-2)^2} = 2\pi i(1 + (-1)) = 0.$$

Step 5 — independent check by partial fractions. We seek A, B, C with

$$\frac{z}{(z-1)(z-2)^2} = \frac{A}{z-1} + \frac{B}{z-2} + \frac{C}{(z-2)^2}.$$

Multiplying by $(z-1)(z-2)^2$: $z = A(z-2)^2 + B(z-1)(z-2) + C(z-1)$. At $z = 1$: $1 = A \cdot 1 \Rightarrow A = 1$. At $z = 2$: $2 = C \cdot 1 \Rightarrow C = 2$. Comparing the coefficients of z^2 : $0 = A + B \Rightarrow B = -1$. Integrating term by term with Lemma 15.5, only the powers $(z-\xi)^{-1}$ contribute:

$$\oint f = 2\pi i(A + B) = 2\pi i(1 - 1) = 0. \checkmark$$

(The term $C/(z-2)^2$ has exponent $-2 \neq -1$ and does not contribute: consistent with the fact that the residue is by definition the coefficient of $(z-\xi)^{-1}$, not of more negative powers.)

Typical error. Applying the simple-pole formula $\lim_{z \rightarrow 2} (z-2)f(z)$ to the double pole: the limit would be infinite and the computation would fail without giving a clear warning. *Always* check the order of the pole before choosing the formula.

Solution. S9. *Step 1 — integral representation of the coefficients.* Since f is holomorphic on an open set containing $\overline{D(z_0, r)}$, it has there a power series expansion $f(z) = \sum_{n \geq 0} a_n(z - z_0)^n$, and by Theorem 15.4 (the case of vanishing principal part)

$$a_n = \frac{1}{2\pi i} \oint_{|\zeta - z_0| = r} \frac{f(\zeta)}{(\zeta - z_0)^{n+1}} d\zeta.$$

Step 2 — ML estimate. Parametrizing $\zeta = z_0 + re^{i\theta}$, we have $|d\zeta| = r d\theta$ and $|\zeta - z_0| = r$, hence

$$|a_n| \leq \frac{1}{2\pi} \oint \frac{|f(\zeta)|}{|\zeta - z_0|^{n+1}} |d\zeta| \leq \frac{1}{2\pi} \cdot \frac{M}{r^{n+1}} \cdot \underbrace{2\pi r}_{\text{length}} = \frac{M}{r^n}.$$

Step 3 — Liouville's theorem. Let f be entire (holomorphic on the whole of $\mathbb{C}$) and bounded, $|f| \leq M$ everywhere. Fixing $z_0 = 0$, Cauchy's estimates hold for *every* $r > 0$:

$$|a_n| \leq \frac{M}{r^n} \quad \text{for every } r > 0.$$

For $n \geq 1$, letting $r \rightarrow +\infty$, the right-hand side tends to 0, while a_n does not depend on r : hence $a_n = 0$ for every $n \geq 1$. What remains is $f(z) = a_0$, constant.

Step 4 — connection with Chapter 2. The estimates of Step 2 are exactly those used in Step 5 of the proof of the Theorem (Volume II, Chapter 2), where they served to bound the Taylor coefficients of the integrand and to obtain the geometric convergence of the periodic trapezoidal rule. It is the same theorem, used once to deduce a structural fact (Liouville) and once for a numerical estimate: a good example of how versatile Cauchy's estimates are.

Solution. S10. *Step 1 — the trick.* By Exercise S2 (Volume II, Chapter 3), on $\mathbb{T}$ one has $\bar{z} = 1/z$. Hence every polynomial expression in z and $\bar{z}$, restricted to $\mathbb{T}$, becomes a Laurent polynomial in z alone:

$$P(z, \bar{z})|_{\mathbb{T}} = P\left(z, \frac{1}{z}\right) = \sum_{m=-M}^M c_m z^m.$$

Step 2 — integration. Integrating over $\mathbb{T}$ term by term and applying Lemma 15.5 with $z_0 = 0$ to each power,

$$\oint_{\mathbb{T}} P(z, \bar{z}) dz = \sum_m c_m \oint_{\mathbb{T}} z^m dz = 2\pi i c_{-1},$$

since all powers other than z^{-1} give a vanishing integral.

Step 3 — application. Compute $\oint_{\mathbb{T}} |z - 1|^2 dz$. On the curve,

$$|z - 1|^2 = (z - 1)(\bar{z} - 1) = (z - 1)\left(\frac{1}{z} - 1\right).$$

Expanding:

$$(z - 1)\left(\frac{1}{z} - 1\right) = 1 - z - \frac{1}{z} + 1 = 2 - z - z^{-1}.$$

Step 4 — reading off the coefficient. The coefficient of z^{-1} is $c_{-1} = -1$, hence

$$\oint_{\mathbb{T}} |z - 1|^2 dz = 2\pi i (-1) = -2\pi i.$$

Step 5 — direct check. Parametrizing $z = e^{i\theta}$, $dz = ie^{i\theta} d\theta$, and using $|e^{i\theta} - 1|^2 = 2 - 2\cos\theta$ (from Step 3 with $z = e^{i\theta}$):

$$\oint_{\mathbb{T}} |z - 1|^2 dz = \int_0^{2\pi} (2 - 2\cos\theta) ie^{i\theta} d\theta = i \int_0^{2\pi} (2e^{i\theta} - 2\cos\theta e^{i\theta}) d\theta.$$

The first integral vanishes by periodicity. For the second, writing $2\cos\theta = e^{i\theta} + e^{-i\theta}$,

$$\int_0^{2\pi} (e^{i\theta} + e^{-i\theta}) e^{i\theta} d\theta = \int_0^{2\pi} (e^{2i\theta} + 1) d\theta = 0 + 2\pi = 2\pi.$$

Hence the integral equals $i(0 - 2\pi) = -2\pi i$. ✓

Remark. The result is *nonzero* even though $|z - 1|^2$ is a real, positive function: there is no contradiction, because $|z - 1|^2$ is not holomorphic (it depends on $\bar{z}$) and the Cauchy–Goursat theorem does not apply to it. This is the typical error to avoid: the vanishing of the integral over a closed contour requires holomorphy, not mere continuity.

Inherited quiz

The items below come from the quiz of Volume II, Chapter 3, and are renumbered here.

1. The residue of f at an isolated singularity ξ is
 - A) $f(\xi)$ B) the coefficient a_{-1} of the Laurent expansion C) the coefficient a_0 D) $f'(\xi)$
2. The residue theorem states that the integral over a closed contour equals
 - A) always zero B) $2\pi i$ times the sum of the *interior* residues C) πi times the sum of all residues D) the sum of the poles
3. The integral $\oint_{\mathbb{T}} |z - 1|^2 dz$ is nonzero because
 - A) the integrand has a pole at $z = 1$
 - B) the integrand is not holomorphic, depending on $\bar{z}$
 - C) the contour is not closed
 - D) the computation is wrong: it equals zero

BEST PRACTICE

Answer key.

1-B: Definition 15.3. **2-B:** Theorem 15.5; the word “interior” is essential (cf. the typical error of Example 15.1). **3-B:** Exercise S10, Step 5: $|z - 1|^2$ depends on $\bar{z}$, so Cauchy–Goursat does not apply.

Inherited formulary

The lines below come from the formulary of Volume II, Chapter 3.

Complex analysis on the circle

$$\oint_{|\zeta - z_0| = \rho} (\zeta - z_0)^m d\zeta = 2\pi i [m = -1], \quad f(z) = \frac{1}{2\pi i} \oint \frac{f(\zeta)}{\zeta - z} d\zeta$$

$$\oint f = 2\pi i \sum_j \text{Res}(f, \xi_j), \quad \text{Res}\left(\frac{p}{q}, \xi\right) = \frac{p(\xi)}{q'(\xi)} \text{ (simple pole)}$$

15.11. Conformal mapping: why the disk is a universal model

INFO

Level D. We use Cauchy's formula and estimates, the maximum principle, the identity theorem, Rouché's theorem and Schwarz's lemma with its equality case, already treated in Chapter 15. Completeness of $\mathbb{C}$, compactness of closed bounded sets and integration along piecewise regular paths are prerequisites. The root lemma, Montel normality and the limit theorem for injective functions are proved here; none of these three steps is imported.

A domain is a nonempty connected open set. Simply connected means that every closed path contracts to a point within the domain. The conclusion concerns the interior; without further hypotheses it does not assert a bijective extension to the boundary. The reference for the extremal method is [1]; the proofs below also supply its analytic prerequisites.

15.11.1 Primitives, logarithms and roots

***Lemma 15.12: Global primitive and logarithm.** Let U be simply connected. Every holomorphic function h on U has a primitive. If h is nowhere zero, there is a holomorphic L with $e^L = h$; for every integer $m \geq 1$, $e^{L/m}$ is a holomorphic m th root of h .*

Proof. 1. Integrals and homotopy. On every disk contained in U there is a local primitive: integrate from a fixed point and apply Goursat to triangles. Let $H : [0, 1]^2 \rightarrow U$ be a fixed-endpoint homotopy between two paths. Its image is compact. Uniform continuity allows a grid fine enough that the image of each cell lies in a disk carrying a primitive. Indeed, cover the image by disks smaller than the primitive disks, take a finite subcover and use a Lebesgue number for the pulled-back cover of the square.

Replace the images of interior edges by line segments joining the images of their endpoints. A common edge stays in both adjacent disks because both disks are convex. The integral around each cell is zero by its local primitive. On summing, interior edges cancel with opposite orientations. On the outer boundary, retain the original paths: their integrals equal those of the replacing segments by the same local primitive. No differentiability of the homotopy has been assumed. Thus the integral is homotopy invariant, and contraction of a closed path shows that its integral is zero.

2. Construction. Fix $a \in U$ and set $F(z) = \int_a^z h(\zeta) d\zeta$ along any path from a to z . The preceding step gives path independence. For w close to z , the final segment can be straight, so

$$\frac{F(w) - F(z)}{w - z} = \int_0^1 h(z + t(w - z)) dt \longrightarrow h(z).$$

3. Logarithm. If $h \neq 0$, apply step 2 to h'/h . Choose ℓ with $e^\ell = h(a)$ and define $L(z) = \ell + \int_a^z h'/h$. Then $(he^{-L})' = 0$ and $h(a)e^{-L(a)} = 1$. Connectedness of U gives $h = e^L$; raising $e^{L/m}$ to the m th power finishes the proof. $\square$

15.11.2 The compactness step: Montel proved here

***Theorem 15.20: Normality of locally bounded families.** Every sequence of holomorphic functions on a domain U , uniformly bounded on each compact subset, has a subsequence converging uniformly on compact subsets to a holomorphic function. The derivatives also converge uniformly on compact subsets.*

Proof. 1. Equicontinuity. Given compact $K \subset U$, choose $\rho > 0$ so that its closed 2ρ -neighbourhood is compact in U . Let M bound all functions there. Cauchy's estimate on

circles of radius ρ gives $|f'_n(z)| \leq M/\rho$ in the ρ -neighbourhood. If $z, w \in K$ and $|z - w| < \rho$, integration along the segment yields

$$|f_n(z) - f_n(w)| \leq (M/\rho)|z - w|.$$

2. Diagonal extraction. Enumerate a countable dense set $D = \{d_1, d_2, \dots\} \subset U$. Each sequence $f_n(d_j)$ is bounded. Bolzano–Weierstrass gives a subsequence converging at d_1 , a subsequence of it converging at d_2 , and so on. Taking the k th term of the k th subsequence yields a single sequence converging at every d_j .

3. Uniformity. Fix K and $\varepsilon > 0$. Take a finite net of points in D , within distance δ of every point of K , with $2M\delta/\rho < \varepsilon/2$. Step 1 also applies to these points chosen in the neighbourhood. For sufficiently large indices, values at all finitely many nodes differ by less than $\varepsilon/2$. The triangle inequality through a nearby node bounds the difference by ε everywhere on K . Thus the extracted sequence is uniformly Cauchy on K and converges. The same subsequence works for every compact set because it was fixed on one dense set.

4. Holomorphy and derivatives. On a circle $|\zeta - z_0| = r$ whose closed disk lies in U , uniform convergence permits passage to the limit in Cauchy's formula. For $|z - z_0| < r$ this gives

$$f(z) = \frac{1}{2\pi i} \int_{|\zeta - z_0| = r} \frac{f(\zeta)}{\zeta - z} d\zeta, \quad f^{(j)}(z) = \frac{j!}{2\pi i} \int_{|\zeta - z_0| = r} \frac{f(\zeta)}{(\zeta - z)^{j+1}} d\zeta.$$

The denominator is uniformly separated from zero on smaller interior disks. Differentiation under the integral is therefore valid, and the same formula applied to $f_n - f$ proves convergence of derivatives. A finite cover proves the assertion on an arbitrary compact set. $\square$

***Lemma 15.13: Derivative and limit of injective functions.** An injective holomorphic function has nowhere-vanishing derivative and a holomorphic inverse on its image. A locally uniform limit of injective holomorphic functions is either constant or injective.*

Proof. 1. Derivative. If $f(z) - f(z_0)$ has a zero of order $m \geq 2$, choose a small disk about z_0 in which f' has no other zeros. For sufficiently small $\eta \neq 0$, Rouché gives m zeros, counted with multiplicity, of $f(z) - f(z_0) - \eta$ in that disk. None is z_0 and their derivatives are nonzero, so they are m distinct points, a contradiction. Hence $m = 1$. The same argument with $m = 1$ gives a unique nearby preimage for nearby values. The inverse is locally continuous and

$$\frac{f^{-1}(w) - z_0}{w - f(z_0)} \longrightarrow \frac{1}{f'(z_0)}.$$

2. Limit. Let f be a nonconstant limit and suppose $f(z_1) = f(z_2)$ with $z_1 \neq z_2$. Zeros of $g(z) = f(z) - f(z_1)$ are isolated. Choose a closed disk around z_2 excluding z_1 , with no zeros of g on its boundary. On that boundary, $f_n(z) - f_n(z_1)$ converges uniformly to g . Rouché gives at least one zero in the disk for large n . Yet injectivity of f_n requires its only zero to be z_1 , outside the disk. This is a contradiction. $\square$

15.11.3 The theorem and the decisive calculation

***Theorem 15.21: Normalized Riemann mapping theorem.** Let $U \subsetneq \mathbb{C}$ be a simply connected domain and $a \in U$. There is a unique holomorphic bijection $f : U \rightarrow \mathbb{D}$, where $\mathbb{D} = \{w : |w| < 1\}$, such that $f(a) = 0$ and $f'(a) > 0$ is real.*

Proof. 1. The admissible family is nonempty. Choose $c \notin U$. Lemma 15.12 gives a holomorphic $q(z) = \sqrt{z - c}$. It is injective since $q(z)^2 = z - c$. The images $q(U)$ and $-q(U)$ are disjoint: an intersection would give $q(z) = -q(w)$, hence $z = w$ and $q(z) = 0$, which is

impossible. Set $q_0 = q(a)$ and choose $\delta > 0$ with $D(q_0, \delta) \subset q(U)$. The disk $D(-q_0, \delta)$ is omitted by q , so

$$T(z) = \frac{\delta}{2(q(z) + q_0)}, \quad |T(z)| \leq \frac{1}{2}.$$

The function T is holomorphic and injective. Recall the disk automorphism

$$\phi_b(w) = \frac{w - b}{1 - \bar{b}w}, \quad 1 - |\phi_b(w)|^2 = \frac{(1 - |b|^2)(1 - |w|^2)}{|1 - \bar{b}w|^2}.$$

Compose T with $\phi_{T(a)}$ and multiply by a unit complex number to make the derivative at a real and positive. That derivative is nonzero by Lemma 15.13. Thus the following family is nonempty:

$$\mathcal{F} = \{f : U \rightarrow \mathbb{D} : f \text{ holomorphic, injective, } f(a) = 0, f'(a) > 0\}.$$

2. Existence of an extremal. Choose $\rho > 0$ with $\overline{D}(a, \rho) \subset U$. Cauchy's estimate gives $0 < f'(a) \leq 1/\rho$ for $f \in \mathcal{F}$. Hence $M = \sup_{\mathcal{F}} f'(a)$ is finite and positive. Choose $f'_n(a) \rightarrow M$. By Theorem 15.20, a subsequence converges locally uniformly to f_* with $f_*(a) = 0$ and $f'_*(a) = M$. The limit is nonconstant and satisfies $|f_*| \leq 1$; the maximum principle strengthens this to $|f_*| < 1$. Lemma 15.13 gives injectivity. Consequently $f_* \in \mathcal{F}$.

3. An omitted value increases the derivative. Suppose $b \in \mathbb{D} \setminus f_*(U)$. Since $f_*(a) = 0$, we have $r = |b| \in (0, 1)$. The function $\phi_b \circ f_*$ has no zeros. Take a holomorphic square root q on U , and put $d = q(a)$. Then

$$q^2 = \phi_b \circ f_*, \quad d^2 = -b, \quad |d| = \sqrt{r}, \quad |q| < 1.$$

The function q is injective: equality of two values implies equality of their squares, then of the values of f_* , and finally of the points. The function $g_0 = \phi_d \circ q$ is also injective, maps into $\mathbb{D}$ and vanishes at a . Keeping every factor, we compute:

$$\begin{aligned} \phi'_b(0) &= 1 - r^2, & \phi'_d(d) &= \frac{1}{1 - |d|^2} = \frac{1}{1 - r}, \\ 2d q'(a) &= (1 - r^2) f'_*(a), & |g'_0(a)| &= \frac{1 - r^2}{2\sqrt{r}(1 - r)} f'_*(a) = \frac{1 + r}{2\sqrt{r}} M. \\ \frac{1 + r}{2\sqrt{r}} - 1 &= \frac{(1 - \sqrt{r})^2}{2\sqrt{r}} > 0. \end{aligned}$$

A rotation of the codomain makes $g'_0(a)$ real and positive without changing its modulus. This gives $g \in \mathcal{F}$ with $g'(a) > M$, a contradiction. Therefore $f_*(U) = \mathbb{D}$.

4. Uniqueness. For two solutions f_1, f_2 , the composition $h = f_2 \circ f_1^{-1}$ is a holomorphic disk automorphism fixing zero. Schwarz applied to h and h^{-1} gives both $|h(z)| \leq |z|$ and $|z| \leq |h(z)|$. The equality case implies $h(z) = e^{i\theta} z$. But $h'(0) = f'_2(a)/f'_1(a) > 0$, so $e^{i\theta} = 1$ and $f_1 = f_2$. $\square$

15.11.4 An explicit map and two different checks

Proposition 15.5: From a strip to the disk. For $h > 0$, the normalized map of the strip $U_h = \{z : |\operatorname{Im} z| < h\}$ with base point zero is

$$f_h(z) = \tanh \frac{\pi z}{4h}, \quad f_h^{-1}(w) = \frac{2h}{\pi} \operatorname{Log} \frac{1 + w}{1 - w}.$$

Proof. The exponential $v = \exp(\pi z/(2h))$ has argument in $(-\pi/2, \pi/2)$, so it maps into the right half-plane. It is injective on the strip: equality of two exponentials would imply $z_1 - z_2 = 4hki$, whereas the imaginary parts differ by less than $2h$. It is onto the right half-plane because the logarithm with argument in that interval gives $z = (2h/\pi) \operatorname{Log} v \in U_h$. The map $(v-1)/(v+1)$ is a bijection from the right half-plane to the disk, as shown by

$$1 - \left| \frac{v-1}{v+1} \right|^2 = \frac{4 \operatorname{Re} v}{|v+1|^2} > 0, \quad v = \frac{1+w}{1-w}.$$

The composition is the stated hyperbolic tangent; $f_h(0) = 0$ and $f'_h(0) = \pi/(4h) > 0$. Inverting the two maps gives the inverse formula. This proves global bijectivity; it is not an inference from a numerical sample. $\square$

In the supplied code, $h = 1$: the $\tanh$ formula is compared with the exponential–Möbius composition on an interior grid, followed by both round trips with the inverse. A second check uses higher-precision arithmetic. To test the extremal factor independently, take $f_0(z) = z/5$ on the disk and the omitted value $b = 1/4$: the derivative after the square-root construction has modulus $1/4$, compared with the initial $1/5$, since the gain is $5/4$. The JSON file records observed discrepancies and tolerances, not universal error bounds.

15.11.5 Exercises with solutions

Exercise 15.4: Normalization is not cosmetic. Which solutions remain when only $f(a) = 0$ is required?

Solution. Step 4 of the proof gives exactly $e^{i\theta} f_*(z)$, $\theta \in \mathbb{R}$. The positive derivative removes one real parameter. Without fixing $f(a)$ either, composition with any disk automorphism is allowed.

Exercise 15.5: Why exclude the plane. Prove that $\mathbb{C}$ is not biholomorphic to the disk.

Solution. Such a map would be entire and bounded by one. Cauchy’s estimate on a circle of radius R gives $|f'(z)| \leq 1/R$ for every $R > 0$. Letting $R \rightarrow \infty$ gives $f' = 0$: the function is constant, not bijective.

Exercise 15.6: Conditioning of the inverse. Compute the derivative of the strip inverse and explain why points near $w = 1$ require numerical care.

Solution.

$$(f_h^{-1})'(w) = \frac{2h}{\pi} \left(\frac{1}{1+w} + \frac{1}{1-w} \right) = \frac{4h}{\pi(1-w^2)}.$$

Its modulus diverges along the real axis as $w \rightarrow 1^-$. A small absolute error in w may therefore produce a much larger error in its preimage. This does not contradict bijectivity: it concerns numerical sensitivity, not existence of the inverse.

15.12. Assigned exercises

These are *new* exercises, distinct both from the inherited ones (Section 15.10) and from those worked out in Section 15.13. Answers are in the Teacher’s key (Section 15.15).

Exercise 15.7: Cauchy's estimates, polynomial growth, and generalized Liouville.

Goal: use Cauchy's estimates as a tool of *exclusion*, i.e. to show that certain coefficients vanish. *Estimated time:* 40 minutes. *Type:* proof-based/numerical.

- Let f be entire and suppose there exist $A, B \geq 0$ and an integer $k \geq 0$ with $|f(z)| \leq A + B|z|^k$ for every $z \in \mathbb{C}$. Prove, using Theorem 15.7, that f is a polynomial of degree $\leq k$.
- Let f be entire with $|f(z)| \leq 3|z|^{5/2}$ for $|z| \geq 1$. Deduce that f is a polynomial of degree ≤ 2 . (Caution: the exponent is not an integer.)
- Let $f(z) = z^2 + 7$. Compute $M(\rho) = \max_{|z|=\rho} |f|$ for $\rho = 1, 2, 5$ and fill in the table of estimates $M(\rho)/\rho^n$ for $n = 0, 1, 2, 3$, comparing them with the true coefficients $a_0 = 7$, $a_1 = 0$, $a_2 = 1$, $a_3 = 0$. Which value of ρ gives the best estimate for a_2 ? And for a_3 ?
- Why does the hypothesis of (a) not allow one to conclude that the degree is *exactly* k ? Exhibit a counterexample.

Exercise 15.8: Three integrals with residues, each to be checked twice.

Goal: choose the contour, identify the interior poles, compute the residues, and check the result by a real route. *Estimated time:* 45 minutes. *Type:* symbolic and numerical computation.

- Compute $\int_{-\infty}^{+\infty} \frac{dx}{x^4 + 1}$ with the D -shaped contour of Proposition 15.4 (one must determine which fourth roots of -1 lie in the upper half-plane) and check the result with a numerical quadrature.
- Compute $\int_0^{2\pi} \frac{\cos 2\theta}{5 - 4 \cos \theta} d\theta$ with the substitution $z = e^{i\theta}$, recalling that $\cos 2\theta = \frac{1}{2}(z^2 + z^{-2})$, and paying attention to the pole that the new integrand acquires at $z = 0$.
- Compute $\int_{-\infty}^{+\infty} \frac{x^2}{(x^2 + 1)(x^2 + 4)} dx$ with residues and then, independently, with partial fraction decomposition in x^2 .
- In (a) and (c), justify the vanishing of the contribution of the arc with the ML estimate (Lemma 15.2), exhibiting in each case the explicit bound.

Exercise 15.9: Schwarz, Blaschke, and automorphisms: explicit computations.

Goal: handle the Blaschke factor and use Schwarz's lemma after "centering" it with an automorphism. *Estimated time:* 40 minutes. *Type:* proof-based/numerical. Let $a = \frac{1}{2}$ and

$$\varphi_a(z) = \frac{z - \frac{1}{2}}{1 - \frac{1}{2}z}.$$

- Let $f : \mathbb{D} \rightarrow \mathbb{D}$ be holomorphic with $f(\frac{1}{2}) = 0$. Prove that $|f(0)| \leq \frac{1}{2}$. (Hint: apply Lemma 15.9 to $g = f \circ \varphi_{-a}$.)
- Determine the unique automorphism f of $\mathbb{D}$ with $f(\frac{1}{2}) = 0$ and $f'(\frac{1}{2})$ real and positive, and compute $f(0)$ and $f'(0)$.
- Numerically verify that $|\varphi_a(e^{i\theta})| = 1$ for $\theta = 0, 1, 2, 3$ radians, and explain the result with Lemma 15.10(i).
- Let $f : \mathbb{D} \rightarrow \mathbb{C}$ be holomorphic with $|f| \leq 1$, $f(0) = 0$ and $f(\frac{1}{2}) = 0$. Prove that $|f(z)| \leq |z| |\varphi_a(z)|$ for every $z \in \mathbb{D}$, and compute the resulting bound for $|f(\frac{1}{4})|$.

15.13. Worked exercises

Exercise 15.10: How many zeros does $z^5 + 3z + 1$ have in the annulus $1 < |z| < 2$?

Type: counting with Rouché, with numerical check. Determine the number of zeros of the polynomial $P(z) = z^5 + 3z + 1$ in the disk $|z| < 1$, in the disk $|z| < 2$, and hence in the annulus $1 < |z| < 2$.

Solution. Strategy. Rouché's theorem (Theorem 15.19) compares P with a *dominant* term on the circle: on each circle one chooses as f the monomial that on that circle is larger than all the others combined, and counts its zeros, which are immediate.

Step 1 — on the circle $|z| = 1$, $3z$ dominates. Take $f(z) = 3z$ and $g = P$. For $|z| = 1$,

$$|f(z) - g(z)| = |z^5 + 1| \leq |z|^5 + 1 = 2 < 3 = |3z| = |f(z)|.$$

The hypothesis of Theorem 15.19 is satisfied. The function $f(z) = 3z$ has exactly one zero in $|z| < 1$, at $z = 0$, of multiplicity 1. Hence P has exactly 1 zero in $|z| < 1$, counted with multiplicity.

Step 2 — on the circle $|z| = 2$, z^5 dominates. Take $f(z) = z^5$ and $g = P$. For $|z| = 2$,

$$|f(z) - g(z)| = |3z + 1| \leq 3 \cdot 2 + 1 = 7 < 32 = 2^5 = |z^5| = |f(z)|.$$

The function z^5 has a zero of multiplicity 5 at $z = 0$, hence P has exactly 5 zeros in $|z| < 2$.

Step 3 — no zeros on either circle. The two strict inequalities of Step 1 and Step 2 imply, by Step 1 of the proof of Theorem 15.19, that P vanishes neither on $|z| = 1$ nor on $|z| = 2$.

Step 4 — the annulus. The number of zeros in $1 < |z| < 2$ is the difference:

$$5 - 1 = \boxed{4}.$$

Independent check 1: the roots. Computing the five roots of $z^5 + 3z + 1$ by the Durand–Kerner method in double precision gives

$$\begin{aligned} \lambda_1 &= -0.3319890, & |\lambda_1| &= 0.3319890, \\ \lambda_{2,3} &= -0.8390724 \pm 0.9438516i, & |\lambda_{2,3}| &= 1.2628928, \\ \lambda_{4,5} &= 1.0050669 \pm 0.9372592i, & |\lambda_{4,5}| &= 1.3742686. \end{aligned}$$

One root has modulus < 1 and four have modulus between 1 and 2. ✓

Independent check 2: the argument principle. Computing numerically $\frac{1}{2\pi i} \oint_{|z|=r} \frac{P'(z)}{P(z)} dz$ with 200,000 points gives 1.0000000 for $r = 1$ and 5.0000000 for $r = 2$ (imaginary part of order 10^{-17}): these are exactly $Z - P = Z$ of Corollary 15.8, with $P = 0$ because the polynomial has no poles. ✓

Interpretation. Rouché says that “perturbing a little does not change the count”: on the small circle the polynomial is, up to a perturbation smaller than 3, the line $3z$, and inherits its single zero; on the large circle it is, up to a perturbation smaller than 32, the monomial z^5 , and inherits its five. This is the same mechanism as Lemma 12.8 of Chapter 12, where the dominant term determines the winding number.

Typical errors. (1) Using the nonstrict inequality: if on the circle one had $|f - g| = |f|$ at a point, g could vanish there and the count would not make sense. (2) Choosing the wrong monomial for f : on $|z| = 1$ the candidate z^5 does not work, because $|3z + 1|$ can equal $4 > 1 = |z^5|$. (3) Counting roots instead of *multiplicities*: Rouché's count is always with multiplicity.

Extension. With the same method one counts the number of zeros of $z^5 + 3z + 1$ in $|z| < \frac{1}{2}$: on $|z| = \frac{1}{2}$ we have $|z^5 + 1| \leq \frac{1}{32} + 1 = 1.03125$ and $|3z| = 1.5$, hence again a single zero — consistent with $|\lambda_1| = 0.3319890 < \frac{1}{2}$. ✓

Exercise 15.11: A pole of order three, and a trigonometric integral that follows from it. *Type:* symbolic computation with three independent checks. Compute

$$J = \oint_{|z|=1} \frac{e^z}{z^3} dz \text{ and deduce from it the value of } K = \int_0^{2\pi} e^{\cos \theta} \cos(\sin \theta - 2\theta) d\theta.$$

Solution. Strategy. Compute the residue at the only singularity, apply the residue theorem, and then *read* the same integral as a real integral by parametrizing the circle.

Step 1 — the singularity. The function $F(z) = e^z/z^3$ is holomorphic on $\mathbb{C} \setminus \{0\}$. From the expansion $e^z = \sum_{m \geq 0} z^m/m!$ it follows that

$$F(z) = \frac{1}{z^3} + \frac{1}{z^2} + \frac{1}{2z} + \frac{1}{6} + \frac{z}{24} + \cdots,$$

hence 0 is a pole of order 3 (Definition 15.6) and $\text{Res}(F, 0) = a_{-1} = \frac{1}{2}$.

Step 2 — checking the residue with the formula. By Proposition 15.2(i) with $k = 3$,

$$\text{Res}(F, 0) = \frac{1}{2!} \lim_{z \rightarrow 0} \frac{d^2}{dz^2} [z^3 F(z)] = \frac{1}{2} \lim_{z \rightarrow 0} \frac{d^2}{dz^2} e^z = \frac{e^0}{2} = \frac{1}{2}. \checkmark$$

Step 3 — the residue theorem. With $\Omega = D(0, 2)$, convex, and $\text{Ind}_{\mathbb{T}}(0) = 1$ (Proposition 15.3), Theorem 15.17 gives

$$J = 2\pi i \cdot \frac{1}{2} = \pi i.$$

Step 4 — check with the formula for the derivatives. Setting $f(z) = e^z$, Theorem 15.6(iii) with $w = 0$, $\rho = 1$, $k = 2$ gives

$$f''(0) = \frac{2!}{2\pi i} \oint_{|z|=1} \frac{e^z}{z^3} dz = \frac{J}{\pi i},$$

and $f''(0) = e^0 = 1$: hence $J = \pi i$. $\checkmark$

Step 5 — a real reading. Parametrizing $z = e^{i\theta}$, $dz = ie^{i\theta} d\theta$:

$$J = \int_0^{2\pi} \frac{e^{e^{i\theta}}}{e^{3i\theta}} ie^{i\theta} d\theta = i \int_0^{2\pi} e^{e^{i\theta}} e^{-2i\theta} d\theta.$$

Since $e^{i\theta} = \cos \theta + i \sin \theta$, we have $e^{e^{i\theta}} = e^{\cos \theta} (\cos(\sin \theta) + i \sin(\sin \theta))$, and multiplying by $e^{-2i\theta}$ and using the addition formulas,

$$e^{e^{i\theta}} e^{-2i\theta} = e^{\cos \theta} [\cos(\sin \theta - 2\theta) + i \sin(\sin \theta - 2\theta)].$$

Hence $J = i(K + iK')$ with $K' = \int_0^{2\pi} e^{\cos \theta} \sin(\sin \theta - 2\theta) d\theta$. From $J = \pi i$ it follows that $iK - K' = \pi i$, i.e., equating real and imaginary parts,

$$\boxed{K = \pi = 3.1415927}, \quad K' = 0.$$

Independent numerical check. Composite Simpson quadrature with 400,000 subintervals: $K = 3.1415927$ and $\oint_{|z|=1} e^z z^{-3} dz = 3.1415927 i$ (real part of order 10^{-16}). $\checkmark$ Repeating with e^z/z^{n+1} gives $\int_0^{2\pi} e^{\cos \theta} \cos(\sin \theta - n\theta) d\theta = \frac{2\pi}{n!}$, i.e. 6.2831853 for $n = 0$ and $n = 1$, 3.1415927 for $n = 2$, 1.0471976 for $n = 3$: all verified numerically. $\checkmark$

Interpretation. The identity $\int_0^{2\pi} e^{\cos \theta} \cos(\sin \theta - n\theta) d\theta = 2\pi/n!$ is nothing but the formula for the Taylor coefficients of e^z read on the unit circle: the residue *is* the coefficient a_n multiplied by 2π . It is the same master identity as Lemma 15.5: on the circle only one exponent survives.

Typical errors. (1) Using the simple-pole formula $\lim_{z \rightarrow 0} zF(z)$: the limit is infinite. (2) Forgetting the $\frac{1}{2!}$ in the formula for the pole of order 3, obtaining $J = 2\pi i$. (3) Confusing $\sin(\sin \theta - 2\theta)$ with $\sin(\sin \theta) - \sin(2\theta)$.

Extension. The same computation with e^{tz} in place of e^z gives $\int_0^{2\pi} e^{t \cos \theta} \cos(t \sin \theta - n\theta) d\theta = \frac{2\pi t^n}{n!}$, which for purely imaginary t produces the Bessel functions of the first kind: this is the bridge to Chapter 18.

Exercise 15.12: Where the maximum of $|z^2 - 1|$ lies on the closed disk. *Type:* direct application of the maximum principle, with numerical check. Determine the maximum and minimum of $|z^2 - 1|$ on $\mathbb{D}$ and the points where they are attained, discussing why the minimum principle does not apply.

Solution. Strategy. $f(z) = z^2 - 1$ is entire, hence continuous on $\overline{\mathbb{D}}$ and holomorphic on $\mathbb{D}$: Corollary 15.5 reduces the search for the maximum to the boundary, where the computation is trigonometric.

Step 1 — the maximum lies on the boundary. $\mathbb{D}$ is open, connected, and bounded, f is continuous on $\overline{\mathbb{D}}$ and holomorphic on $\mathbb{D}$, and is not constant: by Corollary 15.5, $\max_{\overline{\mathbb{D}}} |f| = \max_{\mathbb{T}} |f|$.

Step 2 — the computation on the boundary. For $z = e^{i\theta}$,

$$|z^2 - 1| = |e^{2i\theta} - 1| = |e^{i\theta}(e^{i\theta} - e^{-i\theta})| = |2i \sin \theta| = 2|\sin \theta|,$$

having used $e^{i\theta} - e^{-i\theta} = 2i \sin \theta$ (Volume II, Chapter 3) and $|e^{i\theta}| = 1$.

Step 3 — maximum and maximizing points. $2|\sin \theta|$ is at most 2, with equality at $\theta = \frac{\pi}{2}$ and $\theta = \frac{3\pi}{2}$, i.e. $z = \pm i$. Hence

$$\max_{\overline{\mathbb{D}}} |z^2 - 1| = 2, \quad \text{attained at } z = i \text{ and } z = -i.$$

Direct check: $|i^2 - 1| = |-2| = 2$. ✓

Step 4 — the minimum. f vanishes at $z = \pm 1$, which lie on $\mathbb{T}$: hence $\min_{\overline{\mathbb{D}}} |f| = 0$, attained at ± 1 . Corollary 15.6 does *not* apply, because it requires f never zero; and it is not needed here, because the minimum falls on the boundary regardless. If instead one considered $h(z) = z^2 - 4$, which does not vanish on $\overline{\mathbb{D}}$, Corollary 15.6 would guarantee that the minimum of $|h|$ is on the boundary: $|e^{2i\theta} - 4|$ is minimal for $e^{2i\theta} = 1$, i.e. $z = \pm 1$, where it equals 3; and indeed $|h(0)| = 4 > 3$.

Independent check. A 201×201 grid on the square $[-1, 1]^2$, restricted to $|z| \leq 1$: the maximum of $|z^2 - 1|$ equals 2.0000000; and on the boundary, with 2000 equally spaced points, the maximum is 2.0000000, attained at $\theta = 1.5707963 = \frac{\pi}{2}$. ✓

Interpretation. The maximum of $|z^2 - 1|$ is the maximum distance between z^2 and 1: as z ranges over $\overline{\mathbb{D}}$, z^2 still ranges over $\overline{\mathbb{D}}$ (the map $z \mapsto z^2$ is surjective onto the disk), and the point of the closed disk farthest from 1 is -1 , at distance 2. The preimages of -1 are $\pm i$: the same result is recovered by purely geometric means. ✓

Typical errors. (1) Looking for the stationary points of $|f|$ inside the disk by solving $f'(z) = 2z = 0$: $z = 0$ is a stationary point of f , not a maximum of $|f|$ — and Theorem 15.11 guarantees that an interior maximum cannot exist. (2) Concluding that the minimum is also on the boundary “by symmetry”: it is, but for a different reason (the zeros), not by Corollary 15.6. (3) Writing $|e^{2i\theta} - 1| = e^{2i\theta} - 1$, forgetting the modulus.

Extension. For $f(z) = z^n - 1$ the same computation gives $|e^{in\theta} - 1| = 2|\sin \frac{n\theta}{2}|$, maximum 2 attained at the n points $z = e^{i(2k+1)\pi/n}$, $k = 0, \dots, n-1$: the n -th roots of -1 , i.e. the vertices of the regular polygon “out of phase” relative to that of the n -th roots of unity of Chapter 6.

15.14. Self-assessment quiz

- (Definition) An isolated singularity z_0 of f is a *pole of order k* when, in the Laurent expansion $f(z) = \sum_n a_n(z - z_0)^n$,
A) $f(z_0)$ equals ∞ B) $a_{-k} \neq 0$ and $a_n = 0$ for every $n < -k$ C) infinitely many a_n with $n < 0$ are nonzero D) $a_n = 0$ for every $n < 0$
- (Hypothesis) In Lemma 15.9 the hypothesis $f(0) = 0$ serves to
A) make f injective B) annul the coefficient a_0 , so that $f(z)/z$ extends to a function holomorphic on the whole of $\mathbb{D}$ C) guarantee $|f'(0)| \leq 1$ directly D) make f an automorphism
- (Symbolic computation) $\text{Res}(e^z/z^3, 0)$ equals
A) 1 B) $\frac{1}{2}$ C) $\frac{1}{6}$ D) 0
- (Numerical computation) $\int_0^{2\pi} \frac{d\theta}{5 - 4\cos\theta}$ equals, to seven decimals,
A) 2.0943951 B) 3.1415927 C) 1.0471976 D) 6.2831853
- (Proof step) In the proof of Theorem 15.1, the factor 4^{-n} appearing on the right in the final estimate comes
A) from the ML estimate applied to the starting triangle B) from the fact that at each bisection the diameter and perimeter are halved, and in the product $\text{diam} \cdot L$ the term $2^{-n} \cdot 2^{-n}$ appears C) from the number of sub-triangles, which is four D) from the differentiability of f at z^*
- (Error diagnosis) A student computes $\int_{-\infty}^{+\infty} \frac{dx}{(x^2+1)^2}$ by summing the residues at i and at $-i$ and gets 0. The error is
A) the residue at $-i$ is computed incorrectly B) the D -shaped contour does not enclose $-i$: $\text{Ind}_{\gamma_R}(-i) = 0$ and that residue does not enter C) the integral actually diverges D) the poles are simple, not double
- (Transfer) The number of zeros of $z^5 + 3z + 1$ in the disk $|z| < 1$, counted with multiplicity, is
A) 0 B) 1 C) 2 D) 5
- (Source and metacognition) The *general* form of Cauchy's theorem for simply connected open sets, which this chapter declares it does not prove, is found in
A) Ahlfors, *Complex Analysis*, Ch. 4, §4 “The General Form of Cauchy's Theorem” B) Ahlfors, Ch. 4, §1.4 “Cauchy's Theorem for a Rectangle” C) Rudin, *Real and Complex Analysis*, Ch. 11 “Harmonic Functions” D) Orloff, 18.04, Topic 1 “Complex Algebra and the Complex Plane”

15.15. Teacher's key

BEST PRACTICE

Quiz — answers, rationale, and diagnosis (items 1–4).

1) **B.** *Rationale:* this is Definition 15.6: the principal part is finite and its lowest term has exponent $-k$. *Distractors:* A confuses the behavior of the modulus with a “value” of the

function, which is undefined at z_0 ; C is the definition of an *essential* singularity; D is the definition of a *removable* singularity. *Diagnosed error*: failing to distinguish the three types from the shape of the principal part. *Source*: Conway, *Functions of One Complex Variable I*, 2nd ed., Ch. V, §1 “Classification of singularities”; here Definition 15.6 and Theorem 15.14. *Prerequisite*: the Laurent expansion (Theorem 15.4). *Remediation*: classify the singularity at 0 of $\frac{\sin z}{z}$, $\frac{e^z}{z^3}$, and $e^{1/z}$ as in Example 15.3.

2) B. *Rationale*: Step 1 of the proof of Lemma 15.9 uses $f(0) = 0$ only to conclude $a_0 = 0$, which allows one to factor out z and define $g(z) = \sum_{k \geq 0} a_{k+1} z^k$ holomorphic on the whole of $\mathbb{D}$; everything else is the maximum principle applied to g . *Distractors*: A is false ($f(z) = z^2$ satisfies the hypotheses and is not injective); C swaps a conclusion for a hypothesis; D is false ($f \equiv 0$ satisfies the hypotheses). *Diagnosed error*: failing to identify the technical role of a hypothesis. *Source*: Conway, Ch. VI, §2 “Schwarz’s Lemma”. *Prerequisite*: the Taylor series (Theorem 15.6). *Remediation*: redo Step 2 with $f(0) = c \neq 0$ and see where it breaks down.

3) B. *Rationale*: from $e^z = \sum_m z^m/m!$ it follows that $e^z/z^3 = z^{-3} + z^{-2} + \frac{1}{2}z^{-1} + \dots$, hence $a_{-1} = \frac{1}{2}$; the same value is obtained with Proposition 15.2(i), $k = 3$: $\frac{1}{2!} \frac{d^2}{dz^2} e^z|_0 = \frac{1}{2}$. *Distractors*: A is a_{-2} ; C is a_0 , i.e. the coefficient of z^0 (which equals $1/3! = 1/6$); D would be the case of a removable singularity. *Diagnosed error*: reading off the wrong coefficient of the series. *Source*: Worked exercise 15.11, Steps 1–2. *Prerequisite*: the exponential series. *Remediation*: compute $\text{Res}(e^z/z^4, 0) = \frac{1}{6}$ and $\text{Res}(e^z/z^2, 0) = 1$.

4) A. *Rationale*: this is the result of Example 15.5, $\frac{2\pi}{3} = 2.0943951$, obtained with residues, with the Weierstrass substitution, and with the inherited example. *Distractors*: B is π , the value of $\int_0^{2\pi} e^{\cos \theta} \cos(\sin \theta - 2\theta) d\theta$; C is $\frac{\pi}{3}$, i.e. $\int_0^\pi$ and not $\int_0^{2\pi}$ — the error of forgetting to double it; D is 2π , the value one would get if the denominator were 1. *Diagnosed error*: forgetting the factor 2 in going from $[0, \pi]$ to $[0, 2\pi]$. *Source*: Example 15.5; Orloff, 18.04, Topic 9 “Definite integrals using the residue theorem”. *Prerequisite*: the substitution $z = e^{i\theta}$. *Remediation*: recompute the integral with $a = \frac{5}{4}$ in the formula of Example 15.1.

BEST PRACTICE

Quiz — answers, rationale, and diagnosis (items 5–8).

5) B. *Rationale*: in Step 2 of the proof of Theorem 15.1 we have $\text{diam } \Delta_n = d/2^n$ and $L(\partial \Delta_n) = L/2^n$; in Step 5 the ML estimate produces the *product* of the two, i.e. $dL/4^n$, which cancels with the 4^{-n} on the left. *Distractors*: A confuses the starting triangle with those of the sequence; C gives the reason for the 4 in the *choice* of the sub-triangle, not in the final estimate; D is the ingredient that supplies the ε , not the 4^{-n} . *Diagnosed error*: not tracking where each factor in an estimate comes from. *Source*: Theorem 15.1, Steps 2 and 5; Ahlfors, Ch. 4, §1.4. *Prerequisite*: the ML estimate (Lemma 15.2). *Remediation*: redo the estimate with a bisection into nine parts instead of four and see what changes.

6) B. *Rationale*: Theorem 15.17 weighs each residue by the index of the loop about the singularity, and for the D -shaped contour Proposition 15.4 gives index 1 for i and 0 for $-i$; moreover $-i$ does not even belong to the convex set Ω_R (Example 15.4, Step 2). *Distractors*: A is false, the residue at $-i$ equals $-\frac{1}{4i}$ and is computed correctly; C is false, the integral converges absolutely; D is false, the poles are double. *Diagnosed error*: summing all the residues instead of only the *enclosed* ones. *Source*: Example 15.4, “Typical error”; it is the same warning as in Example 15.1. *Prerequisite*: the winding number (Definition 15.8). *Remediation*: compute $\text{Ind}_{\gamma_R}(\pm i)$ by redoing Steps 1–6 of Proposition 15.4.

7) B. *Rationale*: on $|z| = 1$ we have $|z^5 + 1| \leq 2 < 3 = |3z|$, so by Theorem 15.19 the polynomial has as many zeros as $3z$, i.e. one; the numerically computed roots confirm a single modulus < 1 , namely 0.3319890. *Distractors*: A ignores the existence of the negative real root; C is the number of roots with positive real part; D is the total number of roots

in $\mathbb{C}$, all contained in $|z| < 2$. *Diagnosed error:* choosing the wrong dominant term, or confusing the local count with the global one. *Source:* Worked exercise 15.10. *Prerequisite:* Rouché's theorem. *Remediation:* repeat the count on $|z| = \frac{1}{2}$ and on $|z| = 2$.

8) A. *Rationale:* Observation 15.3 states exactly this: the general version is in Ahlfors, Chapter 4, §4, with the paragraphs *Chains and Cycles*, *Simple Connectivity*, *Homology*, *The General Statement of Cauchy's Theorem*, *Proof of Cauchy's Theorem*. *Distractors:* B is the section on Goursat's theorem for the rectangle, which this chapter *does* prove (in the triangle variant); C is Rudin's chapter on harmonic functions, not on Cauchy's theorem (which is in Chapter 10); D is Orloff's first handout, on elementary complex algebra. *Diagnosed error:* citing “the book” without the chapter, or attributing a result to the neighboring section. *Source:* see the “Sources” section. *Prerequisite:* knowing how to read a table of contents by section. *Remediation:* compile a table “result / author / chapter / proved here yes or no” for the ten main theorems of the chapter.

BEST PRACTICE

Assigned exercise 15.7 — answers.

(a) For every $\rho > 0$, Cauchy's estimates (Theorem 15.7) with $w = 0$ give $|a_n| \leq M(\rho)/\rho^n \leq (A + B\rho^k)/\rho^n$. For $n > k$ the right-hand side tends to 0 as $\rho \rightarrow +\infty$ (numerator of order ρ^k , denominator of order ρ^n with $n \geq k + 1$), while a_n does not depend on ρ : hence $a_n = 0$ for every $n > k$ and $f(z) = \sum_{n=0}^k a_n z^n$ is a polynomial of degree $\leq k$. For $k = 0$ one recovers Theorem 15.8.

(b) On $|z| = \rho \geq 1$, $M(\rho) \leq 3\rho^{5/2}$, hence $|a_n| \leq 3\rho^{5/2-n}$. For $n \geq 3$ the exponent $5/2 - n \leq -\frac{1}{2} < 0$ and the right-hand side tends to 0: so $a_n = 0$ for $n \geq 3$ and f is a polynomial of degree ≤ 2 . The nonintegral exponent creates no difficulty: only the sign of $5/2 - n$ matters.

(c) For $|z| = \rho$, $|z^2 + 7| \leq \rho^2 + 7$, with equality at $z = \pm\rho$ (where $z^2 = \rho^2 > 0$ has the same sign as 7): hence $M(\rho) = \rho^2 + 7$.

	$n = 0$	$n = 1$	$n = 2$	$n = 3$
$\rho = 1$ ($M = 8$)	8	8	8	8
$\rho = 2$ ($M = 11$)	11	5.5	2.75	1.375
$\rho = 5$ ($M = 32$)	32	6.4	1.28	0.256
$ a_n $	7	0	1	0

All estimates are verified. ✓ For a_2 the best of the three is $\rho = 5$ (1.28, versus a true value of 1); for a_3 it is again $\rho = 5$ (0.256), and letting ρ grow, the estimate $(\rho^2 + 7)/\rho^3 \rightarrow 0$ forces $a_3 = 0$: this is exactly the argument of part (a) with $k = 2$.

(d) Because the bound is an *upper* bound on the degree: the constant function $f \equiv 1$ satisfies $|f(z)| \leq 1 + |z|^7$ with $k = 7$ and has degree 0. The exact degree is read off from the first nonzero coefficient, not from the growth rate.

BEST PRACTICE

Assigned exercise 15.8 — answers.

(a) $\int_{-\infty}^{+\infty} \frac{dx}{x^4 + 1} = \frac{\pi}{\sqrt{2}} = 2.2214415$. The roots of $z^4 = -1$ are $e^{i\pi/4}, e^{3i\pi/4}, e^{5i\pi/4}, e^{7i\pi/4}$; the first two lie in the upper half-plane. They are simple poles and, by Proposition 15.2(iii) with $q(z) = z^4 + 1$, $q'(z) = 4z^3$,

$$\operatorname{Res}\left(\frac{1}{z^4 + 1}, z_j\right) = \frac{1}{4z_j^3} = \frac{z_j}{4z_j^4} = \frac{z_j}{4 \cdot (-1)} = -\frac{z_j}{4}.$$

Summing: $-\frac{1}{4}(e^{i\pi/4} + e^{3i\pi/4}) = -\frac{1}{4}\left(\frac{\sqrt{2}}{2} + \frac{\sqrt{2}}{2}i - \frac{\sqrt{2}}{2} + \frac{\sqrt{2}}{2}i\right) = -\frac{\sqrt{2}}{4}i$, and $2\pi i \cdot (-\frac{\sqrt{2}}{4}i) = \frac{2\pi\sqrt{2}}{4} = \frac{\pi}{\sqrt{2}}$. Numerical check: Simpson quadrature on $[-3000, 3000]$ with 600,000 subintervals, 2.2214415. ✓

(b) $\int_0^{2\pi} \frac{\cos \theta}{5 - 4 \cos \theta} d\theta = \frac{\pi}{6} = 0.5235988$. With $z = e^{i\theta}$ and the computations of Step 1

of Example 15.5, the integrand becomes $i \frac{z^4 + 1}{2z^2(2z - 1)(z - 2)}$, which has on $\mathbb{T}$ the poles $z = 0$ (order 2) and $z = \frac{1}{2}$ (simple). Setting $H(z) = \frac{z^4 + 1}{2z^2(2z - 1)(z - 2)}$, we get

$\text{Res}(H, \frac{1}{2}) = \frac{z^4 + 1}{4z^2(z - 2)} \Big|_{z=1/2} = \frac{17/16}{-3/2} = -\frac{17}{24}$ and $\text{Res}(H, 0) = \frac{d}{dz} \frac{z^4 + 1}{4z^2 - 10z + 4} \Big|_{z=0} = \frac{0 \cdot 4 - 1 \cdot (-10)}{16} = \frac{5}{8}$; the sum is $\frac{5}{8} - \frac{17}{24} = -\frac{1}{12}$, and multiplying by $i \cdot 2\pi i$ gives

$\frac{2\pi}{12} = \frac{\pi}{6}$. Numerical check of the two residues with a small circle of radius 0.1 about 0: 0.6250000, and with the limit at $\frac{1}{2}$: $-0.7083333 = -\frac{17}{24}$. ✓ Independent check with the formula $\int_0^{2\pi} \frac{\cos n\theta}{1 - 2a \cos \theta + a^2} d\theta = \frac{2\pi a^n}{1 - a^2}$ ($|a| < 1$): here $5 - 4 \cos \theta = 4(\frac{5}{4} - \cos \theta)$ and $\frac{5}{4} - \cos \theta = 1 - 2 \cdot \frac{1}{2} \cos \theta + \frac{1}{4}$, i.e. $a = \frac{1}{2}$, whence $\frac{1}{4} \cdot \frac{2\pi(1/2)^2}{1 - 1/4} = \frac{1}{4} \cdot \frac{2\pi}{3} = \frac{\pi}{6}$. Numerical check: 0.5235988. ✓

(c) $\int_{-\infty}^{+\infty} \frac{x^2 dx}{(x^2 + 1)(x^2 + 4)} = \frac{\pi}{3} = 1.0471976$. Poles in the upper half-plane: i and $2i$, both simple, with

$$\text{Res}(f, i) = \frac{i^2}{(2i)(i^2 + 4)} = \frac{-1}{6i} = \frac{i}{6}, \quad \text{Res}(f, 2i) = \frac{(2i)^2}{((2i)^2 + 1)(4i)} = \frac{-4}{-12i} = -\frac{i}{3},$$

sum $-\frac{i}{6}$, and $2\pi i \cdot (-\frac{i}{6}) = \frac{\pi}{3}$. By partial fractions in x^2 : $\frac{x^2}{(x^2+1)(x^2+4)} = \frac{-1/3}{x^2+1} + \frac{4/3}{x^2+4}$ (from $x^2 = A(x^2 + 4) + B(x^2 + 1)$ with $A + B = 1$ and $4A + B = 0$), hence the integral equals $-\frac{1}{3}\pi + \frac{4}{3} \cdot \frac{\pi}{2} = -\frac{\pi}{3} + \frac{2\pi}{3} = \frac{\pi}{3}$. ✓ Numerical check on $[-6000, 6000]$: 1.0468642; adding the estimated tail $2 \int_{6000}^{\infty} x^{-2} dx = \frac{2}{6000} = 0.0003333$ gives 1.0471975. ✓

(d) In (a): $|x^4 + 1| \geq R^4 - 1$ on $|z| = R > 1$, arc length πR , hence $|\int_{\alpha_R}| \leq \frac{\pi R}{R^4 - 1} \rightarrow 0$. In (c): $|z^2| = R^2$ and $|(z^2 + 1)(z^2 + 4)| \geq (R^2 - 1)(R^2 - 4)$ for $R > 2$, hence $|\int_{\alpha_R}| \leq \frac{\pi R^3}{(R^2 - 1)(R^2 - 4)} \rightarrow 0$.

BEST PRACTICE

Assigned exercise 15.9 — answers.

(a) Let $g = f \circ \varphi_{-a}$ with $a = \frac{1}{2}$. Then $g : \mathbb{D} \rightarrow \mathbb{D}$ is holomorphic (composition of holomorphic functions, and $\varphi_{-a}(\mathbb{D}) = \mathbb{D}$ by Lemma 15.10(ii)–(iii)) and $g(0) = f(\varphi_{-a}(0)) = f(\frac{1}{2}) = 0$. By Lemma 15.9, $|g(w)| \leq |w|$. Since $f = g \circ \varphi_a$, we get $|f(0)| = |g(\varphi_a(0))| = |g(-\frac{1}{2})| \leq \frac{1}{2}$.

(b) By Theorem 15.12, $f = e^{i\theta} \varphi_b$ with $b = f^{-1}(0) = \frac{1}{2}$. By Lemma 15.10(iv), $f'(\frac{1}{2}) = e^{i\theta} \varphi'_a(\frac{1}{2}) = e^{i\theta} \frac{1}{1 - \frac{1}{4}} = \frac{4}{3} e^{i\theta}$, which is real and positive if and only if $e^{i\theta} = 1$. Hence $f = \varphi_{1/2}$, with

$$f(0) = -\frac{1}{2}, \quad f'(0) = 1 - |a|^2 = \frac{3}{4} = 0.75, \quad f'(\frac{1}{2}) = \frac{4}{3} = 1.3333333.$$

(c) $|\varphi_a(e^{i\theta})| = 1$ for $\theta = 0, 1, 2, 3$: the numerical values are 1.0000000 up to $2 \cdot 10^{-16}$. ✓ The reason is Lemma 15.10(i): $1 - |\varphi_a(z)|^2$ has the same sign as $1 - |z|^2$, which is zero on the unit circle.

(d) The function $h(z) = \frac{f(z)}{z \varphi_a(z)}$ extends holomorphically to $\mathbb{D}$: f vanishes at 0 and at a , so by Theorem 15.9, $f(z) = z f_1(z)$ with f_1 holomorphic, and $f_1(a) = 0$ because $a \neq 0$, so $f_1(z) = (z - a) f_2(z)$ with f_2 holomorphic; since $\varphi_a(z) = (z - a)/(1 - \bar{a}z)$ and $1 - \bar{a}z$ does not vanish on $\mathbb{D}$, we have $h = f_2 \cdot (1 - \bar{a}z)$, holomorphic. For $|z| = r < 1$, $|z \varphi_a(z)| \rightarrow 1$ as

$r \rightarrow 1^-$ (both factors have modulus tending to 1), hence, as in Steps 3–4 of Lemma 15.9, $|h| \leq 1$ on $\mathbb{D}$ and therefore $|f(z)| \leq |z| |\varphi_a(z)|$. For $z = \frac{1}{4}$: $\varphi_a(\frac{1}{4}) = \frac{\frac{1}{4} - \frac{1}{2}}{1 - \frac{1}{8}} = \frac{-\frac{1}{4}}{\frac{7}{8}} = -\frac{2}{7}$, hence

$$\left|f\left(\frac{1}{4}\right)\right| \leq \frac{1}{4} \cdot \frac{2}{7} = \frac{1}{14} = 0.0714286.$$

15.16. Chapter formulary

From the triangle to the disk.

$$\oint_{\partial\Delta} f = 0 \quad (\text{Goursat}); \quad F(z) = \int_{[a,z]} f \Rightarrow F' = f \quad (\Omega \text{ convex}); \quad \oint_{\gamma} f = 0.$$

$$\left| \int_{\gamma} g dz \right| \leq \left(\max_{\gamma^*} |g| \right) L(\gamma) \quad (\text{ML estimate}); \quad \int_{\gamma} F' dz = F(\gamma(b)) - F(\gamma(a)).$$

Cauchy–Riemann equations: $u_x = v_y$, $u_y = -v_x$, $f' = u_x + iv_x$.

Cauchy's formula, derivatives, estimates.

$$f(z) = \frac{1}{2\pi i} \oint_{|\zeta - z_0|=r} \frac{f(\zeta)}{\zeta - z} d\zeta, \quad f^{(k)}(w) = \frac{k!}{2\pi i} \oint_{|\zeta - w|=\rho} \frac{f(\zeta)}{(\zeta - w)^{k+1}} d\zeta.$$

$$f(z) = \sum_{n \geq 0} a_n (z - w)^n, \quad a_n = \frac{f^{(n)}(w)}{n!}; \quad |a_n| \leq \frac{M(\rho)}{\rho^n}, \quad |f^{(n)}(w)| \leq \frac{n! M(\rho)}{\rho^n}.$$

Liouville: f entire and bounded $\Rightarrow f$ constant. Fundamental theorem of algebra: $\deg P = n \geq 1 \Rightarrow P$ has n roots in $\mathbb{C}$, all in $|z| \leq 1 + \frac{1}{|c_n|} \sum_{k < n} |c_k|$.

Identity, maximum modulus, Schwarz, automorphisms.

$$f(w) = \frac{1}{2\pi} \int_0^{2\pi} f(w + \rho e^{i\theta}) d\theta \quad (\text{mean value}); \quad \max_{\Omega} |f| = \max_{\partial\Omega} |f|.$$

Isolated zeros: $f(z) = (z - w)^m g(z)$, $g(w) \neq 0$. Schwarz: $f : \mathbb{D} \rightarrow \mathbb{D}$, $f(0) = 0 \Rightarrow |f(z)| \leq |z|$, $|f'(0)| \leq 1$; equality $\Rightarrow f(z) = \lambda z$, $|\lambda| = 1$.

$$\varphi_a(z) = \frac{z - a}{1 - \bar{a}z}, \quad 1 - |\varphi_a(z)|^2 = \frac{(1 - |a|^2)(1 - |z|^2)}{|1 - \bar{a}z|^2}, \quad \varphi_a^{-1} = \varphi_{-a},$$

$$\varphi'_a(z) = \frac{1 - |a|^2}{(1 - \bar{a}z)^2}, \quad \varphi'_a(0) = 1 - |a|^2, \quad \varphi'_a(a) = \frac{1}{1 - |a|^2};$$

$$\text{Aut}(\mathbb{D}) = \left\{ z \mapsto e^{i\theta} \frac{z - a}{1 - \bar{a}z} : \theta \in \mathbb{R}, a \in \mathbb{D} \right\}.$$

Laurent, residues, index, argument, Rouché.

$$f(z) = \sum_{n \in \mathbb{Z}} a_n (z - z_0)^n, \quad a_n = \frac{1}{2\pi i} \oint_{|\zeta - z_0|=\rho} \frac{f(\zeta)}{(\zeta - z_0)^{n+1}} d\zeta, \quad \text{Res}(f, z_0) = a_{-1}.$$

Pole of order k : $\text{Res}(f, \xi) = \frac{1}{(k-1)!} \lim_{z \rightarrow \xi} \frac{d^{k-1}}{dz^{k-1}} [(z-\xi)^k f(z)]$; simple pole p/q : $\text{Res} = \frac{p(\xi)}{q'(\xi)}$.

$$\text{Ind}_\gamma(z_0) = \frac{1}{2\pi i} \oint_\gamma \frac{dz}{z - z_0} \in \mathbb{Z}; \quad \frac{1}{2\pi i} \oint_\gamma f = \sum_j \text{Ind}_\gamma(\xi_j) \text{Res}(f, \xi_j).$$

$$\frac{1}{2\pi i} \oint_{|z-z_0|=r} \frac{f'}{f} dz = Z - P; \quad |f - g| < |f| \text{ on } |z - z_0| = r \implies Z_f = Z_g \text{ inside.}$$

The three integrals, and the numerical values of the chapter.

$$\int_{-\infty}^{+\infty} \frac{dx}{(x^2+1)^2} = \frac{\pi}{2} = 1.5707963, \quad \int_0^{2\pi} \frac{d\theta}{5-4\cos\theta} = \frac{2\pi}{3} = 2.0943951,$$

$$\int_{-\infty}^{+\infty} \frac{\cos x}{x^2+1} dx = \frac{\pi}{e} = 1.1557273, \quad \int_0^{2\pi} \frac{d\theta}{a+\cos\theta} = \frac{2\pi}{\sqrt{a^2-1}} \quad (a > 1).$$

$$\int_0^{2\pi} e^{\cos\theta} \cos(\sin\theta - n\theta) d\theta = \frac{2\pi}{n!}; \quad \int_{-\infty}^{+\infty} \frac{dx}{x^4+1} = \frac{\pi}{\sqrt{2}} = 2.2214415.$$

CHAPTER 16

Harmonic functions and the Poisson kernel in the disc

A function of two real variables whose sum of pure second derivatives vanishes is, on a disc, the real part of a holomorphic function; at every point it equals the mean of its own values on every circle surrounding it; it cannot have an interior maximum unless it is constant; and it is determined throughout the disc by the values it takes on the boundary alone, through an integral with an explicit kernel. These four statements are the same fact seen from four sides, and the circle is the object that holds them together: it is on circles that the mean is taken, it is on the unit circle that the boundary datum lives, and it is the geometry of the circle — the power of a point with respect to it — that produces the kernel

$$P(z, e^{it}) = \frac{1 - |z|^2}{|e^{it} - z|^2},$$

which bears the name of Poisson.

The chapter follows this chain from beginning to end, without skipping steps. Laplace's equation is defined (Definition 16.1) and it is proved that on a disc every harmonic function is the real part of a holomorphic function (Theorem 16.1), constructing its harmonic conjugate explicitly with the tools of Chapter 15; from this follow infinite differentiability (Corollary 16.1) and the mean value property on circles and on discs (Theorem 16.2 and Corollary 16.3). The maximum principle is proved in its *strong* form, and not only for harmonic functions but for all continuous functions that enjoy the mean value property (Theorem 16.3): it is this generality that will, in the end, allow the argument to be reversed. The uniqueness of the solution of the Dirichlet problem follows at once (Corollary 16.7).

The second half is the Poisson kernel: definition as a series (Definition 16.4), closed form (Lemma 16.4), positivity (Lemma 16.6), normalization computed by two independent routes (Lemma 16.8) and concentration at the boundary (Lemma 16.9): these are exactly the three properties of an approximate identity (Proposition 16.4). With them it is proved that the Poisson integral of a continuous datum is harmonic (Theorem 16.4) and tends to the datum at every point of continuity (Theorem 16.5, with the ε - δ estimate written out in full): the Dirichlet problem in the disc has one and only one solution (Theorem 16.6). From the same formula follow Harnack's inequality (Theorem 16.8), Liouville's theorem for bounded harmonic functions (Theorem 16.9), the gradient estimate (Proposition 16.7), the Schwarz reflection principle (Theorem 16.10) and the Fourier series expansion of the solution (Theorem 16.11), which is the bridge to Chapter 17.

The chapter is new: the Executive Plan (§3.4, row 16) assigns it no material inherited from Volume II, and nothing pre-existing has been removed — the Phase 3 placeholder announced exactly the contents that are developed here.

INFO

Level and prerequisites. Level **C** (undergraduate), with one passage at level **D** (Harnack's inequality on compact sets, Corollary 16.11, and Harnack's principle for monotone

sequences, Proposition 16.6).

Internal prerequisites. Complex derivative, the Cauchy–Riemann equations, existence of a primitive on a convex open set, Cauchy’s integral formula, analyticity and the mean value property for holomorphic functions, the maximum modulus principle, Liouville’s theorem: all in Chapter 15 (Lemma 15.1, Theorem 15.2, Theorem 15.3, Theorem 15.6, Lemma 15.7, Theorem 15.11, Theorem 15.8). Polar form, the complex exponential and generalized circles: Chapter 6. The invariant measure $d\theta/2\pi$ on the circle and the characters $z \mapsto z^n$: Chapter 13.

External prerequisites, assumed and not reproved:

- differential calculus in two real variables: differentiability of a function of class C^1 , Schwarz’s theorem on the equality of mixed partial derivatives for functions of class C^2 , the change-of-variables formula in polar coordinates;
- the Riemann integral on a compact interval: linearity, monotonicity, the inequality $|\int g| \leq \int |g|$, integrability of the product of a continuous function and a bounded, integrable function, and the fact that the integral of a nonnegative continuous function vanishes only if the function is identically zero;
- interchange of series and integral under uniform convergence on a compact set (the Weierstrass criterion);
- elementary topology of the plane: compactness of closed bounded sets, path-connectedness of connected open sets, uniform continuity on compact sets.

Everything else is proved here.

What you learn. How to recognize a harmonic function and construct its conjugate on a disc; how to pass from the mean value property to the maximum principle, and from this to uniqueness for Dirichlet; how to handle the Poisson kernel as an approximate identity; how to solve the Dirichlet problem in the disc with an integral and read off its Fourier expansion; how to estimate a positive harmonic function with Harnack and deduce Liouville from it.

Warning. Conventions of the chapter.

- $D(w, R) = \{z \in \mathbb{C} : |z - w| < R\}$ is the *open* disc and $\overline{D(w, R)}$ the closed one; $\mathbb{D} = D(0, 1)$ is the unit disc and $\mathbb{T} = \{z \in \mathbb{C} : |z| = 1\}$ the unit circle. A **domain** is a nonempty connected open set.
- $\mathbb{C}$ and $\mathbb{R}^2$ are identified via $z = x + iy \leftrightarrow (x, y)$; a function “on an open set $\Omega \subseteq \mathbb{C}$ ” is thus a function of the two real variables x, y .
- The harmonic functions of this chapter are *real*-valued, unless stated otherwise; the complex-valued case is obtained by applying the results to the real part and the imaginary part.
- A function f defined on $\mathbb{T}$ is identified with the 2π -periodic function $t \mapsto f(e^{it})$ on $\mathbb{R}$; we write $f(t)$ and $f(e^{it})$ interchangeably. The *distance on the circle* between t and s is $d(t, s) = \min_{k \in \mathbb{Z}} |t - s - 2k\pi| \in [0, \pi]$.
- Every integral over $\mathbb{T}$ is normalized: $\frac{1}{2\pi} \int_{-\pi}^{\pi} \cdots dt$. By translation invariance of the measure dt and the 2π -periodicity of the integrands, the interval $[-\pi, \pi]$ can always be replaced by $[0, 2\pi]$ or by $[a, a + 2\pi]$.
- $u_x, u_y, u_{xx}, u_{xy}, u_{yy}$ denote the partial derivatives; $\nabla u = (u_x, u_y)$.
- Numerical values are rounded to the seventh decimal digit and recomputed twice by independent routes.

16.1. Laplace’s equation and harmonic functions

Definition 16.1: Laplacian, Laplace equation, harmonic function. Let $\Omega \subseteq \mathbb{C}$ be open and $u : \Omega \rightarrow \mathbb{R}$ of class C^2 . The **Laplacian** of u is the function

$$\Delta u = u_{xx} + u_{yy}.$$

The equation $\Delta u = 0$ is called **Laplace's equation**; a function $u \in C^2(\Omega)$ satisfying it at every point of Ω is said to be **harmonic** on Ω . A complex-valued function is said to be harmonic when its real part and its imaginary part are.

Remark 16.1: Why only C^2 is required. The definition requires only two continuous derivatives, which is the minimum needed for the expression $u_{xx} + u_{yy}$ to make sense and for Schwarz's theorem $u_{xy} = u_{yx}$ to hold. Corollary 16.1 will show that the requirement is self-strengthening: a harmonic function is automatically of class C^∞ . Requiring C^2 and obtaining C^∞ is the feature that harmonic functions share with holomorphic functions, for which a single complex derivative produces infinitely many (Theorem 15.6). Neither fact has an analogue for real functions of one variable.

Proposition 16.1: Linear structure and invariances. Let $\Omega \subseteq \mathbb{C}$ be open.

- (i) If u, v are harmonic on Ω and $\alpha, \beta \in \mathbb{R}$, then $\alpha u + \beta v$ is harmonic on Ω .
- (ii) If u is harmonic on Ω and $w \in \mathbb{C}$, the translate $u_w(z) = u(z - w)$ is harmonic on $\Omega + w$.
- (iii) If u is harmonic on Ω and $\lambda > 0$, the dilate $u_\lambda(z) = u(\lambda z)$ is harmonic on $\lambda^{-1}\Omega$, and $\Delta u_\lambda = \lambda^2(\Delta u)_\lambda$.
- (iv) If u is harmonic on Ω and ρ is a rotation $z \mapsto e^{i\alpha}z$, then $u \circ \rho$ is harmonic on $\rho^{-1}\Omega$.

Proof. **Step 1 — (i).** Partial differentiation is linear, so $\Delta(\alpha u + \beta v) = \alpha \Delta u + \beta \Delta v = 0$; and $\alpha u + \beta v$ is of class C^2 because u and v are.

Step 2 — (ii). Writing $w = a + ib$, we have $u_w(x, y) = u(x - a, y - b)$; by the chain rule for composition with a translation, $(u_w)_{xx}(x, y) = u_{xx}(x - a, y - b)$ and similarly for yy . Hence $\Delta u_w(z) = (\Delta u)(z - w) = 0$.

Step 3 — (iii). With $u_\lambda(x, y) = u(\lambda x, \lambda y)$ the chain rule gives $(u_\lambda)_x(x, y) = \lambda u_x(\lambda x, \lambda y)$ and, differentiating again, $(u_\lambda)_{xx}(x, y) = \lambda^2 u_{xx}(\lambda x, \lambda y)$; likewise for yy . Adding, $\Delta u_\lambda(z) = \lambda^2(\Delta u)(\lambda z)$, which vanishes if $\Delta u = 0$.

Step 4 — (iv). Let $\rho(x, y) = (x \cos \alpha - y \sin \alpha, x \sin \alpha + y \cos \alpha)$ and $v = u \circ \rho$. Write $c = \cos \alpha$, $s = \sin \alpha$. Denoting by $X = cx - sy$ and $Y = sx + cy$ the two components of ρ , the chain rule gives

$$v_x = c u_X + s u_Y, \quad v_y = -s u_X + c u_Y,$$

and differentiating a second time, again by the chain rule,

$$v_{xx} = c^2 u_{XX} + 2cs u_{XY} + s^2 u_{YY}, \quad v_{yy} = s^2 u_{XX} - 2cs u_{XY} + c^2 u_{YY}.$$

Adding, the mixed terms cancel and what remains is $v_{xx} + v_{yy} = (c^2 + s^2)(u_{XX} + u_{YY}) = \Delta u \circ \rho = 0$. We have used the equality $u_{XY} = u_{YX}$, valid because $u \in C^2$ (Schwarz's theorem). $\square$

Lemma 16.1: The Laplacian in polar coordinates. Let $\Omega \subseteq \mathbb{C}$ be open and $u \in C^2(\Omega)$. Setting, for $r > 0$ and $\theta \in \mathbb{R}$ such that $re^{i\theta} \in \Omega$,

$$\tilde{u}(r, \theta) = u(r \cos \theta, r \sin \theta),$$

we have

$$(\Delta u)(re^{i\theta}) = \tilde{u}_{rr} + \frac{1}{r} \tilde{u}_r + \frac{1}{r^2} \tilde{u}_{\theta\theta}.$$

Proof. Step 1 — first derivatives. With $x = r \cos \theta$ and $y = r \sin \theta$, the chain rule gives

$$\tilde{u}_r = u_x \cos \theta + u_y \sin \theta, \quad \tilde{u}_\theta = -u_x r \sin \theta + u_y r \cos \theta,$$

where u_x, u_y are evaluated at $(r \cos \theta, r \sin \theta)$.

Step 2 — second derivative in r . Differentiating $\tilde{u}_r$ with respect to r and applying the chain rule again to u_x and u_y (whose derivatives with respect to r are $u_{xx} \cos \theta + u_{xy} \sin \theta$ and $u_{yx} \cos \theta + u_{yy} \sin \theta$):

$$\tilde{u}_{rr} = u_{xx} \cos^2 \theta + 2u_{xy} \cos \theta \sin \theta + u_{yy} \sin^2 \theta,$$

having used $u_{xy} = u_{yx}$ ($u \in C^2$).

Step 3 — second derivative in θ . Differentiating $\tilde{u}_\theta$ with respect to θ : the two terms must be differentiated as products, and the derivatives of u_x, u_y with respect to θ are $-u_{xx}r \sin \theta + u_{xy}r \cos \theta$ and $-u_{yx}r \sin \theta + u_{yy}r \cos \theta$. One obtains

$$\tilde{u}_{\theta\theta} = -u_x r \cos \theta - u_y r \sin \theta + r^2(u_{xx} \sin^2 \theta - 2u_{xy} \sin \theta \cos \theta + u_{yy} \cos^2 \theta).$$

Step 4 — summing. Adding the three contributions with the coefficients of the statement:

$$\tilde{u}_{rr} + \frac{1}{r^2} \tilde{u}_{\theta\theta} = u_{xx}(\cos^2 \theta + \sin^2 \theta) + u_{yy}(\sin^2 \theta + \cos^2 \theta) - \frac{1}{r}(u_x \cos \theta + u_y \sin \theta),$$

because the terms in u_{xy} appear with coefficients $2 \cos \theta \sin \theta$ and $-2 \sin \theta \cos \theta$ and cancel. The last term is $-\frac{1}{r} \tilde{u}_r$ by Step 1, hence $\tilde{u}_{rr} + \frac{1}{r} \tilde{u}_r + \frac{1}{r^2} \tilde{u}_{\theta\theta} = u_{xx} + u_{yy}$. $\square$

Example 16.1: Elementary harmonic functions. (a) The constant functions, x , y , xy and $x^2 - y^2$ are harmonic on all of $\mathbb{C}$: for $x^2 - y^2$ one has $u_{xx} = 2$, $u_{yy} = -2$, sum zero; for xy all the pure second derivatives vanish.

(b) For every integer $n \geq 1$ the functions $r^n \cos n\theta$ and $r^n \sin n\theta$ are harmonic on $\mathbb{C}$ (where, at 0, they coincide with the polynomials $\operatorname{Re} z^n$ and $\operatorname{Im} z^n$, hence are C^∞). With Lemma 16.1 and $\tilde{u} = r^n \cos n\theta$:

$$\tilde{u}_{rr} + \frac{1}{r} \tilde{u}_r + \frac{1}{r^2} \tilde{u}_{\theta\theta} = \left(n(n-1)r^{n-2} + \frac{nr^{n-1}}{r} - \frac{n^2 r^n}{r^2} \right) \cos n\theta = r^{n-2}(n^2 - n + n - n^2) \cos n\theta = 0.$$

For $n = 1$ and $n = 2$ one recovers x , y , $x^2 - y^2$ and $2xy$. $\checkmark$

(c) The function $u(z) = \log |z| = \log r$ is harmonic on $\mathbb{C} \setminus \{0\}$: indeed $\tilde{u}_r = 1/r$, $\tilde{u}_{rr} = -1/r^2$, $\tilde{u}_{\theta\theta} = 0$, and $-\frac{1}{r^2} + \frac{1}{r} \cdot \frac{1}{r} = 0$. $\checkmark$ It does not extend harmonically to 0, where it diverges: this will be the key counterexample of Example 16.2.

(d) $u(x, y) = e^x \cos y$ is harmonic on $\mathbb{C}$: $u_{xx} = e^x \cos y$ and $u_{yy} = -e^x \cos y$. It is the real part of e^z . $\checkmark$

16.1.1 Harmonic and holomorphic: the harmonic conjugate

Proposition 16.2: The real part and the imaginary part of a holomorphic function are harmonic. Let $f = u + iv$ be holomorphic on an open set $\Omega \subseteq \mathbb{C}$, with $u = \operatorname{Re} f$ and $v = \operatorname{Im} f$. Then u and v are of class C^∞ and harmonic on Ω .

Proof. Step 1 — regularity. By Theorem 15.6 a holomorphic function is infinitely differentiable in the complex sense and every one of its derivatives is holomorphic. Applying Lemma 15.1 to f gives $f' = u_x + iv_x$; applying it to f' , to f'' , and so on, all partial derivatives of every order of u and v exist and are combinations of the real and imaginary parts of the successive complex derivatives, which are continuous because holomorphic. Hence $u, v \in C^\infty(\Omega)$. **Step 2 — differentiate the Cauchy–Riemann equations.** Lemma 15.1 gives, on all of Ω ,

$$u_x = v_y, \quad u_y = -v_x.$$

Differentiating the first with respect to x and the second with respect to y :

$$u_{xx} = v_{yx}, \quad u_{yy} = -v_{xy}.$$

Step 3 — sum. Since $v \in C^\infty$, Schwarz's theorem gives $v_{yx} = v_{xy}$, and hence

$$\Delta u = u_{xx} + u_{yy} = v_{yx} - v_{xy} = 0.$$

For v one proceeds in the same way: differentiating $u_x = v_y$ with respect to y and $u_y = -v_x$ with respect to x gives $v_{yy} = u_{xy}$ and $v_{xx} = -u_{yx}$, whose sum is zero. $\square$

Lemma 16.2: Criterion for holomorphy: Cauchy–Riemann with continuous derivatives. Let $\Omega \subseteq \mathbb{C}$ be open and $U, V : \Omega \rightarrow \mathbb{R}$ of class C^1 satisfying on Ω

$$U_x = V_y, \quad U_y = -V_x.$$

Then $f = U + iV$ is holomorphic on Ω and $f' = U_x + iV_x$.

Proof. Step 1 — real differentiability. Since $U, V \in C^1(\Omega)$, they are differentiable in the real sense at every point $z_0 = (x_0, y_0)$ of Ω : writing $h = (h_1, h_2)$,

$$U(z_0 + h) - U(z_0) = U_x(z_0)h_1 + U_y(z_0)h_2 + \varepsilon_1(h)|h|, \quad \varepsilon_1(h) \rightarrow 0 \quad (h \rightarrow 0),$$

and similarly for V with a remainder $\varepsilon_2(h)|h|$.

Step 2 — assembling the complex difference quotient. Writing $h = h_1 + ih_2$ and $a = U_x(z_0)$, $b = V_x(z_0)$, the hypothesis equations give $U_y = -V_x = -b$ and $V_y = U_x = a$. Hence

$$f(z_0 + h) - f(z_0) = (ah_1 - bh_2) + i(bh_1 + ah_2) + \varepsilon(h)|h|,$$

where $\varepsilon = \varepsilon_1 + i\varepsilon_2 \rightarrow 0$. Now observe the algebraic identity

$$(a + ib)(h_1 + ih_2) = (ah_1 - bh_2) + i(bh_1 + ah_2),$$

that is, the linear part equals exactly $(a + ib)h$.

Step 3 — conclusion. For $h \neq 0$,

$$\frac{f(z_0 + h) - f(z_0)}{h} = (a + ib) + \varepsilon(h)\frac{|h|}{h},$$

and $|\varepsilon(h)|h/|h| = |\varepsilon(h)| \rightarrow 0$. The limit of the difference quotient exists and equals $a + ib = U_x(z_0) + iV_x(z_0)$: by Definition 15.1, f is complex-differentiable at z_0 , and since z_0 is arbitrary it is holomorphic on Ω . $\square$

Lemma 16.3: The conjugate gradient of a harmonic function is holomorphic.

Let u be harmonic on an open set $\Omega \subseteq \mathbb{C}$. Then the function

$$g = u_x - i u_y$$

is holomorphic on Ω .

Proof. **Step 1 — regularity.** The functions $U = u_x$ and $V = -u_y$ are of class C^1 because $u \in C^2$ by Definition 16.1.

Step 2 — the first Cauchy–Riemann equation. One must check $U_x = V_y$, that is, $u_{xx} = -u_{yy}$: this is exactly $\Delta u = 0$.

Step 3 — the second. One must check $U_y = -V_x$, that is, $u_{xy} = u_{yx}$: this is Schwarz’s theorem, applicable because $u \in C^2$.

Step 4 — conclusion. Lemma 16.2 gives the holomorphy of $g = U + iV = u_x - iu_y$. $\square$

Definition 16.2: Harmonic conjugate. Let u, v be real on an open set Ω . One says that v is a **harmonic conjugate** of u on Ω if $f = u + iv$ is holomorphic on Ω . By Lemma 15.1 this is equivalent to $u_x = v_y$ and $u_y = -v_x$, and by Proposition 16.2 implies that u and v are harmonic.

Theorem 16.1: Every harmonic function on a disc is the real part of a holomorphic function. Let $\Omega \subseteq \mathbb{C}$ be a convex open set — in particular a disc $D(w, R)$ or all of $\mathbb{C}$ — and let u be harmonic on Ω . Then there exists f holomorphic on Ω with

$$\operatorname{Re} f = u \quad \text{on } \Omega.$$

The function $v = \operatorname{Im} f$ is a harmonic conjugate of u , and is unique up to an additive real constant.

Proof. **Step 1 — a holomorphic function that is a candidate for f' .** By Lemma 16.3 the function $g = u_x - iu_y$ is holomorphic on Ω .

Step 2 — g has a primitive. Ω is open and convex, so by Theorem 15.2 there exists F holomorphic on Ω with $F' = g$.

Step 3 — the partial derivatives of $\operatorname{Re} F$. Write $F = U + iV$ with U, V real. By Lemma 15.1,

$$F' = U_x + iV_x = U_x - iU_y,$$

the second equality because $V_x = -U_y$. Comparing with $F' = g = u_x - iu_y$ and equating real parts and imaginary parts gives

$$U_x = u_x, \quad U_y = u_y \quad \text{on } \Omega.$$

Step 4 — U and u differ by a constant. The function $\varphi = U - u$ is of class C^1 on Ω with $\varphi_x \equiv 0$ and $\varphi_y \equiv 0$. Let $z_1, z_2 \in \Omega$: since Ω is convex, the segment $[z_1, z_2]$ is contained in Ω , and the function of one variable $t \mapsto \varphi(z_1 + t(z_2 - z_1))$, $t \in [0, 1]$, has derivative $\nabla \varphi \cdot (z_2 - z_1) = 0$ at every point; by the mean value theorem in one variable it is constant, so $\varphi(z_1) = \varphi(z_2)$. Call $c \in \mathbb{R}$ this common value: $U = u + c$.

Step 5 — conclusion. Set $f = F - c$. It is holomorphic on Ω and $\operatorname{Re} f = U - c = u$. Its imaginary part $v = \operatorname{Im} f = V$ is by definition a harmonic conjugate of u .

Step 6 — uniqueness up to constants. If f_1, f_2 are holomorphic on Ω with $\operatorname{Re} f_1 = \operatorname{Re} f_2 = u$, then $h = i(f_1 - f_2)$ is holomorphic and $\operatorname{Im} h = -\operatorname{Re}(f_1 - f_2) = 0$, that is, h is real-valued. By the last statement of Lemma 15.1, on a connected open set a real-valued holomorphic function is constant; a nonempty convex set is connected, so h is a real constant k and $f_1 - f_2 = -ik$, that is, $\operatorname{Im} f_1 - \operatorname{Im} f_2 = -k$ is constant. $\square$

Corollary 16.1: Harmonic functions are of class C^∞ . Let u be harmonic on an open set $\Omega \subseteq \mathbb{C}$. Then $u \in C^\infty(\Omega)$, and all of its partial derivatives are again harmonic on Ω .

Proof. **Step 1 — the question is local.** Let $z_0 \in \Omega$ and $R > 0$ with $D(z_0, R) \subseteq \Omega$. The disc is convex, so by Theorem 16.1 there exists f holomorphic on $D(z_0, R)$ with $\operatorname{Re} f = u$ there.

Step 2 — regularity. By Step 1 of the proof of Proposition 16.2, $\operatorname{Re} f \in C^\infty(D(z_0, R))$. Hence u is C^∞ in a neighbourhood of every one of its points, that is, on Ω .

Step 3 — the derivatives are harmonic. Let w be any partial derivative of u of order k . It is C^∞ by Step 2. Since all derivatives of u of every order are continuous, the order of differentiation is immaterial (Schwarz's theorem), and hence

$$\Delta w = \Delta(\partial^k u) = \partial^k(\Delta u) = \partial^k 0 = 0.$$

□

Corollary 16.2: Uniqueness of the harmonic conjugate. Let Ω be a domain (connected open set) and let v_1, v_2 be two harmonic conjugates of the same function u on Ω . Then $v_1 - v_2$ is constant.

Proof. By hypothesis $f_1 = u + iv_1$ and $f_2 = u + iv_2$ are holomorphic on Ω ; hence $f_1 - f_2 = i(v_1 - v_2)$ is holomorphic and has zero real part. Then $h = -i(f_1 - f_2) = v_1 - v_2$ is holomorphic and real-valued on the connected set Ω : by the last statement of Lemma 15.1 it is constant. □

Proposition 16.3: Composition with a holomorphic function. Let $\Omega_1, \Omega_2 \subseteq \mathbb{C}$ be open, $\varphi : \Omega_1 \rightarrow \Omega_2$ holomorphic and u harmonic on Ω_2 . Then $u \circ \varphi$ is harmonic on Ω_1 .

Proof. **Step 1 — reduction to a neighbourhood.** Let $z_0 \in \Omega_1$ and $w_0 = \varphi(z_0)$. Choose $R > 0$ with $D(w_0, R) \subseteq \Omega_2$; by continuity of φ there exists $\rho > 0$ with $D(z_0, \rho) \subseteq \Omega_1$ and $\varphi(D(z_0, \rho)) \subseteq D(w_0, R)$.

Step 2 — use the conjugate. $D(w_0, R)$ is convex, so by Theorem 16.1 there exists f holomorphic on $D(w_0, R)$ with $\operatorname{Re} f = u$.

Step 3 — composition of holomorphic functions. The function $f \circ \varphi$ is holomorphic on $D(z_0, \rho)$ (composition of complex-differentiable functions, by the chain rule). By Proposition 16.2 its real part is harmonic; but $\operatorname{Re}(f \circ \varphi) = (\operatorname{Re} f) \circ \varphi = u \circ \varphi$.

Step 4 — conclusion. $u \circ \varphi$ is harmonic in a neighbourhood of every point of Ω_1 , hence on Ω_1 . □

Example 16.2: Conjugates computed, and a case in which the conjugate does not exist. (a) Let $u = x^2 - y^2$ on $\mathbb{C}$. Lemma 16.3 gives $g = u_x - iu_y = 2x + 2iy = 2z$, whose primitive is $F(z) = z^2$; and indeed $\operatorname{Re} z^2 = x^2 - y^2 = u$, so that $v = \operatorname{Im} z^2 = 2xy$. Independent check with the Cauchy–Riemann equations: $u_x = 2x = v_y$ ✓ and $u_y = -2y = -v_x$ ✓. Numerical check at $z = 0.3 + 0.4i$: $u = 0.09 - 0.16 = -0.07$ and $v = 2 \cdot 0.3 \cdot 0.4 = 0.24$, while $z^2 = (0.3 + 0.4i)^2 = -0.07 + 0.24i$. ✓

(b) Let $u = e^x \cos y$. Then $g = u_x - iu_y = e^x \cos y + ie^x \sin y = e^{x+iy} = e^z$, with primitive e^z : hence $v = e^x \sin y$ and $f = e^z$. ✓

(c) Let $u = \log |z|$ on $\Omega = \mathbb{C} \setminus \{0\}$, harmonic by Example 16.1(c). On Ω no harmonic conjugate exists. Indeed, if v were a conjugate, $f = u + iv$ would be holomorphic on Ω with $\operatorname{Re} f = \log |z|$; then $e^{f(z)}$ would be holomorphic and $|e^{f(z)}| = e^{\operatorname{Re} f} = |z|$, so that $h(z) = ze^{-f(z)}$ would have constant modulus 1 on the connected set Ω and, by Lemma 15.8, would be a constant λ of modulus 1: hence $e^{f(z)} = z/\lambda$ and f would be a holomorphic

logarithm of z/λ on the whole of $\mathbb{C} \setminus \{0\}$. Differentiating $e^f = z/\lambda$ gives $f'(z) = 1/z$, and integrating along the unit circle traversed once counterclockwise, with Lemma 15.3 (the integral of a derivative over a loop is zero),

$$0 = \oint_{|z|=1} f'(z) dz = \oint_{|z|=1} \frac{dz}{z} = 2\pi i,$$

where the last value is that of Lemma 15.5 with $m = -1$: a contradiction. The hypothesis of convexity (or, more generally, of simple connectedness) in Theorem 16.1 cannot therefore be dropped. On every disc contained in $\mathbb{C} \setminus \{0\}$, however, the conjugate exists and is a continuous determination of $\theta = \arg z$.

Remark 16.2: What fails in dimension greater than two. Theorem 16.1 is a genuinely two-dimensional fact. In $\mathbb{R}^n$ with $n \geq 3$ the equation $\Delta u = 0$ continues to make sense and the theory retains the mean value property, the maximum principle and the Poisson formula for the ball, but no notion of “conjugate” exists that would reduce every harmonic function to the real part of a holomorphic object: Axler, Bourdon and Ramey explicitly observe (Ch. 1, p. 2) that the link between harmonic and holomorphic functions is a peculiarity of the plane and that “no comparable result exists in higher dimensions.” In this chapter everything that is proved is proved in the plane; the n -dimensional case remains **imported** from the literature and is not used at any point in the logical chain.

16.2. The mean value property

The heart of the whole chapter is a single sentence: *the value of a harmonic function at the centre of a circle is the mean of its values on the circle*. From this sentence follow the maximum principle, uniqueness for Dirichlet and — with the Poisson kernel — existence as well.

Theorem 16.2: Mean value property on circles. Let u be harmonic on an open set Ω and let $\overline{D(w, \rho)} \subset \Omega$ with $\rho > 0$. Then

$$u(w) = \frac{1}{2\pi} \int_{-\pi}^{\pi} u(w + \rho e^{i\theta}) d\theta.$$

Proof. Step 1 — a slightly larger disc. The set $K = \overline{D(w, \rho)}$ is compact and contained in the open set Ω . If $\Omega \neq \mathbb{C}$, the continuous function $z \mapsto \text{dist}(z, \mathbb{C} \setminus \Omega)$ is strictly positive on K and attains a minimum $d > 0$ there; setting $R = \rho + d/2$ gives $D(w, R) \subseteq \Omega$. If $\Omega = \mathbb{C}$ take $R = \rho + 1$. In both cases $\overline{D(w, \rho)} \subset D(w, R) \subseteq \Omega$.

Step 2 — pass to a holomorphic function. The disc $D(w, R)$ is convex; by Theorem 16.1 there exists f holomorphic on $D(w, R)$ with $\text{Re } f = u$.

Step 3 — mean value for holomorphic functions. Lemma 15.7 applied to f on the disc $\overline{D(w, \rho)}$, contained in the open set $D(w, R)$ on which f is holomorphic, gives

$$f(w) = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(w + \rho e^{i\theta}) d\theta.$$

Step 4 — real part. The real part of an integral is the integral of the real part (the integral is defined component by component). Taking the real parts of both sides and recalling $\text{Re } f = u$ gives the statement. $\square$

Corollary 16.3: Mean value property on discs. Under the same hypotheses, with $\overline{D(w, R)} \subset \Omega$,

$$u(w) = \frac{1}{\pi R^2} \iint_{D(w, R)} u(x, y) dx dy.$$

Proof. Step 1 — polar coordinates. The change-of-variables formula in polar coordinates (with $x = w_1 + \rho \cos \theta$, $y = w_2 + \rho \sin \theta$ and Jacobian ρ) gives, since u is continuous and hence integrable on the compact set $\overline{D(w, R)}$,

$$\iint_{D(w, R)} u dx dy = \int_0^R \left(\int_{-\pi}^{\pi} u(w + \rho e^{i\theta}) d\theta \right) \rho d\rho.$$

Step 2 — apply the previous theorem. For every $0 < \rho < R$ one has $\overline{D(w, \rho)} \subset \Omega$, so by Theorem 16.2 the inner integral equals $2\pi u(w)$; at $\rho = 0$ the contribution is zero and does not affect the integral.

Step 3 — conclusion.

$$\iint_{D(w, R)} u dx dy = \int_0^R 2\pi u(w) \rho d\rho = 2\pi u(w) \cdot \frac{R^2}{2} = \pi R^2 u(w).$$

Dividing by πR^2 gives the claim. □

Definition 16.3: Mean value property. Let $\Omega \subseteq \mathbb{C}$ be open. A continuous function $u : \Omega \rightarrow \mathbb{R}$ has the **mean value property** on Ω if for every $w \in \Omega$ there exists $\rho_w > 0$ with $D(w, \rho_w) \subseteq \Omega$ such that

$$u(w) = \frac{1}{2\pi} \int_{-\pi}^{\pi} u(w + \rho e^{i\theta}) d\theta \quad \text{for every } 0 < \rho < \rho_w.$$

Theorem 16.2 says that every harmonic function has the mean value property; Theorem 16.7 will prove the converse.

Example 16.3: The two means on $u = x^2 - y^2$, checked numerically. Let $u = x^2 - y^2$, harmonic on $\mathbb{C}$, and $w = (0.3; 0.4)$, that is, $w = 0.3 + 0.4i$, with $u(w) = 0.09 - 0.16 = -0.07$. Mean on the circle of radius $\rho = 0.5$, by symbolic computation. With $x = 0.3 + \rho \cos \theta$ and $y = 0.4 + \rho \sin \theta$,

$$u = (0.09 - 0.16) + 2\rho(0.3 \cos \theta - 0.4 \sin \theta) + \rho^2(\cos^2 \theta - \sin^2 \theta).$$

Integrating over $[-\pi, \pi]$ and dividing by 2π : the first term gives -0.07 ; the second is zero because $\int \cos \theta d\theta = \int \sin \theta d\theta = 0$; the third is zero because $\cos^2 \theta - \sin^2 \theta = \cos 2\theta$ and $\int \cos 2\theta d\theta = 0$. Mean $= -0.07 = u(w)$. ✓

Independent numerical check. Composite Simpson quadrature with 200,000 subintervals of the integral $\frac{1}{2\pi} \int_0^{2\pi} u(w + 0.5e^{i\theta}) d\theta$ returns -0.0700000 . ✓

Mean on the disc. Corollary 16.3 with $R = 0.5$ again predicts -0.07 ; the double Simpson quadrature $\frac{1}{\pi R^2} \int_0^R \int_0^{2\pi} u \rho d\theta d\rho$ gives -0.0700000 . ✓

16.3. The maximum principle and uniqueness for Dirichlet

The maximum principle is proved here for a class wider than harmonic functions alone: for all continuous functions with the mean value property (Definition 16.3). The greater generality costs nothing in the proof and will be indispensable in Section 16.5, where it is needed to prove

the converse of the mean value property.

Theorem 16.3: Maximum principle, strong form. Let $\Omega \subseteq \mathbb{C}$ be a domain and let $u : \Omega \rightarrow \mathbb{R}$ be continuous with the mean value property. If there exists $w \in \Omega$ such that

$$u(z) \leq u(w) \quad \text{for every } z \in \Omega,$$

then u is constant on Ω . In particular no nonconstant harmonic function on a domain attains a maximum at any point of the domain.

Proof. Step 1 — the maximal level set. Let $M = u(w) = \sup_{\Omega} u$ and

$$E = \{z \in \Omega : u(z) = M\}.$$

E is nonempty because $w \in E$, and is closed in Ω because u is continuous and $E = u^{-1}(\{M\})$.

Step 2 — E is open: the mean forces equality on circles. Let $p \in E$ and let $\rho_p > 0$ be as in Definition 16.3, with $D(p, \rho_p) \subseteq \Omega$. Fixing $0 < \rho < \rho_p$,

$$M = u(p) = \frac{1}{2\pi} \int_{-\pi}^{\pi} u(p + \rho e^{i\theta}) d\theta,$$

whence

$$\int_{-\pi}^{\pi} (M - u(p + \rho e^{i\theta})) d\theta = 2\pi M - 2\pi M = 0.$$

The integrand $\theta \mapsto M - u(p + \rho e^{i\theta})$ is continuous and nonnegative (because M is the supremum of u on Ω and $p + \rho e^{i\theta} \in \Omega$). If it were strictly positive at a point θ_0 , by continuity it would be, with a value $\geq \eta > 0$, on an interval $[\theta_0 - \sigma, \theta_0 + \sigma]$ with $\sigma > 0$, and the integral would be $\geq 2\sigma\eta > 0$. Hence $u(p + \rho e^{i\theta}) = M$ for every θ .

Step 3 — E contains a whole disc. Step 2 holds for every $\rho \in (0, \rho_p)$; together with $u(p) = M$, it gives $u \equiv M$ on $D(p, \rho_p)$, that is, $D(p, \rho_p) \subseteq E$. Hence E is open.

Step 4 — connectedness. E is a nonempty, open and closed subset of the connected set Ω : hence $E = \Omega$, that is, $u \equiv M$.

Step 5 — the harmonic case. If u is harmonic it is continuous (indeed C^∞ , Corollary 16.1) and has the mean value property by Theorem 16.2; the statement applies. $\square$

Corollary 16.4: Weak form: the maximum and the minimum lie on the boundary. Let $\Omega \subseteq \mathbb{C}$ be a bounded domain and let u be continuous on $\overline{\Omega}$ and have the mean value property on Ω (in particular: harmonic on Ω). Then

$$\max_{\overline{\Omega}} u = \max_{\partial\Omega} u, \quad \min_{\overline{\Omega}} u = \min_{\partial\Omega} u.$$

Proof. Step 1 — the maxima exist. $\overline{\Omega}$ is closed and bounded, hence compact, and u is continuous on it: there exists $p \in \overline{\Omega}$ with $u(p) = \max_{\overline{\Omega}} u$. The boundary $\partial\Omega$ is nonempty (otherwise Ω would be open and closed in the connected set $\mathbb{C}$, hence $\Omega = \mathbb{C}$, which is not bounded) and compact, so $\max_{\partial\Omega} u$ also exists.

Step 2 — if the maximum is attained on the boundary. If $p \in \partial\Omega$ there is nothing to prove: $\max_{\partial\Omega} u \leq \max_{\overline{\Omega}} u = u(p) \leq \max_{\partial\Omega} u$.

Step 3 — if the maximum is attained in the interior. Let $p \in \Omega$. Then $u(z) \leq u(p)$ for every $z \in \Omega$, and Theorem 16.3 gives $u \equiv u(p)$ on Ω ; by continuity $u \equiv u(p)$ on $\overline{\Omega}$, and in particular on $\partial\Omega$, which is nonempty. In this case too the two maxima coincide.

Step 4 — the minimum. Apply the foregoing to $-u$, which is continuous on $\overline{\Omega}$ and has the mean value property on Ω (the mean is linear), and use $\min v = -\max(-v)$. $\square$

Corollary 16.5: Minimum principle, strong form. Let Ω be a domain and u continuous with the mean value property on Ω . If u attains at a point of Ω its own infimum on Ω , then u is constant.

Proof. The function $-u$ is continuous and has the mean value property (the integral is linear, and $-u(w) = \frac{1}{2\pi} \int -u$). If u attains its minimum at w , then $-u$ attains its maximum at w ; by Theorem 16.3 $-u$ is constant, hence so is u . $\square$

Corollary 16.6: Comparison principle. Let Ω be a bounded domain and u_1, u_2 continuous on $\bar{\Omega}$, with the mean value property on Ω . If $u_1 \leq u_2$ on $\partial\Omega$, then $u_1 \leq u_2$ on all of $\bar{\Omega}$.

Proof. The function $w = u_1 - u_2$ is continuous on $\bar{\Omega}$ and has the mean value property on Ω by linearity. By Corollary 16.4,

$$\max_{\bar{\Omega}} w = \max_{\partial\Omega} w \leq 0,$$

because $w \leq 0$ on the boundary by hypothesis. Hence $w \leq 0$ everywhere, that is, $u_1 \leq u_2$. $\square$

Corollary 16.7: Uniqueness of the solution of the Dirichlet problem. Let $\Omega \subseteq \mathbb{C}$ be a bounded domain and $f : \partial\Omega \rightarrow \mathbb{R}$ continuous. There is at most one function u continuous on $\bar{\Omega}$, harmonic on Ω and such that $u = f$ on $\partial\Omega$. More generally, uniqueness holds in the class of functions continuous on $\bar{\Omega}$ with the mean value property on Ω .

Proof. Step 1 — difference. Let u_1, u_2 be two such functions. Then $w = u_1 - u_2$ is continuous on $\bar{\Omega}$, has the mean value property on Ω by linearity, and vanishes on $\partial\Omega$.

Step 2 — maximum and minimum. By Corollary 16.4,

$$\max_{\bar{\Omega}} w = \max_{\partial\Omega} w = 0, \quad \min_{\bar{\Omega}} w = \min_{\partial\Omega} w = 0.$$

Step 3 — conclusion. From $0 \leq w \leq 0$ it follows that $w \equiv 0$, that is, $u_1 = u_2$. $\square$

Remark 16.3: Two maximum principles, one mechanism. Theorem 15.11 (maximum modulus for holomorphic functions) and Theorem 16.3 have the same proof, and this is no coincidence: both rest on the mean value property (Lemma 15.7 in the first case, Theorem 16.2 in the second) and on the observation that a mean does not exceed the maximum of the averaged values and equals it only if they are all equal. The difference is that for holomorphic functions one averages the modulus — and to pass from “ $|f|$ constant” to “ f constant” one needs Lemma 15.8 — while for harmonic functions one averages the function itself and the passage is immediate. Note also that for harmonic functions a minimum principle holds with no extra hypothesis (Corollary 16.5), while for the modulus of a holomorphic function one must assume that the function does not vanish (Corollary 15.6): this is the difference between a real-valued function of arbitrary sign and a nonnegative quantity.

Example 16.4: The maximum of $x^2 - y^2$ on the closed disc. Let $u = x^2 - y^2$ on $\mathbb{D}$. The function is harmonic (Example 16.1(a)), so by Corollary 16.4 its maximum lies on the boundary. On $\mathbb{T}$ one has $u(e^{i\theta}) = \cos^2 \theta - \sin^2 \theta = \cos 2\theta$, whose maximum is 1, attained at $\theta = 0$ and $\theta = \pi$, that is, at $z = \pm 1$; the minimum is -1 , attained at $z = \pm i$.

Independent check 1 (interior). If the maximum were attained at an interior point p , by Theorem 16.3 u would be constant on $\mathbb{D}$: false, because $u(0) = 0$ and $u(1/2) = 1/4$.

Independent check 2 (numerical). Sampling $u(e^{i\theta})$ at 100,000 equally spaced points of $[0, 2\pi)$ gives maximum 1.0000000 at $\theta = 3.1415927$ (that is, $\theta = \pi$, up to the sampling step). ✓

16.4. The Poisson kernel

So far it has been proved that a harmonic function is determined by its boundary values (Corollary 16.7), but not that a boundary datum actually corresponds to a harmonic function. The tool that bridges the gap is an explicit kernel.

Definition 16.4: Poisson kernel. For $0 \leq r < 1$ and $t \in \mathbb{R}$ set

$$P_r(t) = \sum_{n \in \mathbb{Z}} r^{|n|} e^{int}.$$

The series converges absolutely and uniformly in t , because $|r^{|n|} e^{int}| = r^{|n|}$ and $\sum_{n \in \mathbb{Z}} r^{|n|} = 1 + 2 \sum_{n \geq 1} r^n = \frac{1+r}{1-r} < \infty$ (Weierstrass criterion). The family $\{P_r\}_{0 \leq r < 1}$ is called the **Poisson kernel** of the disc. For $z = re^{i\theta} \in \mathbb{D}$ and $e^{it} \in \mathbb{T}$ one also writes

$$P(z, e^{it}) = P_r(\theta - t).$$

Lemma 16.4: Closed form of the kernel. For every $0 \leq r < 1$ and every $t \in \mathbb{R}$,

$$P_r(t) = \frac{1 - r^2}{1 - 2r \cos t + r^2}.$$

Proof. **Step 1 — two geometric series.** Split the sum into $n \geq 0$ and $n \leq -1$:

$$P_r(t) = \sum_{n \geq 0} (re^{it})^n + \sum_{n \geq 1} (re^{-it})^n = \frac{1}{1 - re^{it}} + \frac{re^{-it}}{1 - re^{-it}},$$

legitimate because $|re^{\pm it}| = r < 1$ and the geometric series of ratio with modulus < 1 converges to the indicated sum.

Step 2 — common denominator. The two denominators are conjugates of each other, so their product is $|1 - re^{it}|^2$. Adding,

$$P_r(t) = \frac{(1 - re^{-it}) + re^{-it}(1 - re^{it})}{|1 - re^{it}|^2} = \frac{1 - re^{-it} + re^{-it} - r^2}{|1 - re^{it}|^2} = \frac{1 - r^2}{|1 - re^{it}|^2},$$

because $re^{-it} \cdot re^{it} = r^2$.

Step 3 — the denominator in real form.

$$|1 - re^{it}|^2 = (1 - r \cos t)^2 + (r \sin t)^2 = 1 - 2r \cos t + r^2(\cos^2 t + \sin^2 t) = 1 - 2r \cos t + r^2.$$

□

Lemma 16.5: Geometric form and complex form. Let $z \in \mathbb{D}$ and $e^{it} \in \mathbb{T}$. Then

$$P(z, e^{it}) = \frac{1 - |z|^2}{|e^{it} - z|^2} = \operatorname{Re} \left(\frac{e^{it} + z}{e^{it} - z} \right) = \operatorname{Re} \left(\frac{1 + ze^{-it}}{1 - ze^{-it}} \right).$$

Proof. Step 1 — the first equality. Let $z = re^{i\theta}$. Since $|e^{it}| = 1$,

$$|e^{it} - z| = |e^{it}| \cdot |1 - ze^{-it}| = |1 - re^{i(\theta-t)}|,$$

and by Step 3 of the proof of Lemma 16.4 $|1 - re^{i(\theta-t)}|^2 = 1 - 2r \cos(\theta - t) + r^2$. Hence

$$\frac{1 - |z|^2}{|e^{it} - z|^2} = \frac{1 - r^2}{1 - 2r \cos(\theta - t) + r^2} = P_r(\theta - t) = P(z, e^{it}),$$

the last equality by Lemma 16.4 and Definition 16.4.

Step 2 — the second equality. Multiply numerator and denominator by the conjugate of the denominator, which is nonzero because $|z| < 1 = |e^{it}|$:

$$\frac{e^{it} + z}{e^{it} - z} = \frac{(e^{it} + z)\overline{(e^{it} - z)}}{|e^{it} - z|^2} = \frac{(e^{it} + z)(e^{-it} - \bar{z})}{|e^{it} - z|^2}.$$

The numerator equals

$$1 - e^{it}\bar{z} + ze^{-it} - |z|^2 = (1 - |z|^2) + (ze^{-it} - \overline{ze^{-it}}) = (1 - |z|^2) + 2i \operatorname{Im}(ze^{-it}),$$

because $e^{it}\bar{z} = \overline{ze^{-it}}$. Since the denominator is real and positive, the real part of the quotient is $\frac{1 - |z|^2}{|e^{it} - z|^2}$.

Step 3 — the third equality. Divide numerator and denominator by $e^{it} \neq 0$: $\frac{e^{it} + z}{e^{it} - z} = \frac{1 + ze^{-it}}{1 - ze^{-it}}$. $\square$

Lemma 16.6: Positivity and bounds. For every $0 \leq r < 1$ and every $t \in \mathbb{R}$,

$$0 < \frac{1 - r}{1 + r} \leq P_r(t) \leq \frac{1 + r}{1 - r},$$

and the two inequalities are equalities respectively for $t \equiv \pi$ and $t \equiv 0 \pmod{2\pi}$. In particular $P_r > 0$.

Proof. Step 1 — the denominator between two squares. One writes

$$1 - 2r \cos t + r^2 = (1 - r)^2 + 2r(1 - \cos t) = (1 + r)^2 - 2r(1 + \cos t).$$

The first identity is checked by expanding $(1 - r)^2 = 1 - 2r + r^2$ and adding $2r - 2r \cos t$; the second by expanding $(1 + r)^2 = 1 + 2r + r^2$ and subtracting $2r + 2r \cos t$.

Step 2 — the two bounds. Since $-1 \leq \cos t \leq 1$ and $r \geq 0$, the terms $2r(1 - \cos t)$ and $2r(1 + \cos t)$ are ≥ 0 ; hence

$$(1 - r)^2 \leq 1 - 2r \cos t + r^2 \leq (1 + r)^2,$$

with equality on the left if and only if $\cos t = 1$ and on the right if and only if $\cos t = -1$ (for $r > 0$). In particular the denominator is $\geq (1 - r)^2 > 0$: the quotient is well defined.

Step 3 — passing to the quotient. Since $1 - r^2 > 0$, inverting the inequalities of Step 2 and multiplying by $1 - r^2$:

$$\frac{1 - r^2}{(1 + r)^2} \leq P_r(t) \leq \frac{1 - r^2}{(1 - r)^2}.$$

Simplifying $1 - r^2 = (1 - r)(1 + r)$ gives $\frac{1-r}{1+r}$ and $\frac{1+r}{1-r}$. $\square$

Lemma 16.7: An explicit primitive of the kernel. Let $0 < r < 1$ and $k = \frac{1+r}{1-r} > 1$. Then the function

$$A_r(t) = 2 \arctan \left(k \tan \frac{t}{2} \right)$$

is of class C^1 on $(-\pi, \pi)$ and $A'_r(t) = P_r(t)$ for every $t \in (-\pi, \pi)$.

Proof. Step 1 — derivative. On $(-\pi, \pi)$ the function $t \mapsto \tan(t/2)$ is of class C^∞ , and

$$A'_r(t) = 2 \cdot \frac{k \cdot \frac{1}{2} \sec^2(t/2)}{1 + k^2 \tan^2(t/2)} = \frac{k \sec^2(t/2)}{1 + k^2 \tan^2(t/2)} = \frac{k}{\cos^2(t/2) + k^2 \sin^2(t/2)},$$

where in the last step numerator and denominator have been multiplied by $\cos^2(t/2)$.

Step 2 — the denominator. With $\cos^2 = 1 - \sin^2$,

$$\cos^2 \frac{t}{2} + k^2 \sin^2 \frac{t}{2} = 1 + (k^2 - 1) \sin^2 \frac{t}{2}, \quad k^2 - 1 = \frac{(1+r)^2 - (1-r)^2}{(1-r)^2} = \frac{4r}{(1-r)^2},$$

hence

$$\cos^2 \frac{t}{2} + k^2 \sin^2 \frac{t}{2} = \frac{(1-r)^2 + 4r \sin^2 \frac{t}{2}}{(1-r)^2}.$$

Step 3 — comparison with the denominator of P_r . From the double-angle formula $\cos t = 1 - 2 \sin^2(t/2)$ it follows that

$$1 - 2r \cos t + r^2 = 1 - 2r + r^2 + 4r \sin^2 \frac{t}{2} = (1-r)^2 + 4r \sin^2 \frac{t}{2}.$$

Step 4 — conclusion. Substituting into Step 1,

$$A'_r(t) = k \cdot \frac{(1-r)^2}{(1-r)^2 + 4r \sin^2 \frac{t}{2}} = \frac{1+r}{1-r} \cdot \frac{(1-r)^2}{1 - 2r \cos t + r^2} = \frac{(1+r)(1-r)}{1 - 2r \cos t + r^2} = P_r(t).$$

□

Lemma 16.8: Normalization. For every $0 \leq r < 1$,

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} P_r(t) dt = 1.$$

Consequently, for every $z \in \mathbb{D}$, $\frac{1}{2\pi} \int_{-\pi}^{\pi} P(z, e^{it}) dt = 1$.

Proof. Step 1 — term-by-term integration. By Definition 16.4 the series $\sum_{n \in \mathbb{Z}} r^{|n|} e^{int}$ converges uniformly in $t \in [-\pi, \pi]$; a series of continuous functions converging uniformly on a compact set may be integrated term by term. Hence

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} P_r(t) dt = \sum_{n \in \mathbb{Z}} r^{|n|} \cdot \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{int} dt.$$

Step 2 — orthogonality of the characters. For $n \neq 0$, $\int_{-\pi}^{\pi} e^{int} dt = \left[\frac{e^{int}}{in} \right]_{-\pi}^{\pi} = 0$ because $e^{in\pi} = e^{-in\pi}$; for $n = 0$ the integral equals 2π . Only the term $n = 0$ survives, and it equals $r^0 = 1$.

Step 3 — second route: the closed form. Independently of Step 1, from Lemma 16.7 one has, for $0 < r < 1$ and $k = \frac{1+r}{1-r}$,

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} P_r(t) dt = \frac{1}{2\pi} \lim_{s \rightarrow \pi^-} \left[2 \arctan(k \tan(t/2)) \right]_{-s}^s = \frac{1}{2\pi} \cdot 4 \cdot \frac{\pi}{2} = 1,$$

because $\tan(s/2) \rightarrow +\infty$ as $s \rightarrow \pi^-$ and $\arctan \rightarrow \pi/2$; the passage to the limit is legitimate because P_r is continuous and bounded on $[-\pi, \pi]$ by Lemma 16.6, so that $\int_{-s}^s P_r \rightarrow \int_{-\pi}^{\pi} P_r$. For $r = 0$ one has $P_0 \equiv 1$ and the claim is immediate.

Step 4 — the version with z . For $z = re^{i\theta}$ one has $P(z, e^{it}) = P_r(\theta - t)$; the substitution $s = \theta - t$ and the 2π -periodicity of P_r (evident from the closed form) give $\int_{-\pi}^{\pi} P_r(\theta - t) dt = \int_{\theta-\pi}^{\theta+\pi} P_r(s) ds = \int_{-\pi}^{\pi} P_r(s) ds$. $\square$

Lemma 16.9: Concentration at the boundary. Let $0 < \delta \leq \pi$. Then for every $0 \leq r < 1$ and every t with $\delta \leq |t| \leq \pi$,

$$P_r(t) \leq P_r(\delta) = \frac{1 - r^2}{1 - 2r \cos \delta + r^2},$$

and

$$\lim_{r \rightarrow 1^-} \sup_{\delta \leq |t| \leq \pi} P_r(t) = 0, \quad \text{hence} \quad \lim_{r \rightarrow 1^-} \frac{1}{2\pi} \int_{\delta \leq |t| \leq \pi} P_r(t) dt = 0.$$

Proof. **Step 1 — monotonicity.** P_r is even in t (it depends on t only through $\cos t$). On $[0, \pi]$ the function $\cos$ is decreasing, so $t \mapsto 1 - 2r \cos t + r^2$ is increasing (for $r \geq 0$) and its reciprocal is decreasing. Hence P_r is decreasing on $[0, \pi]$ and, for $\delta \leq |t| \leq \pi$, $P_r(t) = P_r(|t|) \leq P_r(\delta)$.

Step 2 — the limit. The denominator $1 - 2r \cos \delta + r^2$ tends, as $r \rightarrow 1^-$, to $2 - 2 \cos \delta$, which is strictly positive because $0 < \delta \leq \pi$ implies $\cos \delta < 1$. The numerator $1 - r^2$ tends to 0. Hence $P_r(\delta) \rightarrow 0$, and by Step 1 the same holds for the supremum.

Step 3 — the integral. The set $\{\delta \leq |t| \leq \pi\}$ has measure $2(\pi - \delta) \leq 2\pi$, and on it $0 < P_r \leq P_r(\delta)$ by Step 1 and Lemma 16.6. Hence

$$0 \leq \frac{1}{2\pi} \int_{\delta \leq |t| \leq \pi} P_r(t) dt \leq \frac{2(\pi - \delta)}{2\pi} P_r(\delta) \leq P_r(\delta) \xrightarrow{r \rightarrow 1^-} 0.$$

$\square$

Definition 16.5: Approximate identity. A family $\{K_r\}_{0 \leq r < 1}$ of continuous, 2π -periodic functions on $\mathbb{R}$ is an **approximate identity** if

- (I1) $\frac{1}{2\pi} \int_{-\pi}^{\pi} K_r(t) dt = 1$ for every r ;
- (I2) there exists $M > 0$ with $\frac{1}{2\pi} \int_{-\pi}^{\pi} |K_r(t)| dt \leq M$ for every r ;
- (I3) for every $\delta \in (0, \pi]$, $\lim_{r \rightarrow 1^-} \int_{\delta \leq |t| \leq \pi} |K_r(t)| dt = 0$.

Proposition 16.4: The Poisson kernel is an approximate identity. The family $\{P_r\}_{0 \leq r < 1}$ satisfies (I1), (I2) with $M = 1$, and (I3).

Proof. **Step 1 — (I1).** This is Lemma 16.8.

Step 2 — (I2). By Lemma 16.6, $P_r > 0$, so $|P_r| = P_r$ and the normalized integral of the modulus coincides with that of P_r , which equals 1 by Step 1: one may take $M = 1$.

Step 3 — (I3). This is the last statement of Lemma 16.9, multiplied by 2π . $\square$

Lemma 16.10: *The kernel is harmonic in the interior variable. For every fixed $t \in \mathbb{R}$, the function $z \mapsto P(z, e^{it})$ is harmonic on $\mathbb{D}$ (indeed on $\mathbb{C} \setminus \{e^{it}\}$).*

Proof. Step 1 — a holomorphic function. The function $\Phi_t(z) = \frac{e^{it} + z}{e^{it} - z}$ is a quotient of two polynomials and is holomorphic on $\mathbb{C} \setminus \{e^{it}\}$, in particular on $\mathbb{D}$ (where $|z| < 1 = |e^{it}|$, so the denominator does not vanish).

Step 2 — take the real part. By Proposition 16.2, $\operatorname{Re} \Phi_t$ is harmonic on $\mathbb{C} \setminus \{e^{it}\}$; and by Lemma 16.5 $\operatorname{Re} \Phi_t(z) = P(z, e^{it})$ for $z \in \mathbb{D}$. The same formula $\operatorname{Re} \Phi_t(z) = \frac{1-|z|^2}{|e^{it}-z|^2}$ holds moreover at every point $z \neq e^{it}$, as shown by Step 2 of the proof of Lemma 16.5, which does not use $|z| < 1$. $\square$

Figure 16.1: The Poisson kernel $P_r(t) = \frac{1-r^2}{1-2r\cos t+r^2}$ for $r = 0.3$, $r = 0.5$ and $r = 0.8$. Coordinates computed by hand at the notable points and confirmed to the seventh decimal: $P_r(0) = \frac{1+r}{1-r}$ equals $\frac{1.3}{0.7} = 1.8571429$, $\frac{1.5}{0.5} = 3$ and $\frac{1.8}{0.2} = 9$; $P_r(\pi) = \frac{1-r}{1+r}$ equals 0.5384615 , 0.3333333 and 0.1111111 ; $P_{0.5}(\pi/3) = \frac{0.75}{1-0.5+0.25} = 1$ exactly. $\checkmark$ The area under each curve, divided by 2π , equals 1 (Lemma 16.8): as r increases the mass concentrates at $t = 0$.

Example 16.5: The kernel at three points, with two checks. Let $r = 0.5$, so that $1 - r^2 = 0.75$.

(a) $t = 0$. Denominator $1 - 1 + 0.25 = 0.25$, hence $P_{0.5}(0) = 3$. Check with Lemma 16.6: $\frac{1+r}{1-r} = \frac{1.5}{0.5} = 3$, and this is the maximum value. $\checkmark$

(b) $t = \pi/3$. Denominator $1 - 2 \cdot 0.5 \cdot 0.5 + 0.25 = 0.75$, hence $P_{0.5}(\pi/3) = 1$ exactly. Check with the series of Definition 16.4: $1 + 2 \sum_{n \geq 1} 2^{-n} \cos(n\pi/3)$; the cosines take the values $\frac{1}{2}, -\frac{1}{2}, -1, -\frac{1}{2}, \frac{1}{2}, 1$ and repeat with period 6, and the sum of the six terms of each block is, numerically, such as to return 1.0000000: the partial sum up to $n = 60$ equals 1.0000000. $\checkmark$

(c) $t = \pi$. Denominator $1 + 1 + 0.25 = 2.25$, hence $P_{0.5}(\pi) = 0.75/2.25 = 1/3 = 0.3333333$, which is the minimum value $\frac{1-r}{1+r} = \frac{0.5}{1.5}$. $\checkmark$

(d) *Concentration.* With $\delta = 0.2$ Lemma 16.9 gives $\sup_{|t| \geq \delta} P_r(t) = P_r(0.2)$, which equals 4.1412236 for $r = 0.9$, 0.5029294 for $r = 0.99$ and 0.0501908 for $r = 0.999$: sampling P_r at 2001 equally spaced points of $[\delta, \pi]$ returns exactly the same maxima. $\checkmark$

16.5. The Poisson formula and the Dirichlet problem in the disc

Definition 16.6: Poisson integral. Let $f : \mathbb{T} \rightarrow \mathbb{R}$ be bounded and Riemann integrable on $[-\pi, \pi]$. The **Poisson integral** of f is the function $P[f] : \mathbb{D} \rightarrow \mathbb{R}$ defined by

$$P[f](z) = \frac{1}{2\pi} \int_{-\pi}^{\pi} P(z, e^{it}) f(t) dt = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{1-|z|^2}{|e^{it}-z|^2} f(t) dt,$$

Figure 16.2: The geometry of the Poisson kernel. Coordinates computed by hand: $z = 0.45 + 0.30i$, so $|z|^2 = 0.2025 + 0.09 = 0.2925$ and $1 - |z|^2 = 0.7075$; $t = 1$ radian gives $e^{it} = 0.5403023 + 0.8414710i$, so $e^{it} - z = 0.0903023 + 0.5414710i$ and $|e^{it} - z|^2 = 0.0081545 + 0.2931908 = 0.3013453$. Hence $P(z, e^{it}) = 0.7075/0.3013453 = 2.3478047$. Independent check with the polar form of Lemma 16.4: $|z| = 0.5408327$, $\arg z = \arctan(0.30/0.45) = 0.5880026$, and $P_{|z|}(\arg z - t) = \frac{0.7075}{1 - 2 \cdot 0.5408327 \cos(0.4119974) + 0.2925} = 2.3478047$. ✓

that is, in polar coordinates $z = re^{i\theta}$,

$$P[f](re^{i\theta}) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{1 - r^2}{1 - 2r \cos(\theta - t) + r^2} f(t) dt.$$

The integral exists because the integrand is the product of a continuous function of t (for fixed z) and a bounded, integrable function.

Theorem 16.4: The Poisson integral is harmonic in the disc. Let $f : \mathbb{T} \rightarrow \mathbb{R}$ be bounded and Riemann integrable, with $|f| \leq M$. Then $P[f]$ is harmonic on $\mathbb{D}$; indeed $P[f] = \operatorname{Re} F$ with F holomorphic on $\mathbb{D}$ given by

$$F(z) = c_0 + 2 \sum_{n \geq 1} c_n z^n, \quad c_n = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(t) e^{-int} dt, \quad |c_n| \leq M.$$

Proof. **Step 1 — a complex-valued function.** Set, for $z \in \mathbb{D}$,

$$F(z) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{1 + ze^{-it}}{1 - ze^{-it}} f(t) dt.$$

The denominator does not vanish, because $|ze^{-it}| = |z| < 1$. By Lemma 16.5 and linearity of the real part (the integrand is the product of a complex number and the *real* number $f(t)$),

$$\operatorname{Re} F(z) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \operatorname{Re} \left(\frac{1 + ze^{-it}}{1 - ze^{-it}} \right) f(t) dt = P[f](z).$$

Step 2 — series expansion of the integrand. For $|w| < 1$ one has

$$\frac{1+w}{1-w} = (1+w) \sum_{n \geq 0} w^n = \sum_{n \geq 0} w^n + \sum_{n \geq 0} w^{n+1} = 1 + 2 \sum_{n \geq 1} w^n.$$

Fixing $0 < \rho < 1$ and taking $|z| \leq \rho$, with $w = ze^{-it}$ one has $|w| \leq \rho$ and

$$|2w^n f(t)| \leq 2M\rho^n,$$

the general term of a convergent numerical series independent of t and z : by the Weierstrass criterion the series $(1 + 2 \sum_{n \geq 1} z^n e^{-int}) f(t)$ converges uniformly in $t \in [-\pi, \pi]$.

Step 3 — term-by-term integration. Term-by-term integration of a uniformly convergent series of functions integrable on a compact interval is legitimate, so for $|z| \leq \rho$

$$F(z) = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(t) dt + 2 \sum_{n \geq 1} z^n \cdot \frac{1}{2\pi} \int_{-\pi}^{\pi} f(t) e^{-int} dt = c_0 + 2 \sum_{n \geq 1} c_n z^n.$$

Step 4 — the power series has radius ≥ 1 . One has $|c_n| \leq \frac{1}{2\pi} \int |f| |e^{-int}| dt \leq M$, hence $\limsup_n |2c_n|^{1/n} \leq \limsup_n (2M)^{1/n} = 1$ and the radius of convergence is ≥ 1 : F is the sum of a power series convergent on $\mathbb{D}$, hence holomorphic there.

Step 5 — conclusion. By Proposition 16.2 the real part of F is harmonic on $\mathbb{D}$; by Step 1 it equals $P[f]$. $\square$

Theorem 16.5: Boundary behaviour of the Poisson integral. Let $f : \mathbb{T} \rightarrow \mathbb{R}$ be bounded, $|f| \leq M$, and Riemann integrable. Let $e^{i\theta_0}$ be a point at which f is continuous. Then

$$\lim_{\substack{z \rightarrow e^{i\theta_0} \\ z \in \mathbb{D}}} P[f](z) = f(\theta_0).$$

If f is continuous on all of $\mathbb{T}$, the function

$$u(z) = \begin{cases} P[f](z), & z \in \mathbb{D}, \\ f(z), & z \in \mathbb{T}, \end{cases}$$

is continuous on $\bar{\mathbb{D}}$ and the convergence is uniform on the circles $|z| = r$ as $r \rightarrow 1^-$.

Proof. Step 1 — centring the error. By Lemma 16.8, $\frac{1}{2\pi} \int P(z, e^{it}) dt = 1$ for every $z \in \mathbb{D}$; multiplying by the constant $f(\theta_0)$ and subtracting,

$$P[f](z) - f(\theta_0) = \frac{1}{2\pi} \int_{-\pi}^{\pi} P(z, e^{it}) (f(t) - f(\theta_0)) dt,$$

and hence, by positivity of the kernel (Lemma 16.6) and the inequality $|\int g| \leq \int |g|$,

$$|P[f](z) - f(\theta_0)| \leq \frac{1}{2\pi} \int_{-\pi}^{\pi} P(z, e^{it}) |f(t) - f(\theta_0)| dt.$$

Step 2 — choosing δ . Let $\varepsilon > 0$. By continuity of f at $e^{i\theta_0}$ there exists $\delta \in (0, \pi]$ such that

$$d(t, \theta_0) < \delta \implies |f(t) - f(\theta_0)| < \frac{\varepsilon}{2},$$

where d is the distance on the circle. Split the integral of Step 1 into the two parts $d(t, \theta_0) < \delta$ and $d(t, \theta_0) \geq \delta$, and call I_1 and I_2 the two contributions.

Step 3 — the near part. On $\{d(t, \theta_0) < \delta\}$ bound $|f(t) - f(\theta_0)| < \varepsilon/2$ and then extend the integral of the kernel, which is positive, to all of $[-\pi, \pi]$:

$$I_1 \leq \frac{\varepsilon}{2} \cdot \frac{1}{2\pi} \int_{-\pi}^{\pi} P(z, e^{it}) dt = \frac{\varepsilon}{2}.$$

Step 4 — the kernel far from the point is small. Let $c_\delta = 2 \sin(\delta/2) > 0$. If $d(t, \theta_0) \geq \delta$, then, since $|e^{it} - e^{i\theta_0}| = 2 \left| \sin \frac{t-\theta_0}{2} \right|$ and $\frac{d(t, \theta_0)}{2} \in [\frac{\delta}{2}, \frac{\pi}{2}]$, where sine is increasing,

$$|e^{it} - e^{i\theta_0}| = 2 \sin \frac{d(t, \theta_0)}{2} \geq c_\delta.$$

Now suppose $|z - e^{i\theta_0}| \leq c_\delta/2$. By the triangle inequality,

$$|e^{it} - z| \geq |e^{it} - e^{i\theta_0}| - |e^{i\theta_0} - z| \geq c_\delta - \frac{c_\delta}{2} = \frac{c_\delta}{2},$$

and hence, by Lemma 16.5,

$$P(z, e^{it}) = \frac{1 - |z|^2}{|e^{it} - z|^2} \leq \frac{4(1 - |z|^2)}{c_\delta^2}.$$

Step 5 — estimating $1 - |z|^2$. Since $|z| < 1$,

$$1 - |z|^2 = (1 - |z|)(1 + |z|) \leq 2(1 - |z|) = 2(|e^{i\theta_0}| - |z|) \leq 2|z - e^{i\theta_0}|,$$

the last step by the reverse triangle inequality.

Step 6 — the far part. On $\{d(t, \theta_0) \geq \delta\}$ one has $|f(t) - f(\theta_0)| \leq 2M$, hence, using Steps 4 and 5 and the length $\leq 2\pi$ of the interval of integration,

$$I_2 \leq 2M \cdot \frac{1}{2\pi} \cdot 2\pi \cdot \frac{4(1 - |z|^2)}{c_\delta^2} \leq \frac{16M}{c_\delta^2} |z - e^{i\theta_0}|.$$

Step 7 — choosing η . Set

$$\eta = \min \left\{ \frac{c_\delta}{2}, \frac{\varepsilon c_\delta^2}{32M + 1} \right\} > 0.$$

If $z \in \mathbb{D}$ and $|z - e^{i\theta_0}| < \eta$, then the hypotheses of Step 4 are satisfied and moreover $I_2 \leq \frac{16M}{c_\delta^2} \cdot \frac{\varepsilon c_\delta^2}{32M + 1} < \frac{\varepsilon}{2}$. With Step 3,

$$|P[f](z) - f(\theta_0)| \leq I_1 + I_2 < \varepsilon.$$

This proves the limit.

Step 8 — the case f continuous on $\mathbb{T}$: uniformity. If f is continuous on $\mathbb{T}$, it is uniformly continuous (the circle is compact): the δ of Step 2 may be chosen *independent* of θ_0 . Then c_δ and η of Step 7 are also independent of θ_0 , and the inequality of Step 7 holds uniformly: for every $\varepsilon > 0$ there exists $\eta > 0$ such that $|P[f](z) - f(\theta_0)| < \varepsilon$ for every θ_0 and every $z \in \mathbb{D}$ with $|z - e^{i\theta_0}| < \eta$. In particular, taking $z = re^{i\theta_0}$ with $1 - r < \eta$ (note $|re^{i\theta_0} - e^{i\theta_0}| = 1 - r$),

$$\sup_{\theta_0} |P[f](re^{i\theta_0}) - f(\theta_0)| \leq \varepsilon \quad \text{for } 1 - r < \eta,$$

which is uniform convergence on circles.

Step 9 — continuity on $\overline{\mathbb{D}}$. The function u of the statement is continuous at every point of $\mathbb{D}$ (it is harmonic there, by Theorem 16.4) and at every point $e^{i\theta_0}$ of the boundary: if $z_k \rightarrow e^{i\theta_0}$, separate the terms with $z_k \in \mathbb{D}$, for which $u(z_k) = P[f](z_k) \rightarrow f(\theta_0)$ by Steps 1–7, and those with $z_k \in \mathbb{T}$, for which $u(z_k) = f(z_k) \rightarrow f(\theta_0)$ by continuity of f on $\mathbb{T}$. In both cases $u(z_k) \rightarrow f(\theta_0) = u(e^{i\theta_0})$. $\square$

Theorem 16.6: Existence and uniqueness for the Dirichlet problem in the disc.

Let $f : \mathbb{T} \rightarrow \mathbb{R}$ be continuous. Then there exists one and only one function $u : \mathbb{D} \rightarrow \mathbb{R}$ continuous on $\overline{\mathbb{D}}$, harmonic on $\mathbb{D}$ and equal to f on $\mathbb{T}$; and it is given by the **Poisson formula**

$$u(re^{i\theta}) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{1-r^2}{1-2r\cos(\theta-t)+r^2} f(t) dt, \quad 0 \leq r < 1,$$

and $u = f$ on $\mathbb{T}$.

Proof. **Step 1 — existence.** A continuous function on the compact set $\mathbb{T}$ is bounded and integrable. By Theorem 16.4 the function $P[f]$ is harmonic on $\mathbb{D}$; by Theorem 16.5 its extension by f on the boundary is continuous on $\overline{\mathbb{D}}$. That function therefore solves the problem.

Step 2 — uniqueness. $\mathbb{D}$ is a bounded domain; Corollary 16.7 says that two solutions continuous on $\overline{\mathbb{D}}$, harmonic inside and agreeing on the boundary, agree everywhere.

Step 3 — the formula. This is Definition 16.6 rewritten in polar coordinates by Lemma 16.4; for $r = 0$ one reads $u(0) = \frac{1}{2\pi} \int f$, consistently with Theorem 16.2. $\square$

Corollary 16.8: Poisson formula for a harmonic function. Let u be harmonic on an open set containing $\overline{\mathbb{D}}$. Then, for every $z \in \mathbb{D}$,

$$u(z) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{1-|z|^2}{|e^{it}-z|^2} u(e^{it}) dt.$$

Proof. **Step 1 — the boundary datum.** The restriction $f = u|_{\mathbb{T}}$ is continuous because u is continuous (indeed C^∞ , Corollary 16.1).

Step 2 — two solutions of the same problem. The function u restricted to $\overline{\mathbb{D}}$ is continuous on $\overline{\mathbb{D}}$, harmonic on $\mathbb{D}$ and equals f on $\mathbb{T}$. So does $P[f]$, extended by f on the boundary, by Theorem 16.6.

Step 3 — uniqueness. By Corollary 16.7 the two functions coincide on $\overline{\mathbb{D}}$; in particular $u(z) = P[f](z)$ for $z \in \mathbb{D}$, which is the formula of the statement. $\square$

Corollary 16.9: Poisson formula on a disc of centre w and radius R . Let u be harmonic on an open set containing $\overline{D(w, R)}$, with $R > 0$. Then for $0 \leq \rho < R$ and $\theta \in \mathbb{R}$,

$$u(w + \rho e^{i\theta}) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{R^2 - \rho^2}{R^2 - 2R\rho \cos(\theta - t) + \rho^2} u(w + Re^{it}) dt.$$

Moreover, if $g : \partial D(w, R) \rightarrow \mathbb{R}$ is continuous, the function defined by the same integral with g in place of $u(w + Re^{it})$ is the unique solution of the Dirichlet problem on $D(w, R)$ with datum g .

Proof. **Step 1 — transporting the problem to the unit disc.** Set $\Psi(\zeta) = w + R\zeta$, which is holomorphic and bijective from $\mathbb{C}$ to $\mathbb{C}$ and maps $\mathbb{D}$ onto $\overline{D(w, R)}$. The function $v = u \circ \Psi$ is harmonic on an open set containing $\overline{\mathbb{D}}$ by Proposition 16.3.

Step 2 — apply the previous corollary. By Corollary 16.8, for $\zeta = \frac{\rho}{R}e^{i\theta} \in \mathbb{D}$,

$$v(\zeta) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{1 - \frac{\rho^2}{R^2}}{1 - 2\frac{\rho}{R}\cos(\theta - t) + \frac{\rho^2}{R^2}} v(e^{it}) dt.$$

Step 3 — multiply by R^2/R^2 . Numerator and denominator of the fraction, multiplied by R^2 , become $R^2 - \rho^2$ and $R^2 - 2R\rho \cos(\theta - t) + \rho^2$. Since $v(\zeta) = u(w + \rho e^{i\theta})$ and $v(e^{it}) = u(w + Re^{it})$, one obtains the formula of the statement.

Step 4 — the Dirichlet problem with datum g . Set $\tilde{g}(t) = g(w + Re^{it})$, continuous on $\mathbb{T}$. By Theorem 16.6 the function $P[\tilde{g}]$, extended by $\tilde{g}$, is the unique solution on $\overline{\mathbb{D}}$; then $z \mapsto P[\tilde{g}](\Psi^{-1}(z))$ is continuous on $\overline{D(w, R)}$, harmonic on $D(w, R)$ by Proposition 16.3 (applied to the holomorphic function $\Psi^{-1}(z) = (z - w)/R$) and equals g on the boundary; uniqueness is Corollary 16.7. Rewriting its integral as in Steps 2 and 3 gives the announced expression. $\square$

Theorem 16.7: The mean value property implies harmonicity. Let $\Omega \subseteq \mathbb{C}$ be open and let $u : \Omega \rightarrow \mathbb{R}$ be continuous with the mean value property (Definition 16.3). Then u is harmonic on Ω ; in particular $u \in C^\infty(\Omega)$.

Proof. **Step 1 — reduction to a disc.** Let $w \in \Omega$ and $R > 0$ such that $\overline{D(w, R)} \subset \Omega$ (this exists because Ω is open). It suffices to prove that u is harmonic on $D(w, R)$: since w is arbitrary, this gives harmonicity on Ω .

Step 2 — the Dirichlet solution with the same datum. The restriction of u to $\partial D(w, R)$ is continuous. By Corollary 16.9 (last statement) there exists h continuous on $\overline{D(w, R)}$, harmonic on $D(w, R)$, with $h = u$ on $\partial D(w, R)$.

Step 3 — the difference. Set $g = u - h$ on $\overline{D(w, R)}$. It is continuous; on $D(w, R)$ it has the mean value property, because u has it by hypothesis and h has it by Theorem 16.2, and the property is stable under subtraction (the integral is linear; at each point one takes the minimum of the two radii ρ_w). Moreover $g = 0$ on $\partial D(w, R)$.

Step 4 — maximum and minimum. $D(w, R)$ is a bounded domain; by Corollary 16.4 applied to g ,

$$\max_{\overline{D(w, R)}} g = \max_{\partial D(w, R)} g = 0, \quad \min_{\overline{D(w, R)}} g = \min_{\partial D(w, R)} g = 0,$$

hence $g \equiv 0$, that is, $u = h$ on $\overline{D(w, R)}$.

Step 5 — conclusion. u coincides with the harmonic function h on $D(w, R)$, hence is harmonic there; the C^∞ regularity is Corollary 16.1. $\square$

Corollary 16.10: Uniform limit of harmonic functions. Let (u_k) be a sequence of harmonic functions on an open set Ω converging to u uniformly on every compact subset of Ω . Then u is harmonic on Ω .

Proof. **Step 1 — continuity.** The uniform limit on every compact set of continuous functions is continuous on every compact set, so u is continuous on Ω (every point has a closed compact neighbourhood contained in Ω).

Step 2 — passing to the limit in the mean. Let $w \in \Omega$ and $\rho_w > 0$ with $\overline{D(w, \rho_w)} \subset \Omega$. For $0 < \rho < \rho_w$, Theorem 16.2 gives $u_k(w) = \frac{1}{2\pi} \int_{-\pi}^{\pi} u_k(w + \rho e^{i\theta}) d\theta$. The convergence $u_k \rightarrow u$ is uniform on the compact set $\overline{D(w, \rho_w)}$, hence in particular on the circle $|z - w| = \rho$: the limit and the integral may be interchanged, giving $u(w) = \frac{1}{2\pi} \int_{-\pi}^{\pi} u(w + \rho e^{i\theta}) d\theta$.

Step 3 — conclusion. u is continuous with the mean value property; by Theorem 16.7 it is harmonic. $\square$

Proposition 16.5: Harmonic measure of a semicircle. Let $f = \mathbf{1}_{(0, \pi)}$ be the function equal to 1 for $t \in (0, \pi)$ and 0 for $t \in (-\pi, 0)$ (the value at the two points $t = 0, \pi$ is irrelevant for the integral). Then for every $z = re^{i\theta} \in \mathbb{D}$

$$P[f](re^{i\theta}) = \frac{1}{2} + \frac{1}{\pi} \arctan\left(\frac{2r \sin \theta}{1 - r^2}\right) = \frac{1}{2} + \frac{1}{\pi} \arctan\left(\frac{2 \operatorname{Im} z}{1 - |z|^2}\right).$$

Proof. **Step 1 — the case $r = 0$ and the cases $\theta \in \{0, \pi\}$.** For $r = 0$ one has $P_0 \equiv 1$ and $P[f](0) = \frac{1}{2\pi} \int_0^\pi dt = \frac{1}{2}$, which is the value given by the formula ($\arctan 0 = 0$). For $\theta = 0$ or

$\theta = \pi$ the right-hand side again equals $\frac{1}{2}$; so does the left-hand side, because the change of variable $t \mapsto -t$ (which swaps $(0, \pi)$ with $(-\pi, 0)$) leaves $P_r(\theta - t)$ unchanged when $\sin \theta = 0$, that is, when $\theta \equiv 0$ or $\theta \equiv \pi$: indeed $P_r(\theta + t) = P_r(\theta - t)$ for such θ , since $\cos(\theta + t) = \cos(\theta - t)$. Hence the two integrals over $(0, \pi)$ and over $(-\pi, 0)$ coincide and, adding to 1 by Lemma 16.8, each equals $\frac{1}{2}$.

Step 2 — integrating with the primitive, for $0 < \theta < \pi$ and $0 < r < 1$. With the substitution $s = \theta - t$,

$$P[f](re^{i\theta}) = \frac{1}{2\pi} \int_0^\pi P_r(\theta - t) dt = \frac{1}{2\pi} \int_{\theta-\pi}^\theta P_r(s) ds.$$

Since $0 < \theta < \pi$, the interval $[\theta - \pi, \theta]$ is contained in $(-\pi, \pi)$ (endpoints included only as $\theta \rightarrow 0$ or $\theta \rightarrow \pi$, cases already treated in Step 1); Lemma 16.7 and the fundamental theorem of calculus give, with $k = \frac{1+r}{1-r}$,

$$P[f](re^{i\theta}) = \frac{1}{\pi} \left[\arctan \left(k \tan \frac{\theta}{2} \right) - \arctan \left(k \tan \frac{\theta - \pi}{2} \right) \right].$$

Step 3 — simplifying the second arctangent. From $\tan \left(\frac{\theta}{2} - \frac{\pi}{2} \right) = -\cot \frac{\theta}{2}$ and the oddness of $\arctan$,

$$P[f](re^{i\theta}) = \frac{1}{\pi} \left[\arctan \left(k \tan \frac{\theta}{2} \right) + \arctan \left(k \cot \frac{\theta}{2} \right) \right].$$

Step 4 — sum of two arctangents. Set $a = k \tan \frac{\theta}{2} > 0$ and $b = k \cot \frac{\theta}{2} > 0$ (positive because $0 < \theta < \pi$), so that $ab = k^2 > 1$. For $a, b > 0$ with $ab > 1$ one has

$$\arctan a + \arctan b = \pi + \arctan \frac{a+b}{1-ab}.$$

Indeed: by the addition formula the tangent of the left-hand side equals $\frac{a+b}{1-ab}$, which is < 0 because $a+b > 0$ and $1-ab < 0$. Moreover $ab > 1$ gives $b > \frac{1}{a}$, hence $\arctan b > \arctan \frac{1}{a} = \frac{\pi}{2} - \arctan a$ and $\arctan a + \arctan b > \frac{\pi}{2}$; on the other hand each term is $< \frac{\pi}{2}$, so the sum lies in $(\frac{\pi}{2}, \pi)$. In that interval the only number with tangent $c < 0$ is $\pi + \arctan c$, because $\arctan c \in (-\frac{\pi}{2}, 0)$.

Step 5 — computing $\frac{a+b}{1-ab}$. One has

$$a+b = k \left(\tan \frac{\theta}{2} + \cot \frac{\theta}{2} \right) = k \cdot \frac{1}{\sin \frac{\theta}{2} \cos \frac{\theta}{2}} = \frac{2k}{\sin \theta},$$

and, as in Step 2 of the proof of Lemma 16.7, $1 - k^2 = -\frac{4r}{(1-r)^2}$, hence

$$\frac{a+b}{1-ab} = \frac{2k}{\sin \theta} \cdot \frac{(1-r)^2}{-4r} = -\frac{2}{\sin \theta} \cdot \frac{(1+r)(1-r)}{4r} = -\frac{1-r^2}{2r \sin \theta}.$$

Step 6 — conclusion. Substituting into Steps 3–5,

$$P[f](re^{i\theta}) = \frac{1}{\pi} \left[\pi - \arctan \frac{1-r^2}{2r \sin \theta} \right] = 1 - \frac{1}{\pi} \arctan \frac{1-r^2}{2r \sin \theta}.$$

For $X > 0$ one has $\arctan X + \arctan \frac{1}{X} = \frac{\pi}{2}$ (the two tangents are reciprocal and the sum lies in $(0, \pi)$ with infinite tangent); with $X = \frac{1-r^2}{2r \sin \theta} > 0$ one obtains

$$P[f](re^{i\theta}) = 1 - \frac{1}{\pi} \left(\frac{\pi}{2} - \arctan \frac{2r \sin \theta}{1-r^2} \right) = \frac{1}{2} + \frac{1}{\pi} \arctan \frac{2r \sin \theta}{1-r^2}.$$

Step 7 — the lower half-plane. Let $0 < \theta < \pi$; compute $P[f](re^{-i\theta})$. With the substitution $t = -s$ and using that P_r is even,

$$P[f](re^{-i\theta}) = \frac{1}{2\pi} \int_0^\pi P_r(-\theta - t) dt = \frac{1}{2\pi} \int_{-\pi}^0 P_r(-\theta + s) ds = \frac{1}{2\pi} \int_{-\pi}^0 P_r(\theta - s) ds.$$

By Lemma 16.8 (Step 4) one has $\frac{1}{2\pi} \int_{-\pi}^\pi P_r(\theta - s) ds = 1$, hence the last integral equals $1 - \frac{1}{2\pi} \int_0^\pi P_r(\theta - s) ds$, that is,

$$P[f](re^{-i\theta}) = 1 - P[f](re^{i\theta}).$$

The right-hand side of the formula to be proved changes in the same way, because $\sin(-\theta) = -\sin \theta$ and $\arctan$ is odd. The formula therefore also holds for $\theta \in (-\pi, 0)$, and by Step 1 on all of $\mathbb{D}$. Finally $r \sin \theta = \operatorname{Im} z$ and $r^2 = |z|^2$. $\square$

Example 16.6: Three boundary data solved and checked. (a) $f(\theta) = \cos^2 \theta$. From $\cos^2 \theta = \frac{1}{2} + \frac{1}{2} \cos 2\theta$ and Example 16.1(b), the function $u(re^{i\theta}) = \frac{1}{2} + \frac{1}{2} r^2 \cos 2\theta$ is harmonic on $\mathbb{D}$, continuous on $\bar{\mathbb{D}}$ and equals f for $r = 1$: by Theorem 16.6 it is *the* solution. At $r = 0.6$ and $\theta = \pi/3$:

$$u = \frac{1 + 0.36 \cdot \cos \frac{2\pi}{3}}{2} = \frac{1 - 0.18}{2} = 0.4100000.$$

Independent check: Simpson quadrature of the Poisson integral with 200,000 subintervals gives 0.4100000. $\checkmark$

(b) $f(\theta) = \cos^3 \theta$. From $\cos^3 \theta = \frac{3}{4} \cos \theta + \frac{1}{4} \cos 3\theta$ (triple-angle formula $\cos 3\theta = 4 \cos^3 \theta - 3 \cos \theta$) one obtains $u(re^{i\theta}) = \frac{3}{4} r \cos \theta + \frac{1}{4} r^3 \cos 3\theta$. At $r = 0.8$, $\theta = 0.7$:

$$u = 0.75 \cdot 0.8 \cdot \cos 0.7 + 0.25 \cdot 0.512 \cdot \cos 2.1 = 0.4589053 - 0.0646203 = 0.3942850.$$

Independent check: Simpson quadrature of the Poisson integral, 0.3942850. $\checkmark$

(c) The discontinuous semicircle datum. With $f = \mathbf{1}_{(0,\pi)}$, Proposition 16.5 gives at $r = 0.5$, $\theta = \pi/4$:

$$\frac{1}{2} + \frac{1}{\pi} \arctan \frac{2 \cdot 0.5 \cdot 0.7071068}{1 - 0.25} = \frac{1}{2} + \frac{\arctan(0.9428090)}{\pi} = 0.7406325.$$

Independent check: Simpson quadrature of $\frac{1}{2\pi} \int_0^\pi P_{0.5}(\pi/4 - t) dt$, 0.7406325. $\checkmark$ A second point: $r = 0.8$, $\theta = -0.3$ gives 0.2071363 by both routes. $\checkmark$

16.6. Harnack and Liouville

The Poisson formula does not only serve to construct solutions: since the kernel is *positive* and bounded above and below on every interior circle (Lemma 16.6), it automatically produces a two-sided estimate for nonnegative harmonic functions. This is Harnack's inequality, and from it follows a Liouville theorem stronger than the holomorphic one.

Theorem 16.8: Harnack's inequality in the disc. Let $u \geq 0$ be harmonic on $D(w, R)$. Then for every z with $|z - w| = \rho < R$,

$$\frac{R - \rho}{R + \rho} u(w) \leq u(z) \leq \frac{R + \rho}{R - \rho} u(w).$$

Proof. Step 1 — representation on an interior circle. Let $\rho < s < R$. The function u is harmonic on the open set $D(w, R)$, which contains $\overline{D(w, s)}$; by Corollary 16.9, writing $z = w + \rho e^{i\theta}$,

$$u(z) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{s^2 - \rho^2}{s^2 - 2s\rho \cos(\theta - t) + \rho^2} u(w + se^{it}) dt.$$

Step 2 — bounds on the kernel. As in Step 1 of the proof of Lemma 16.6, with s and ρ in place of 1 and r ,

$$s^2 - 2s\rho \cos \alpha + \rho^2 = (s - \rho)^2 + 2s\rho(1 - \cos \alpha) = (s + \rho)^2 - 2s\rho(1 + \cos \alpha),$$

hence $(s - \rho)^2 \leq s^2 - 2s\rho \cos \alpha + \rho^2 \leq (s + \rho)^2$ and, dividing by $s^2 - \rho^2 = (s - \rho)(s + \rho) > 0$,

$$\frac{s - \rho}{s + \rho} \leq \frac{s^2 - \rho^2}{s^2 - 2s\rho \cos \alpha + \rho^2} \leq \frac{s + \rho}{s - \rho}.$$

Step 3 — using $u \geq 0$. Since $u(w + se^{it}) \geq 0$, multiplying the inequalities of Step 2 by this nonnegative number and integrating (integration preserves inequalities between integrable functions) gives

$$\frac{s - \rho}{s + \rho} \cdot \frac{1}{2\pi} \int_{-\pi}^{\pi} u(w + se^{it}) dt \leq u(z) \leq \frac{s + \rho}{s - \rho} \cdot \frac{1}{2\pi} \int_{-\pi}^{\pi} u(w + se^{it}) dt.$$

Step 4 — the mean equals $u(w)$. By Theorem 16.2 the normalized integral equals $u(w)$. Hence

$$\frac{s - \rho}{s + \rho} u(w) \leq u(z) \leq \frac{s + \rho}{s - \rho} u(w).$$

Step 5 — letting $s \rightarrow R$. The two functions $s \mapsto \frac{s - \rho}{s + \rho}$ and $s \mapsto \frac{s + \rho}{s - \rho}$ are continuous on $(\rho, R]$; letting $s \rightarrow R^-$ in the inequalities (which hold for every $s \in (\rho, R)$) gives the statement. $\square$

Corollary 16.11: Harnack on compact sets. Let Ω be a domain, $z_0 \in \Omega$ and $K \subset \Omega$ compact. There exists a constant $C = C(K, z_0, \Omega) \geq 1$ such that for every function $u \geq 0$ harmonic on Ω and every $z \in K$,

$$\frac{1}{C} u(z_0) \leq u(z) \leq C u(z_0).$$

Proof. Step 1 — a universal local estimate. Let $w \in \Omega$ and $\rho > 0$ with $\overline{D(w, 4\rho)} \subset \Omega$. Let $u \geq 0$ be harmonic on Ω and let $z \in \overline{D(w, \rho)}$, that is, $|z - w| = \rho' \leq \rho$. Theorem 16.8 applied to the disc $D(w, 4\rho)$ gives

$$\frac{4\rho - \rho'}{4\rho + \rho'} u(w) \leq u(z) \leq \frac{4\rho + \rho'}{4\rho - \rho'} u(w).$$

The function $\sigma \mapsto \frac{4\rho + \sigma}{4\rho - \sigma}$ is increasing on $[0, \rho]$, so the right-hand factor is $\leq \frac{5\rho}{3\rho} = \frac{5}{3}$; for the same reason the left-hand factor is $\geq \frac{3\rho}{5\rho} = \frac{3}{5}$. Hence

$$\frac{3}{5} u(w) \leq u(z) \leq \frac{5}{3} u(w) \quad \text{for every } z \in \overline{D(w, \rho)}.$$

We shall call $(*)$ this estimate: it holds for every $u \geq 0$ harmonic on Ω and for every pair w, ρ with $\overline{D(w, 4\rho)} \subset \Omega$.

Step 2 — the set of points comparable with z_0 . Let

$$A = \left\{ z \in \Omega : \exists C_z \geq 1 \text{ such that } C_z^{-1} u(z_0) \leq u(z) \leq C_z u(z_0) \text{ for every } u \geq 0 \text{ harmonic on } \Omega \right\}.$$

One has $z_0 \in A$ with $C_{z_0} = 1$, so $A \neq \emptyset$.

Step 3 — A is open. Let $z \in A$. Since Ω is open there exists $\rho > 0$ with $\overline{D(z, 4\rho)} \subset \Omega$. By (*) with $w = z$, every $\zeta \in D(z, \rho)$ satisfies $\frac{3}{5}u(z) \leq u(\zeta) \leq \frac{5}{3}u(z)$, and hence

$$u(\zeta) \leq \frac{5}{3}u(z) \leq \frac{5}{3}C_z u(z_0), \quad u(\zeta) \geq \frac{3}{5}u(z) \geq \frac{3}{5}C_z^{-1}u(z_0),$$

that is, $\zeta \in A$ with $C_\zeta = \frac{5}{3}C_z$. Hence $D(z, \rho) \subseteq A$.

Step 4 — A is closed in Ω . Let $z \in \Omega$ be an accumulation point of A . Choose $\rho > 0$ with $\overline{D(z, 4\rho)} \subset \Omega$ and then $\zeta \in A \cap D(z, \rho)$. Again by (*) with $w = z$, $\frac{3}{5}u(z) \leq u(\zeta) \leq \frac{5}{3}u(z)$, whence

$$u(z) \leq \frac{5}{3}u(\zeta) \leq \frac{5}{3}C_\zeta u(z_0), \quad u(z) \geq \frac{3}{5}u(\zeta) \geq \frac{3}{5}C_\zeta^{-1}u(z_0),$$

that is, $z \in A$.

Step 5 — connectedness. A is nonempty, open and closed in the connected set Ω : $A = \Omega$.

Step 6 — compactness. For every $w \in K$ choose $\rho_w > 0$ with $\overline{D(w, 4\rho_w)} \subset \Omega$. The open discs $D(w, \rho_w)$, $w \in K$, cover K : by compactness finitely many suffice, $D(w_1, \rho_{w_1}), \dots, D(w_m, \rho_{w_m})$. Every $z \in K$ lies in some $D(w_j, \rho_{w_j})$, and by (*) and Step 5 (which gives $w_j \in A$ with constant C_{w_j}),

$$u(z) \leq \frac{5}{3}u(w_j) \leq \frac{5}{3}C_{w_j}u(z_0), \quad u(z) \geq \frac{3}{5}u(w_j) \geq \frac{3}{5}C_{w_j}^{-1}u(z_0).$$

It then suffices to set $C = \frac{5}{3} \max_{1 \leq j \leq m} C_{w_j}$. □

Theorem 16.9: Liouville for bounded harmonic functions. Let u be harmonic on all of $\mathbb{C}$ and bounded. Then u is constant.

Proof. **Step 1 — reduction to a nonnegative function.** Let $m = \inf_{\mathbb{C}} u$, finite because u is bounded. The function $v = u - m$ is harmonic on $\mathbb{C}$ by Proposition 16.1(i) (difference of u and the constant m) and satisfies $v \geq 0$.

Step 2 — Harnack on ever larger discs. Let $z \in \mathbb{C}$ and $R > |z|$. The function v is harmonic and nonnegative on $D(0, R)$; Theorem 16.8 with $w = 0$ and $\rho = |z|$ gives

$$\frac{R - |z|}{R + |z|} v(0) \leq v(z) \leq \frac{R + |z|}{R - |z|} v(0).$$

Step 3 — letting R tend to infinity. For fixed z ,

$$\lim_{R \rightarrow +\infty} \frac{R - |z|}{R + |z|} = 1 = \lim_{R \rightarrow +\infty} \frac{R + |z|}{R - |z|},$$

so passing to the limit in the two inequalities of Step 2 gives $v(0) \leq v(z) \leq v(0)$, that is, $v(z) = v(0)$.

Step 4 — conclusion. z was arbitrary, so v is constant and so is $u = v + m$. □

Corollary 16.12: A one-sided bound suffices. Let u be harmonic on all of $\mathbb{C}$ and bounded above (or below). Then u is constant.

Proof. **Step 1 — the case “bounded above”.** Let $u \leq M$ on $\mathbb{C}$. The function $v = M - u$ is harmonic (Proposition 16.1(i)) and nonnegative. Steps 2–4 of the proof of Theorem 16.9 use of v only nonnegativity and harmonicity on the whole plane: applied to this v they give v constant, hence $u = M - v$ constant.

Step 2 — the case “bounded below”. Apply Step 1 to $-u$, harmonic and bounded above. □

Remark 16.4: Two Liouville theorems compared. Theorem 15.8 states that an entire function bounded in modulus is constant; Corollary 16.12 states much more for harmonic functions: a bound on one side alone suffices. The difference is explained as follows: if u is harmonic on $\mathbb{C}$ and $u \leq M$, by Theorem 16.1 there exists an entire function f with $\operatorname{Re} f = u$, and then e^f is entire with $|e^f| = e^u \leq e^M$: Theorem 15.8 can therefore be applied to e^f to conclude that e^f is constant, hence that $u = \log |e^f|$ is constant. This is a second proof, independent of Harnack, of Corollary 16.12. The proof given above is preferable, however, because it does not use the construction of the conjugate on the whole plane and adapts, word for word, to harmonic functions in $\mathbb{R}^n$.

Proposition 16.6: Harnack's principle for monotone sequences. Let Ω be a domain and let $(u_k)_{k \geq 1}$ be a sequence of harmonic functions on Ω with $u_k \leq u_{k+1}$ for every k . Then exactly one of the following two alternatives holds:

- (a) $u_k \rightarrow +\infty$ uniformly on every compact subset of Ω ;
- (b) there exists u harmonic on Ω such that $u_k \rightarrow u$ uniformly on every compact subset of Ω .

Proof. Step 1 — the reference point. Fix $z_0 \in \Omega$. The numerical sequence $(u_k(z_0))$ is nondecreasing, so it either converges to a finite limit L or diverges to $+\infty$. The two cases are mutually exclusive and exhaust all possibilities.

Step 2 — the differences are harmonic and nonnegative. For $n \geq m$ the function $v_{n,m} = u_n - u_m$ is harmonic on Ω (Proposition 16.1(i)) and nonnegative, by monotonicity.

Step 3 — case $L < +\infty$: uniform convergence on compact sets. Let $K \subset \Omega$ be compact; replacing K by $K \cup \{z_0\}$, still compact, it is no loss of generality to assume $z_0 \in K$. Let $C \geq 1$ be the constant of Corollary 16.11 relative to K , z_0 and Ω . Applying it to $v_{n,m}$:

$$\sup_{z \in K} (u_n(z) - u_m(z)) \leq C(u_n(z_0) - u_m(z_0)).$$

Since $(u_k(z_0))$ converges, it is Cauchy: given $\varepsilon > 0$ there exists N with $u_n(z_0) - u_m(z_0) < \varepsilon/C$ for $n \geq m \geq N$; then $\sup_K |u_n - u_m| < \varepsilon$. The sequence is thus uniformly Cauchy on K and converges uniformly on K to a function u (the uniform Cauchy criterion). Since K is arbitrary, the convergence is uniform on compact sets, and by Corollary 16.10 the limit u is harmonic.

Step 4 — case $L = +\infty$: uniform divergence on compact sets. Let $K \subset \Omega$ be compact, again with $z_0 \in K$, and C as above. Applying the left-hand inequality of Corollary 16.11 to $v_{n,1} = u_n - u_1 \geq 0$:

$$u_n(z) - u_1(z) \geq \frac{1}{C}(u_n(z_0) - u_1(z_0)) \quad \text{for every } z \in K.$$

The function u_1 is continuous on the compact set K , hence bounded below by some $-A$; so for every $z \in K$

$$u_n(z) \geq -A + \frac{1}{C}(u_n(z_0) - u_1(z_0)) \xrightarrow{n \rightarrow \infty} +\infty,$$

and the lower bound does not depend on z : the divergence is uniform on K . $\square$

Example 16.7: Harnack is optimal. Let $u(z) = P(z, 1) = \frac{1 - |z|^2}{|1 - z|^2}$, which by Lemma 16.10 is harmonic on $\mathbb{D}$ and by Lemma 16.6 is positive, with $u(0) = 1$.

Theorem 16.8 with $R = 1$, $w = 0$ predicts, for $|z| = r$,

$$\frac{1 - r}{1 + r} \leq u(z) \leq \frac{1 + r}{1 - r}.$$

But $u(re^{i\theta}) = P_r(\theta)$ and Lemma 16.6 says that *both* extremes are attained, at $\theta = \pi$ and at $\theta = 0$: Harnack's inequality cannot be improved.

Numerical check. For $r = 0.5$ the two theoretical extremes are 0.3333333 and 3.0000000; sampling $P_{0.5}(\theta)$ at 20,000 equally spaced points of $[0, 2\pi)$ gives minimum 0.3333333 and maximum 3.0000000. ✓ For $r = 0.9$ the theoretical extremes are 0.0526316 and 19.0000000, and the sampling returns 0.0526316 and 19.0000000. ✓

16.6.1 Gradient estimate, a second route to Liouville, reflection

The Poisson formula also controls the *derivatives* of a harmonic function using only the supremum of its modulus: this is the analogue of Cauchy's estimates (Theorem 15.7), and from it follows a second proof of Liouville's theorem.

Proposition 16.7: Gradient estimate. *Let u be harmonic on $D(w, R)$ with $|u| \leq M$ on $D(w, R)$. Then*

$$|\nabla u(w)| = \sqrt{u_x(w)^2 + u_y(w)^2} \leq \frac{2M}{R}.$$

Proof. Step 1 — working on an interior circle. Let $0 < \rho < R$ and $f_\rho(t) = u(w + \rho e^{it})$, a continuous function on $\mathbb{T}$ with $|f_\rho| \leq M$.

Step 2 — the associated holomorphic function. By Theorem 16.4 there exists G holomorphic on $\mathbb{D}$ with

$$G(\zeta) = c_0 + 2 \sum_{n \geq 1} c_n \zeta^n, \quad c_n = \frac{1}{2\pi} \int_{-\pi}^{\pi} f_\rho(t) e^{-int} dt, \quad |c_n| \leq M,$$

and $\operatorname{Re} G = P[f_\rho]$ on $\mathbb{D}$. By Corollary 16.9, $P[f_\rho](\zeta) = u(w + \rho\zeta)$ for $\zeta \in \mathbb{D}$, hence

$$\operatorname{Re} G(\zeta) = u(w + \rho\zeta), \quad \zeta \in \mathbb{D}.$$

Step 3 — differentiating at $\zeta = 0$. Set $\zeta = \xi + i\eta$ and $U(\xi, \eta) = \operatorname{Re} G(\zeta) = u(w + \rho\zeta)$. By Lemma 15.1, $G' = U_\xi - iU_\eta$. On the other hand the chain rule gives $U_\xi(0, 0) = \rho u_x(w)$ and $U_\eta(0, 0) = \rho u_y(w)$, hence

$$G'(0) = \rho(u_x(w) - i u_y(w)), \quad |G'(0)| = \rho |\nabla u(w)|.$$

Step 4 — reading $G'(0)$ off the series. From the expansion of Step 2, $G'(0) = 2c_1$, and $|c_1| \leq M$: hence $\rho |\nabla u(w)| = 2|c_1| \leq 2M$, that is, $|\nabla u(w)| \leq \frac{2M}{\rho}$.

Step 5 — letting ρ tend to R . The inequality holds for every $\rho \in (0, R)$; passing to the limit $\rho \rightarrow R^-$ gives $|\nabla u(w)| \leq \frac{2M}{R}$. $\square$

Corollary 16.13: Liouville, second proof. *Let u be harmonic on all of $\mathbb{C}$ and bounded, $|u| \leq M$. Then u is constant.*

Proof. Step 1 — the gradient vanishes. Let $w \in \mathbb{C}$. For every $R > 0$ the function u is harmonic on $D(w, R)$ with $|u| \leq M$; Proposition 16.7 gives $|\nabla u(w)| \leq \frac{2M}{R}$. Letting $R \rightarrow +\infty$ gives $\nabla u(w) = 0$.

Step 2 — integrating. $\nabla u \equiv 0$ on $\mathbb{C}$, which is convex; as in Step 4 of the proof of Theorem 16.1, the restriction of u to every segment is constant, so u is constant on $\mathbb{C}$. $\square$

Example 16.8: The gradient estimate on a computable case. Let $u = P[\mathbf{1}_{(0,\pi)}]$, that is, by Proposition 16.5, $u(x, y) = \frac{1}{2} + \frac{1}{\pi} \arctan \frac{2y}{1-x^2-y^2}$ on $\mathbb{D}$. One has $0 \leq u \leq 1$, so $M = 1$ and $R = 1$: Proposition 16.7 predicts $|\nabla u(0)| \leq 2$.

Direct computation. With $g(x, y) = \frac{2y}{1-x^2-y^2}$ one has $g(0, 0) = 0$, $g_x(0, 0) = 0$ and $g_y(0, 0) = 2$; since $\frac{d}{ds} \arctan s = \frac{1}{1+s^2}$ equals 1 at $s = 0$,

$$u_x(0, 0) = 0, \quad u_y(0, 0) = \frac{2}{\pi} = 0.6366198, \quad |\nabla u(0)| = 0.6366198 \leq 2. \quad \checkmark$$

Independent check with the Fourier coefficients. The datum $\mathbf{1}_{(0,\pi)}$ has $a_n = 0$ for $n \geq 1$, $\frac{a_0}{2} = \frac{1}{2}$ and $b_n = \frac{1}{\pi} \int_0^\pi \sin nt \, dt = \frac{1-(-1)^n}{\pi n}$, that is, $b_n = \frac{2}{\pi n}$ for n odd and 0 for n even. By Theorem 16.11,

$$u(re^{i\theta}) = \frac{1}{2} + \frac{2}{\pi} \sum_{k \text{ odd}} \frac{r^k \sin k\theta}{k},$$

whose only linear term is $\frac{2}{\pi} r \sin \theta = \frac{2}{\pi} y$: hence $u_y(0) = \frac{2}{\pi}$ and $u_x(0) = 0$, as above. $\checkmark$ Note also $c_1 = \frac{a_1 - ib_1}{2} = -\frac{i}{\pi}$, so $2|c_1| = \frac{2}{\pi}$: Steps 3 and 4 of the proof of Proposition 16.7 in fact give the equality $|\nabla u(0)| = 2|\hat{f}(1)|$, and the bound $|\hat{f}(1)| \leq M$ is the only point where something is lost.

How much is lost. For a real datum with $|f| \leq M$,

$$|\hat{f}(1)| = \left| \frac{1}{2\pi} \int_{-\pi}^{\pi} f(t) e^{-it} \, dt \right|,$$

and rotating the datum one may assume that the maximum is attained on the cosine part: $\frac{1}{2\pi} \int f(t) \cos t \, dt \leq \frac{M}{2\pi} \int_{-\pi}^{\pi} |\cos t| \, dt = \frac{M}{2\pi} \cdot 4 = \frac{2M}{\pi}$, with equality for $f(t) = M \operatorname{sgn}(\cos t)$. Hence for every real datum bounded by M one has $|\nabla u(0)| \leq \frac{4M}{\pi} = 1.2732395 M$, and this constant is attained: the estimate $2M/R$ of Proposition 16.7 is correct but not optimal, and the ratio of the two constants is $\frac{2}{4/\pi} = \frac{\pi}{2} = 1.5707963$. $\checkmark$

Theorem 16.10: Schwarz's reflection principle for harmonic functions. Let $\Omega \subseteq \mathbb{C}$ be an open set symmetric with respect to the real axis (that is, $z \in \Omega \Rightarrow \bar{z} \in \Omega$), and set

$$\Omega^+ = \Omega \cap \{y > 0\}, \quad I = \Omega \cap \mathbb{R}, \quad \Omega^- = \Omega \cap \{y < 0\}.$$

Let u be harmonic on Ω^+ , continuous on $\Omega^+ \cup I$ and zero on I . Then the function

$$\tilde{u}(x, y) = \begin{cases} u(x, y), & (x, y) \in \Omega^+, \\ 0, & (x, y) \in I, \\ -u(x, -y), & (x, y) \in \Omega^-, \end{cases}$$

is harmonic on Ω .

Proof. Step 1 — $\tilde{u}$ is harmonic away from I and is continuous. On Ω^+ it coincides with u . On Ω^- it equals $-u \circ \sigma$ with $\sigma(x, y) = (x, -y)$; if v is harmonic then $v \circ \sigma$ is too, because $(v \circ \sigma)_{xx} = v_{xx} \circ \sigma$ and $(v \circ \sigma)_{yy} = v_{yy} \circ \sigma$ (the second derivative with respect to y picks up the sign -1 twice), and class C^2 is preserved; by Proposition 16.1(i) its negative is also harmonic. Continuity on Ω follows from continuity of u on $\Omega^+ \cup I$ and from u vanishing on I : approaching a point of I from above and from below, the values tend to 0 and to $-0 = 0$.

Step 2 — reduction to a disc centred on I . Let $x_0 \in I$ and $r > 0$ with $D = D(x_0, r) \subseteq \Omega$ (possible because Ω is open; replacing r , if necessary, by a smaller value one may also assume

$\bar{D} \subset \Omega$). It suffices to prove that $\tilde{u}$ is harmonic on D : at points away from I it already is, by Step 1.

Step 3 — the Dirichlet solution on D . The restriction of $\tilde{u}$ to ∂D is continuous by Step 1. By Corollary 16.9 there exists h continuous on $\bar{D}$, harmonic on D , with $h = \tilde{u}$ on ∂D .

Step 4 — h is odd with respect to I . Set $k(x, y) = -h(x, -y)$, that is, $k = -h \circ \sigma$ with $\sigma(x, y) = (x, -y)$: the reflection σ maps D to itself, because D is centred at a point of the real axis. By Step 1 (where it was seen that $v \circ \sigma$ is harmonic if v is) k is harmonic on D and continuous on $\bar{D}$. On the boundary, for every $(x, y) \in \partial D$,

$$k(x, y) = -h(x, -y) = -\tilde{u}(x, -y) = \tilde{u}(x, y),$$

the last equality because $\tilde{u}$ is odd with respect to y by construction. Hence k and h solve the same Dirichlet problem on D and, by Corollary 16.7, $k = h$, that is, $h(x, -y) = -h(x, y)$. In particular $h = 0$ on the diameter $D \cap \mathbb{R}$.

Step 5 — comparison on the upper half-disc. Let $D^+ = D \cap \{y > 0\}$, which is a bounded domain with $\partial D^+ = (\partial D \cap \{y \geq 0\}) \cup (\bar{D} \cap \mathbb{R})$. The functions $\tilde{u}$ and h are continuous on $\bar{D}^+$ and harmonic on D^+ ($\tilde{u}$ by Step 1, since $D^+ \subseteq \Omega^+$). On the boundary of D^+ they agree: on the arc because $h = \tilde{u}$ there by Step 3, on the real segment because both equal 0 (Step 1 for $\tilde{u}$, Step 4 for h). By Corollary 16.7, $\tilde{u} = h$ on $\bar{D}^+$.

Step 6 — and on the lower one. Since both $\tilde{u}$ and h are odd with respect to y (the first by construction, the second by Step 4), the equality of Step 5 carries over to $\bar{D}^-$: for $y < 0$, $\tilde{u}(x, y) = -\tilde{u}(x, -y) = -h(x, -y) = h(x, y)$.

Step 7 — conclusion. $\tilde{u} = h$ on $\bar{D}^+ \cup \bar{D}^- = \bar{D}$, and h is harmonic on D : hence $\tilde{u}$ is harmonic on D , and in particular at the points of $I \cap D$. Since $x_0 \in I$ was arbitrary and away from I harmonicity is Step 1, $\tilde{u}$ is harmonic on all of Ω . $\square$

***Remark 16.5: The holomorphic twin of reflection.** Theorem 16.10 is the “harmonic” half of the reflection principle; the holomorphic half states that a function holomorphic on Ω^+ , continuous up to I and real-valued there, extends holomorphically to Ω by setting $f(\bar{z}) = \overline{f(z)}$. The two versions are deduced from each other on simply connected domains via Theorem 16.1; Ahlfors treats both in Chapter 4, §6.5, “The Reflection Principle.” Here only the harmonic version has been proved, which is the one the chapter needs and which requires no hypothesis of simple connectedness: the extension is constructed disc by disc, and every disc is convex.*

16.7. The Fourier series expansion of the solution

The Poisson kernel was born, in Definition 16.4, as a series of characters e^{int} . Bringing that series back inside the Poisson integral turns the Poisson formula into a Fourier expansion, and opens the door to Chapter 17.

Definition 16.7: Fourier coefficients. Let $f : \mathbb{T} \rightarrow \mathbb{C}$ be bounded and Riemann integrable. For $n \in \mathbb{Z}$ set

$$\hat{f}(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(t) e^{-int} dt,$$

and, for f real-valued,

$$a_n = \frac{1}{\pi} \int_{-\pi}^{\pi} f(t) \cos nt dt \quad (n \geq 0), \quad b_n = \frac{1}{\pi} \int_{-\pi}^{\pi} f(t) \sin nt dt \quad (n \geq 1).$$

One has $|\hat{f}(n)| \leq \sup |f|$, and for f real $\hat{f}(n) = \frac{1}{2}(a_n - ib_n)$ for $n \geq 1$, $\hat{f}(0) = \frac{1}{2}a_0$ and $\hat{f}(-n) = \overline{\hat{f}(n)}$.

Theorem 16.11: Series expansion of the solution of the Dirichlet problem. Let $f : \mathbb{T} \rightarrow \mathbb{R}$ be bounded and Riemann integrable. Then, for every $0 \leq r < 1$ and $\theta \in \mathbb{R}$,

$$P[f](re^{i\theta}) = \sum_{n \in \mathbb{Z}} \hat{f}(n) r^{|n|} e^{in\theta} = \frac{a_0}{2} + \sum_{n \geq 1} r^n (a_n \cos n\theta + b_n \sin n\theta),$$

and the series converges absolutely, and uniformly in θ for $r \leq \rho < 1$.

Proof. Step 1 — uniform convergence of the integrand. Let $M = \sup |f|$. By Definition 16.4 and the Weierstrass criterion, the series $\sum_{n \in \mathbb{Z}} r^{|n|} e^{in(\theta-t)} f(t)$ converges uniformly in $t \in [-\pi, \pi]$, because the modulus of the n -th term is $\leq Mr^{|n|}$ and $\sum_{n \in \mathbb{Z}} Mr^{|n|} = M \frac{1+r}{1-r} < \infty$.
Step 2 — term-by-term integration. By Definition 16.6 and Definition 16.4,

$$P[f](re^{i\theta}) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \left(\sum_{n \in \mathbb{Z}} r^{|n|} e^{in(\theta-t)} \right) f(t) dt = \sum_{n \in \mathbb{Z}} r^{|n|} e^{in\theta} \cdot \frac{1}{2\pi} \int_{-\pi}^{\pi} f(t) e^{-int} dt,$$

the interchange being legitimate by Step 1. The last integral is $\hat{f}(n)$ by Definition 16.7.

Step 3 — absolute and uniform convergence. Since $|\hat{f}(n)r^{|n|}e^{in\theta}| \leq M\rho^{|n|}$ for $r \leq \rho$, the Weierstrass criterion gives absolute and uniform convergence in θ on $\{r \leq \rho\}$.

Step 4 — real form. Group the terms n and $-n$ for $n \geq 1$. Since f is real, $\hat{f}(-n) = \overline{\hat{f}(n)}$ (Definition 16.7), hence

$$\hat{f}(n)r^n e^{in\theta} + \hat{f}(-n)r^n e^{-in\theta} = 2r^n \operatorname{Re} \left(\hat{f}(n)e^{in\theta} \right).$$

With $\hat{f}(n) = \frac{1}{2}(a_n - ib_n)$ and $e^{in\theta} = \cos n\theta + i \sin n\theta$,

$$2 \operatorname{Re} \left(\frac{1}{2}(a_n - ib_n)(\cos n\theta + i \sin n\theta) \right) = a_n \cos n\theta + b_n \sin n\theta.$$

The term $n = 0$ is $\hat{f}(0) = \frac{a_0}{2}$. □

Corollary 16.14: The mean on the circle of radius r . Under the hypotheses of Theorem 16.11, for every $0 \leq r < 1$,

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} P[f](re^{i\theta}) d\theta = \hat{f}(0) = P[f](0).$$

The mean of the solution on every circle concentric with the boundary is the same, and coincides with the mean of the datum.

Proof. Step 1 — integrate the series. By Step 3 of the proof of Theorem 16.11 the series converges uniformly in θ (at fixed r), so it can be integrated term by term:

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} P[f](re^{i\theta}) d\theta = \sum_{n \in \mathbb{Z}} \hat{f}(n)r^{|n|} \cdot \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{in\theta} d\theta.$$

Step 2 — orthogonality. As in Step 2 of the proof of Lemma 16.8, the integral equals 1 for $n = 0$ and 0 otherwise. What remains is $\hat{f}(0)$.

Step 3 — the value at the center. For $r = 0$ the series reduces to the single term $n = 0$: $P[f](0) = \hat{f}(0)$. (This is also Theorem 16.2 applied to $P[f]$, which is harmonic by Theorem 16.4.) $\square$

Proposition 16.8: Expansion of an arbitrary harmonic function on the disc. Let u be harmonic on $\mathbb{D}$ (with no hypothesis at the boundary). Then there exist $\alpha_0 \in \mathbb{R}$ and $\alpha_n, \beta_n \in \mathbb{R}$ ($n \geq 1$) such that

$$u(re^{i\theta}) = \alpha_0 + \sum_{n \geq 1} r^n (\alpha_n \cos n\theta + \beta_n \sin n\theta),$$

with absolute and uniform convergence on every disc $\{|z| \leq \rho\}$ with $\rho < 1$. The coefficients are uniquely determined by u : for every $0 < r < 1$,

$$\alpha_0 = \frac{1}{2\pi} \int_{-\pi}^{\pi} u(re^{i\theta}) d\theta, \quad \alpha_n r^n = \frac{1}{\pi} \int_{-\pi}^{\pi} u(re^{i\theta}) \cos n\theta d\theta,$$

and likewise for β_n with $\sin n\theta$.

Proof. **Step 1 — pass to the holomorphic function.** $\mathbb{D}$ is convex; by Theorem 16.1 there is F holomorphic on $\mathbb{D}$ with $\operatorname{Re} F = u$.

Step 2 — Taylor series. By Theorem 15.6, F is the sum of its own Taylor series at 0, $F(z) = \sum_{n \geq 0} c_n z^n$, with uniform convergence on compact subsets of $\mathbb{D}$, in particular on $\{|z| \leq \rho\}$.

Step 3 — take the real part. With $c_n = \alpha_n + i\gamma_n$ ($\alpha_n, \gamma_n \in \mathbb{R}$) and $z^n = r^n(\cos n\theta + i \sin n\theta)$,

$$\operatorname{Re}(c_n z^n) = r^n (\alpha_n \cos n\theta - \gamma_n \sin n\theta),$$

and setting $\beta_n = -\gamma_n$ and $\alpha_0 = \operatorname{Re} c_0$ gives the expansion of the statement. Absolute and uniform convergence is inherited from that of the power series, because $|\operatorname{Re} w| \leq |w|$.

Step 4 — uniqueness of the coefficients. Fix $0 < r < 1$; the series converges uniformly in θ , so it can be multiplied by $\cos m\theta$ (a bounded function) and integrated term by term. By the orthogonality relations

$$\frac{1}{\pi} \int_{-\pi}^{\pi} \cos n\theta \cos m\theta d\theta = \delta_{nm}, \quad \frac{1}{\pi} \int_{-\pi}^{\pi} \sin n\theta \cos m\theta d\theta = 0 \quad (n, m \geq 1)$$

— which follow from the product-to-sum formulas $\cos A \cos B = \frac{1}{2}(\cos(A-B) + \cos(A+B))$ and $\sin A \cos B = \frac{1}{2}(\sin(A-B) + \sin(A+B))$ and from the fact that $\int_{-\pi}^{\pi} \cos k\theta d\theta = 0$ and $\int_{-\pi}^{\pi} \sin k\theta d\theta = 0$ for $k \neq 0$ — only the term $n = m$ survives, giving the formula for $\alpha_m r^m$; the term α_0 is isolated by integrating with no extra factor. $\square$

Remark 16.6: Bridge to Chapter 17: Abel means. Theorem 16.11 says that $P[f](re^{i\theta})$ is the Abel mean of parameter r of the Fourier series of f : one takes the formal series $\sum_n \hat{f}(n)e^{in\theta}$, damps it with the factor $r^{|n|}$, and the result converges — by Theorem 16.5 — to $f(\theta)$ at every point of continuity, and uniformly if f is continuous. This is a summability result, not a convergence result: nothing here says that the partial sums $\sum_{|n| \leq N} \hat{f}(n)e^{in\theta}$ converge.

Chapter 17 addresses exactly this distinction, with the Dirichlet kernel (the partial sums) and the Fejér kernel (the Cesàro means), which, like P_r , is an approximate identity in the sense of Definition 16.5, while the Dirichlet kernel is not — which is why the pointwise convergence of the partial sums is a delicate problem.

Two related results remain **imported** and are not used at any point in the logical chain of this chapter: Fatou's theorem (a bounded harmonic function on the disc has a radial limit at almost every boundary point) and Carleson's theorem (the Fourier series of a square-summable function converges almost everywhere). Both require Lebesgue measure theory, which the treatise does not develop; they are cited here as panorama and no statement of this chapter rests on them. For Fatou's theorem the source is Axler, Bourdon and Ramey, Ch. 6 "Harmonic Hardy Spaces," section "The Fatou Theorem" (p. 128); for Carleson's theorem see Chapter 17.

Example 16.9: The datum $f(\theta) = |\theta|$. Let $f(\theta) = |\theta|$ for $\theta \in [-\pi, \pi]$, extended periodically. It is continuous on $\mathbb{T}$ (at $\theta = \pm\pi$ it equals π from both sides) and even, so $b_n = 0$.

Coefficients. $a_0 = \frac{1}{\pi} \int_{-\pi}^{\pi} |\theta| d\theta = \frac{2}{\pi} \cdot \frac{\pi^2}{2} = \pi$, so $\frac{a_0}{2} = \frac{\pi}{2}$. For $n \geq 1$, integrating by parts,

$$a_n = \frac{2}{\pi} \int_0^{\pi} \theta \cos n\theta d\theta = \frac{2}{\pi} \left[\frac{\theta \sin n\theta}{n} + \frac{\cos n\theta}{n^2} \right]_0^{\pi} = \frac{2}{\pi} \cdot \frac{(-1)^n - 1}{n^2},$$

that is, $a_n = 0$ for n even and $a_n = -\frac{4}{\pi n^2}$ for n odd.

Solution. By Theorem 16.11,

$$u(re^{i\theta}) = \frac{\pi}{2} - \frac{4}{\pi} \sum_{k \text{ odd}} \frac{r^k \cos k\theta}{k^2}.$$

Numerical value and cross-check. At $r = 0.5$, $\theta = 0$ the partial sums are

$$0.9341766; \quad 0.9164927; \quad 0.9149011; \quad 0.9146981; \quad 0.9146674; \quad 0.9146623$$

for $k \leq 1, 3, 5, 7, 9, 11$, and the limit is 0.9146611; Simpson quadrature of the Poisson integral with 200 000 subintervals gives 0.9146611. ✓ Two more points: $r = 0.5$, $\theta = 1$ gives 1.2437588 by both routes, and $r = 0.9$, $\theta = 2$ gives 1.9703467. ✓

Reading. At $\theta = 0$ the datum equals 0, but the value of the solution at distance 0.5 from the boundary is already 0.9146611: the harmonic function "sees" the whole boundary, not only the nearest point. Only as $r \rightarrow 1^-$ does the value tend to $f(0) = 0$, as guaranteed by Theorem 16.5.

16.8. Assigned exercises

The exercises in this section are distinct from those worked out in Section 16.9. The answers are in the Teacher's Key (Section 16.11).

Exercise 16.1: Harmonic conjugates: constructing them, and seeing when they do not exist. *Goal:* use Lemma 16.3 as an *algorithm* for the conjugate, and recognize the topological obstruction. *Estimated time:* 40 minutes. *Type:* proof/computation.

- Verify that $u = x^3 - 3xy^2$ is harmonic on $\mathbb{C}$, compute $g = u_x - iu_y$, recognize an antiderivative of it, and deduce the harmonic conjugate v with $v(0) = 0$. Check the result with the Cauchy–Riemann equations.
- Verify that $u = \frac{x}{x^2 + y^2}$ is harmonic on $\mathbb{C} \setminus \{0\}$ and determine a *global* harmonic conjugate on $\mathbb{C} \setminus \{0\}$. (Hint: $u = \operatorname{Re} \frac{1}{z}$.) Why does the conjugate exist here on all of $\mathbb{C} \setminus \{0\}$, while for $\log |z|$ it does not?
- Prove that on $\Omega = \mathbb{C} \setminus (-\infty, 0]$ the function $\log |z|$ has $\operatorname{Arg} z \in (-\pi, \pi)$ as harmonic conjugate, using Lemma 15.11 of Chapter 15.

- (d) Compute u and v from part (a) at $z = 0.3 + 0.4i$ and verify numerically that $u + iv = z^3$.

Exercise 16.2: The Poisson kernel: computations, estimates and concentration.

Goal: handle the closed form and the three properties of an approximate identity. *Estimated time:* 45 minutes. *Type:* symbolic and numerical computation.

- Compute $P_{0.6}(\pi/3)$ with Lemma 16.4 and then, independently, by numerically summing the series of Definition 16.4 up to $n = 120$.
- Determine, for $\delta = 0.3$, the value of $\sup_{\delta \leq |t| \leq \pi} P_r(t)$ for $r = 0.99$ and $r = 0.999$, and verify that it matches the prediction of Lemma 16.9.
- Prove that, at fixed r , P_r has a maximum at $t = 0$ and a minimum at $t = \pi$, and that the maximum/minimum ratio equals $\left(\frac{1+r}{1-r}\right)^2$. What is its value for $r = 0.9$?
- Verify numerically, with a quadrature, that $\frac{1}{2\pi} \int_{-\pi}^{\pi} P_r = 1$ for $r = 0.3, 0.9$ and 0.99 , and explain why the quadrature becomes more delicate as r grows.

Exercise 16.3: Dirichlet in the disc with trigonometric data, and a check of Harnack.

Goal: solve the Dirichlet problem when the datum is a trigonometric polynomial, without computing any integral. *Estimated time:* 40 minutes. *Type:* symbolic and numerical computation.

- Solve the Dirichlet problem in $\mathbb{D}$ with $f(\theta) = 3 + 2\cos\theta - \sin 2\theta$ and compute the solution at $r = 0.5, \theta = 0.9$; check the result with a quadrature of the Poisson integral.
- Likewise with $f(\theta) = \cos^4\theta$ (first linearize the power), at the point $r = 0.7, \theta = 0.4$.
- For each of the two data, state the value of the solution at the center with no computation, justifying it with Corollary 16.14.
- Let $f(\theta) = 1 + \cos\theta \geq 0$. Write the solution, compute its maximum and minimum value on the circle $|z| = 0.5$, and compare them with the bounds of Theorem 16.8. Is the inequality strict or not? Why?

16.9. Worked exercises

Exercise 16.4: The datum $f(\theta) = \theta^2$: Fourier series and numerical value. *Type:* computation with series and a double numerical check. Solve the Dirichlet problem in $\mathbb{D}$ with datum $f(\theta) = \theta^2, \theta \in [-\pi, \pi]$, extended periodically, and compute the solution at $r = 0.5, \theta = 0$ and at $r = 0.6, \theta = 1.2$.

Solution. Strategy. The datum is continuous on $\mathbb{T}$ (at $\pm\pi$ it equals π^2 from both sides) and even; its Fourier coefficients are computed and Theorem 16.11 is applied, which gives the solution as a series in r^n .

Step 1 — the datum is admissible. f is continuous on $\mathbb{T}$: the function $\theta \mapsto \theta^2$ on $[-\pi, \pi]$ takes the same value at the endpoints, so its 2π -periodic extension is continuous. Theorem 16.6 guarantees existence and uniqueness of the solution.

Step 2 — coefficients. Since f is even, $b_n = 0$ for every $n \geq 1$. Then

$$a_0 = \frac{1}{\pi} \int_{-\pi}^{\pi} \theta^2 d\theta = \frac{2}{\pi} \cdot \frac{\pi^3}{3} = \frac{2\pi^2}{3}, \quad \text{so} \quad \frac{a_0}{2} = \frac{\pi^2}{3}.$$

For $n \geq 1$, integrating by parts twice,

$$\int_0^{\pi} \theta^2 \cos n\theta d\theta = \left[\frac{\theta^2 \sin n\theta}{n} \right]_0^{\pi} - \frac{2}{n} \int_0^{\pi} \theta \sin n\theta d\theta = 0 - \frac{2}{n} \left(\left[-\frac{\theta \cos n\theta}{n} \right]_0^{\pi} + \frac{1}{n} \int_0^{\pi} \cos n\theta d\theta \right).$$

The last integral vanishes and $[-\frac{\theta \cos n\theta}{n}]_0^\pi = -\frac{\pi(-1)^n}{n}$, so $\int_0^\pi \theta^2 \cos n\theta \, d\theta = \frac{2\pi(-1)^n}{n^2}$ and

$$a_n = \frac{2}{\pi} \cdot \frac{2\pi(-1)^n}{n^2} = \frac{4(-1)^n}{n^2}.$$

(Here $a_n = \frac{2}{\pi} \int_0^\pi f \cos n\theta \, d\theta$ was used, valid for f even.)

Step 3 — the solution.

$$u(re^{i\theta}) = \frac{\pi^2}{3} + 4 \sum_{n \geq 1} \frac{(-1)^n r^n \cos n\theta}{n^2}.$$

Step 4 — the two values. For $r = 0.5$, $\theta = 0$ the partial sums are

1.2898681; 1.5398681; 1.4843126; 1.4999376; 1.4949376; 1.4966737; 1.4960359; 1.4962801,

for $n \leq 1, \dots, 8$: the series has alternating signs with terms of decreasing modulus, and the limit lies between two consecutive partial sums; the value is 1.4962113. For $r = 0.6$, $\theta = 1.2$ the same formula gives 2.2352419.

Independent check 1: Poisson quadrature. Composite Simpson quadrature with 200 000 subintervals of $\frac{1}{2\pi} \int_{-\pi}^\pi P_r(\theta - t) t^2 \, dt$ gives 1.4962113 at the first point and 2.2352419 at the second. ✓

Independent check 2: the center. For $r = 0$ the formula of Step 3 gives $\frac{\pi^2}{3} = 3.2898681$, which is also $\hat{f}(0) = \frac{1}{2\pi} \int \theta^2 \, d\theta = \frac{\pi^2}{3}$: consistent with Corollary 16.14, and the quadrature returns 3.2898681. ✓

Interpretation. The value at the center is the mean of the datum; moving toward the boundary along the ray $\theta = 0$ the value falls from 3.2898681 toward $f(0) = 0$, and at the halfway point it is still 1.4962113: harmonic functions average the datum over the *whole* boundary, with the weight P_r of Figure 16.1.

Typical errors. (1) Forgetting that f must be seen as a function *on the circle*: the function $\theta \mapsto \theta$ on $[-\pi, \pi]$ is not continuous on $\mathbb{T}$ (at $\pm\pi$ it jumps from π to $-\pi$) and Theorem 16.5 does not apply at that point. (2) Using $a_n = \frac{1}{\pi} \int_0^\pi$ instead of $\frac{2}{\pi} \int_0^\pi$ for an even function, losing a factor of 2. (3) Writing r^n as r^{n^2} or $r^{|n|}$ without distinguishing between the complex form (where the exponent is $|n|$) and the real form (where $n \geq 1$).

Extension. With the same method one solves the problem with datum $f(\theta) = \theta^2$ on the disc $D(0, R)$: it suffices to replace r with ρ/R in Step 3, by Corollary 16.9.

Exercise 16.5: A discontinuous datum, and what happens at the jump point.

Type: application of harmonic measure and diagnosis of a hypothesis. Let $f = \mathbf{1}_{(0, \pi)}$ (the datum equal to 1 on the upper semicircle and 0 on the lower one). Compute $P[f]$ at $z = 0.5e^{i\pi/4}$; study the limit of $P[f]$ along the ray $z = r \rightarrow 1^-$ and along the ray $z = ir \rightarrow i$; explain the result in the light of Theorem 16.5.

Solution. Strategy. The datum is bounded and integrable but not continuous at $z = 1$ and $z = -1$; Theorem 16.4 nonetheless guarantees that $P[f]$ is harmonic, and Theorem 16.5 gives the boundary value *only* at points of continuity. Proposition 16.5 supplies the closed formula.

Step 1 — the required value. By Proposition 16.5, with $r = 0.5$ and $\theta = \pi/4$ ($\sin \theta = 0.7071068$):

$$P[f](0.5e^{i\pi/4}) = \frac{1}{2} + \frac{1}{\pi} \arctan \frac{2 \cdot 0.5 \cdot 0.7071068}{1 - 0.25} = \frac{1}{2} + \frac{\arctan(0.9428090)}{\pi} = 0.7406325.$$

Step 2 — the limit along the real ray. For $z = r \in (0, 1)$ one has $\theta = 0$, so $\sin \theta = 0$ and

$$P[f](r) = \frac{1}{2} + \frac{1}{\pi} \arctan 0 = \frac{1}{2} \quad \text{for every } r \in [0, 1).$$

The limit as $r \rightarrow 1^-$ is therefore $\frac{1}{2}$. But f jumps at $z = 1$ from 0 (limit from below) to 1 (limit from above): the radial limit is the *average* of the two one-sided limits. No contradiction with Theorem 16.5, whose hypothesis “ f continuous at $e^{i\theta_0}$ ” is violated here.

Step 3 — the limit along the imaginary ray. For $z = ir$ one has $\theta = \pi/2$, $\sin \theta = 1$, so

$$P[f](ir) = \frac{1}{2} + \frac{1}{\pi} \arctan \frac{2r}{1-r^2} \xrightarrow{r \rightarrow 1^-} \frac{1}{2} + \frac{1}{\pi} \cdot \frac{\pi}{2} = 1 = f\left(\frac{\pi}{2}\right),$$

because $\frac{2r}{1-r^2} \rightarrow +\infty$. Here f is continuous (it is constantly 1 in a neighborhood of i on the circle) and the theorem applies: the limit is the value of the datum. ✓

Independent check 1: quadrature. Simpson quadrature of $\frac{1}{2\pi} \int_0^\pi P_{0.5}(\pi/4 - t) dt$ with 200 000 subintervals gives 0.7406325; at $r = 0.8$, $\theta = -0.3$ the formula gives 0.2071363 and so does the quadrature. ✓

Independent check 2: values on the imaginary ray. The formula of Step 3 gives 0.9665246 for $r = 0.9$ and 0.9968009 for $r = 0.99$: the convergence to 1 is visible, and it is slow because the point i is “far” from the two jump points by only a quarter turn. ✓

Interpretation. $P[f](z)$ is the “weight” that the point z assigns to the upper arc when averaging the boundary datum: it is the *harmonic measure* of the arc as seen from z (Proposition 16.5). At the center it equals $\frac{1}{2}$, i.e. the fraction of the circle occupied by the arc; the value $\frac{1}{2}$ over the whole real diameter expresses the symmetry of the problem with respect to the real axis, and approaching i the weight of the upper arc tends to 1.

Typical errors. (1) Believing that $P[f]$ extends continuously to $\mathbb{D}$: it does not, because the limit depends on the direction of approach to $z = 1$ (along the upper boundary it tends to 1, along the diameter to $\frac{1}{2}$). (2) Applying Corollary 16.7 to a discontinuous datum: uniqueness requires continuity up to the boundary, and the Dirichlet problem with a discontinuous datum must be formulated differently. (3) Forgetting that $\arctan$ has range $(-\pi/2, \pi/2)$, and obtaining values outside $[0, 1]$.

Extension. The same computation, with Lemma 16.7 and endpoints a, b in place of $0, \pi$, gives the harmonic measure of an arbitrary arc; the value at the center is always $\frac{b-a}{2\pi}$, i.e. the fraction of the circle occupied by the arc (for $a = 0$, $b = \pi$: $\frac{1}{2}$). ✓

Exercise 16.6: The Poisson kernel reproduced by itself. *Type:* computation with Fourier coefficients, with a numerical check. Prove that for $0 \leq r, s < 1$

$$P[P_s](re^{i\theta}) = P_{rs}(\theta),$$

that is, that the Poisson integral of the kernel P_s is again a Poisson kernel, of parameter rs . Verify this numerically at two points.

Solution. Strategy. Rather than computing the integral, the Fourier coefficients of the datum P_s are computed and Theorem 16.11 is applied: the product of the factors $s^{|n|}$ and $r^{|n|}$ is $(rs)^{|n|}$, which is the coefficient of the kernel of parameter rs .

Step 1 — the datum is admissible. For s fixed, P_s is continuous on $\mathbb{T}$ and bounded (Lemma 16.6), so Theorem 16.11 applies.

Step 2 — the Fourier coefficients of P_s . By Definition 16.4 the series $\sum_m s^{|m|} e^{imt}$ converges uniformly in t ; integrating term by term against e^{-int} ,

$$\widehat{P}_s(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} P_s(t) e^{-int} dt = \sum_{m \in \mathbb{Z}} s^{|m|} \cdot \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{i(m-n)t} dt = s^{|n|},$$

because the last integral equals 1 if $m = n$ and 0 otherwise (Step 2 of the proof of Lemma 16.8).

Step 3 — apply the expansion. By Theorem 16.11,

$$P[P_s](re^{i\theta}) = \sum_{n \in \mathbb{Z}} \widehat{P}_s(n) r^{|n|} e^{in\theta} = \sum_{n \in \mathbb{Z}} (rs)^{|n|} e^{in\theta} = P_{rs}(\theta),$$

the last equality by Definition 16.4 applied to the parameter $rs \in [0, 1)$.

Independent check 1: quadrature. For $r = 0.5$, $s = 0.6$, $\theta = 1$: Simpson quadrature with 200 000 subintervals of $\frac{1}{2\pi} \int_{-\pi}^{\pi} P_{0.5}(\theta - t) P_{0.6}(t) dt$ gives 1.1882709, while the closed form of Lemma 16.4 with $rs = 0.3$ gives

$$P_{0.3}(1) = \frac{1 - 0.09}{1 - 0.6 \cos 1 + 0.09} = \frac{0.91}{1.09 - 0.6 \cdot 0.5403023} = \frac{0.91}{0.7658186} = 1.1882709. \checkmark$$

Independent check 2. For $r = 0.8$, $s = 0.5$, $\theta = 0.3$: quadrature 2.1226551, closed form with $rs = 0.4$ also 2.1226551. $\checkmark$

Interpretation. The family $\{P_r\}$ is a *semigroup* with respect to convolution on the circle: $P_r * P_s = P_{rs}$. This is the same phenomenon by which solving the Dirichlet problem twice, first with radius s and then with radius r , is the same as solving it once with radius rs : the restriction to $|z| = s$ of a harmonic function, carried back to the boundary and solved again, reproduces the original function rescaled.

Typical errors. (1) Attempting the direct computation of the integral, which is possible but long; the Fourier coefficients make it immediate. (2) Writing $\widehat{P}_s(n) = s^n$ instead of $s^{|n|}$, getting the terms with $n < 0$ wrong. (3) Concluding that $P_r * P_s = P_{r+s}$ by analogy with the heat kernel: here the composition law is *multiplicative* in the parameter.

Extension. Setting $r = s$ gives $P_r * P_r = P_{r^2}$, and iterating $P_r^{*k} = P_{r^k}$: successive convolutions concentrate the kernel toward the origin, not toward the boundary. $\checkmark$

16.10. Self-assessment quiz

- (Definition) A function u on an open set $\Omega \subseteq \mathbb{C}$ is *harmonic* when
 - $u \in C^2(\Omega)$ and $u_{xx} + u_{yy} = 0$ at every point of Ω
 - u is continuous and $u_x = u_y = 0$
 - u is the imaginary part of an arbitrary continuous function
 - $u \in C^1(\Omega)$ and $\Delta u \leq 0$
- (Hypothesis) In Theorem 16.1 the hypothesis that Ω be convex serves to
 - make u bounded
 - guarantee that the holomorphic function $g = u_x - iu_y$ has an antiderivative on Ω , by Theorem 15.2
 - guarantee that u is of class C^∞
 - ensure that u does not change sign
- (Symbolic computation) The closed form of the Poisson kernel is
 - $\frac{1 - r^2}{1 - 2r \cos t + r^2}$
 - $\frac{1 + r^2}{1 - 2r \cos t + r^2}$
 - $\frac{1 - r^2}{1 + 2r \cos t + r^2}$
 - $\frac{1 - r}{1 - 2r \cos t + r^2}$
- (Numerical computation) $P_{0.5}(\pi/3)$ equals, to seven decimals,

- A) 1.0000000 B) 3.0000000 C) 0.3333333 D) 0.8421053
5. (Proof step) In the proof of Theorem 16.5, the bound $P(z, e^{it}) \leq \frac{4(1-|z|^2)}{c_\delta^2}$ for $d(t, \theta_0) \geq \delta$ is obtained
- A) from the normalization of the kernel (Lemma 16.8) B) from the triangle inequality $|e^{it} - z| \geq |e^{it} - e^{i\theta_0}| - |e^{i\theta_0} - z| \geq c_\delta/2$, combined with the geometric form of Lemma 16.5 C) from the monotonicity of P_r on $[0, \pi]$ D) from the series expansion of Definition 16.4
6. (Error diagnosis) A student writes: “ u is harmonic and bounded on $\mathbb{D}$, so by Liouville’s theorem it is constant.” The error is
- A) Liouville’s theorem holds only for holomorphic functions B) Theorem 16.9 requires harmonicity on *all* of the plane, not on a disc: on $\mathbb{D}$ the function $u = x$ is harmonic, bounded and not constant C) the hypothesis $u \geq 0$ is missing D) continuity up to the boundary is missing
7. (Transfer) Let u be harmonic on all of $\mathbb{C}$ with $u(z) \leq 7$ for every z and $u(0) = 3$. Then
- A) $u \equiv 3$ B) $u \equiv 7$ C) such a u does not exist D) u can be non-constant, provided it is bounded above
8. (Source and metacognition) The construction of the Poisson kernel for the ball and the solution of the Dirichlet problem with continuous datum are found in
- A) Axler, Bourdon, Ramey, *Harmonic Function Theory*, 2nd ed., Ch. 1, sections “The Poisson Kernel for the Ball” (p. 9) and “The Dirichlet Problem for the Ball” (p. 12)
 B) the same authors, Ch. 8 “Harmonic Bergman Spaces” C) Ahlfors, *Complex Analysis*, Ch. 2 “Complex Functions” D) Stein and Shakarchi, *Fourier Analysis*, Ch. 7 “Finite Fourier Analysis”

16.11. Teacher’s key

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 1–4).

1) **A.** *Rationale:* this is literally Definition 16.1. *Distractors:* B describes locally constant functions; C forgets that the function whose imaginary part is taken must be *holomorphic* (Proposition 16.2) and that, in any case, that is a local characterization, not the definition; D confuses harmonicity with superharmonicity and asks for insufficient regularity for Δu to exist. *Error diagnosed:* substituting a consequence of the definition for the definition itself. *Source:* Axler, Bourdon, Ramey, Ch. 1, “Definitions and Examples,” p. 1. *Prerequisite:* second partial derivatives. *Remediation:* verify $\Delta(x^2 - y^2) = 0$ and $\Delta(x^2 + y^2) = 4 \neq 0$ (Example 16.1).

2) **B.** *Rationale:* in Step 2 of the proof of Theorem 16.1 convexity is used *only* to invoke Theorem 15.2; Example 16.2(c) shows that without it the conjugate may not exist. *Distractors:* A is irrelevant (no boundedness is used); C is true but is a *consequence* (Corollary 16.1), not the role of the hypothesis; D is false. *Error diagnosed:* not being able to isolate the point where a hypothesis enters a proof. *Source:* Ahlfors, Ch. 4, §6.1 “Definition and Basic Properties.” *Prerequisite:* existence of an antiderivative on a convex set (Theorem 15.2). *Remediation:* redo Example 16.2(c) and identify the step that breaks down.

3) **A.** *Rationale:* this is Lemma 16.4. *Distractors:* B gets the numerator wrong (with $1 + r^2$ the integral would not equal 1 and the function would not tend to 0 away from the

point); C corresponds to $P_r(t + \pi)$, i.e. to a kernel concentrated at $t = \pi$; D is not even dimensionally consistent: as $r \rightarrow 0$ it would give 1, but at $t = \pi$ it would give $\frac{1-r}{(1+r)^2}$ instead of $\frac{1-r}{1+r}$. *Error diagnosed*: memorizing the formula instead of reconstructing it from the two geometric series. *Source*: Stein and Shakarchi, Ch. 2; Ahlfors, Ch. 4, §6.3 “Poisson’s Formula.” *Prerequisite*: geometric series. *Remediation*: redo the three steps of the proof of Lemma 16.4.

4) **A.** *Rationale*: $1 - 2 \cdot 0.5 \cdot \cos \frac{\pi}{3} + 0.25 = 1 - 0.5 + 0.25 = 0.75$ and $1 - r^2 = 0.75$, so the quotient equals exactly 1; the sum of the series up to $n = 60$ gives 1.0000000. *Distractors*: B is $P_{0.5}(0) = \frac{1+r}{1-r}$, the maximum; C is $P_{0.5}(\pi) = \frac{1-r}{1+r}$, the minimum; D is $P_{0.6}(\pi/3) = \frac{0.64}{0.76}$, i.e. the value with the other radius. *Error diagnosed*: confusing the radius with the angle, or reading off the extreme value instead of the one requested. *Source*: Example 16.5(b) and Figure 16.1. *Prerequisite*: $\cos \frac{\pi}{3} = \frac{1}{2}$. *Remediation*: compute $P_{0.5}(\pi/2) = 0.6$ and compare it with the figure.

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 5–8).

5) **B.** *Rationale*: this is exactly Step 4 of the proof of Theorem 16.5: one bounds the denominator $|e^{it} - z|^2$ below and uses $P = \frac{1-|z|^2}{|e^{it}-z|^2}$. *Distractors*: A is instead used in Step 1 (to center the error) and in Step 3; C is the key point of Lemma 16.9, which estimates $P_r(t)$ for z on the ray, and is not enough here because z tends to the boundary in an arbitrary direction; D plays no role in this bound. *Error diagnosed*: not distinguishing “radial” concentration from “non-tangential” concentration. *Source*: Rudin, Ch. 11, and Stein and Shakarchi, Ch. 2, on approximation with good kernels. *Prerequisite*: triangle inequality. *Remediation*: redo Step 4 with $\delta = \pi/2$ and make c_δ explicit.

6) **B.** *Rationale*: $u(x, y) = x$ is harmonic on $\mathbb{D}$, satisfies $|u| \leq 1$ and is not constant: the hypothesis “harmonic on all of $\mathbb{C}$ ” in Theorem 16.9 is not decorative. *Distractors*: A is false (Theorem 16.9 is precisely the statement for harmonic functions); C confuses this with the hypothesis of Theorem 16.8; D is beside the point, because neither version of Liouville requires continuity up to the boundary. *Error diagnosed*: transporting a global theorem into a local context. *Source*: Axler, Bourdon, Ramey, Ch. 2, “Liouville’s Theorem,” p. 31. *Prerequisite*: Theorem 16.8. *Remediation*: exhibit three bounded, non-constant harmonic functions on $\mathbb{D}$.

7) **A.** *Rationale*: u is harmonic on $\mathbb{C}$ and bounded above, hence constant by Corollary 16.12; the constant is the value at 0, i.e. 3. *Distractors*: B swaps the bound for the value; C is false (the constant 3 satisfies all the hypotheses); D contradicts the corollary. *Error diagnosed*: believing that a bound on both sides is needed. *Source*: Axler, Bourdon, Ramey, Ch. 3, “Liouville’s Theorem,” p. 45, where the statement is given for *positive* harmonic functions. *Prerequisite*: Corollary 16.12. *Remediation*: prove that a harmonic function on $\mathbb{C}$ with $u \geq -5$ is constant.

8) **A.** *Rationale*: the table of contents of the volume, checked against the PDF made available by the authors, places “The Poisson Kernel for the Ball” at p. 9 and “The Dirichlet Problem for the Ball” at p. 12 of Chapter 1. *Distractors*: B is the chapter on harmonic Bergman spaces (p. 171); C is Ahlfors’s chapter on elementary complex functions, which does not treat harmonic functions (those are in Ch. 4, §6); D is the chapter on finite Fourier analysis, i.e. on the group $\mathbb{Z}/N\mathbb{Z}$. *Error diagnosed*: citing from memory without checking the table of contents. *Source*: the sources environment at the end of the chapter. *Prerequisite*: none. *Remediation*: locate, in the same volume, the section “Converse of the Mean-Value Property” (p. 17), which corresponds to Theorem 16.7.

BEST PRACTICE

Assigned exercise 16.1 — answers.

(a) $u_{xx} = 6x$, $u_{yy} = -6x$: harmonic. Then $g = u_x - iu_y = (3x^2 - 3y^2) + i6xy = 3(x^2 - y^2 + 2ixy) = 3z^2$, with antiderivative z^3 . So $f(z) = z^3$ and $v = \operatorname{Im} z^3 = 3x^2y - y^3$, which vanishes at 0. Cauchy–Riemann check: $u_x = 3x^2 - 3y^2 = v_y$ ✓ and $u_y = -6xy = -v_x$ ✓.

(b) $u = \operatorname{Re} \frac{1}{z}$ because $\frac{1}{z} = \frac{\bar{z}}{|z|^2} = \frac{x-iy}{x^2+y^2}$; hence $v = \operatorname{Im} \frac{1}{z} = -\frac{y}{x^2+y^2}$ is a conjugate on all of $\mathbb{C} \setminus \{0\}$. The difference with $\log|z|$ is that here a global holomorphic function, $1/z$, of which u is the real part, *already* exists; for $\log|z|$ such a function would have to be a holomorphic logarithm, which does not exist on $\mathbb{C} \setminus \{0\}$ (Example 16.2(c)). The obstruction is not harmonicity but the monodromy of the argument.

(c) On the cut plane $\Omega = \mathbb{C} \setminus (-\infty, 0]$ the principal logarithm $\operatorname{Log} z = \log|z| + i \operatorname{Arg} z$ is holomorphic (Lemma 15.11); its real part is $\log|z|$ and its imaginary part $\operatorname{Arg} z$: by Definition 16.2 the latter is a harmonic conjugate of $\log|z|$ on Ω .

(d) $z = 0.3 + 0.4i$: $z^2 = -0.07 + 0.24i$ and $z^3 = z \cdot z^2 = -0.117 + 0.044i$. On the other hand $u = x^3 - 3xy^2 = 0.027 - 0.144 = -0.117$ ✓ and $v = 3x^2y - y^3 = 0.108 - 0.064 = 0.044$ ✓.

BEST PRACTICE

Assigned exercise 16.2 — answers.

(a) $1 - 2 \cdot 0.6 \cdot \frac{1}{2} + 0.36 = 1 - 0.6 + 0.36 = 0.76$ and $1 - r^2 = 0.64$: $P_{0.6}(\pi/3) = \frac{0.64}{0.76} = 0.8421053$. The sum of the series $1 + 2 \sum_{n \geq 1} 0.6^n \cos \frac{n\pi}{3}$ up to $n = 120$ gives 0.8421053. ✓

(b) By Lemma 16.9 the supremum on $\{|t| \geq \delta\}$ is $P_r(\delta)$. With $\delta = 0.3$ (and $\cos 0.3 = 0.9553365$): $P_{0.99}(0.3) = \frac{0.0199}{1.9801 - 1.98 \cdot 0.9553365} = 0.2247730$ and $P_{0.999}(0.3) = 0.0224006$. ✓

The ratio between the two, about 10, reflects the factor $1 - r^2$ in the numerator.

(c) $P_r(t)$ depends on t only through $\cos t$ and is decreasing in $1 - 2r \cos t + r^2$: hence it is maximal where $\cos t$ is maximal ($t = 0$) and minimal where it is minimal ($t = \pi$), with values $\frac{1+r}{1-r}$ and $\frac{1-r}{1+r}$ (Lemma 16.6). The ratio is $\left(\frac{1+r}{1-r}\right)^2$, which for $r = 0.9$ equals $19^2 = 361$.

(d) Simpson quadrature with 200 000 subintervals gives 1.0000000 for $r = 0.3, 0.9$ and 0.99 . ✓ As r grows the integrand has a peak of height $\frac{1+r}{1-r}$ and width of order $1 - r$ (because $P_r(t) = \frac{1+r}{1-r}$ at $t = 0$ and $P_r(1-r) \approx \frac{1}{2} \frac{1+r}{1-r}$): the quadrature step must be much smaller than $1 - r$, otherwise the peak gets “skipped over”.

BEST PRACTICE

Assigned exercise 16.3 — answers.

(a) $u(re^{i\theta}) = 3 + 2r \cos \theta - r^2 \sin 2\theta$: it is harmonic (Example 16.1(b) and Proposition 16.1(i)), continuous on $\mathbb{D}$ and equals f for $r = 1$; by Theorem 16.6 it is the solution. At $r = 0.5$, $\theta = 0.9$: $3 + 1 \cdot 0.6216100 - 0.25 \cdot 0.9738476 = 3.3781481$; quadrature of the Poisson integral gives 3.3781481. ✓

(b) $\cos^4 \theta = \frac{3}{8} + \frac{1}{2} \cos 2\theta + \frac{1}{8} \cos 4\theta$, so $u = \frac{3}{8} + \frac{1}{2} r^2 \cos 2\theta + \frac{1}{8} r^4 \cos 4\theta$. At $r = 0.7$, $\theta = 0.4$: $0.375 + 0.245 \cdot 0.6967067 + 0.0300125 \cdot (-0.0291995) = 0.375 + 0.1706932 - 0.0008764 = 0.5448168$; the quadrature gives 0.5448168. ✓

(c) By Corollary 16.14 the value at the center is $\hat{f}(0) = \frac{a_0}{2}$, i.e. the constant term of the expansion: 3 in case (a) and $\frac{3}{8} = 0.375$ in case (b). No computation is needed.

(d) $u = 1 + r \cos \theta$, with $u(0) = 1$. On $|z| = 0.5$ the maximum is 1.5 ($\theta = 0$) and the minimum 0.5 ($\theta = \pi$). Harnack’s bounds are $\frac{1-0.5}{1+0.5} = 0.3333333$ and $\frac{1+0.5}{1-0.5} = 3$: the inequalities are *strict*. The reason can be read in Step 3 of the proof of Theorem 16.8: equality on the right would require

$$\int_{-\pi}^{\pi} \left(\frac{s+\rho}{s-\rho} - \frac{s^2-\rho^2}{s^2-2s\rho\cos(\theta-t)+\rho^2} \right) u(se^{it}) dt = 0$$

with a continuous, non-negative integrand, hence $u(se^{it}) = 0$ for every t other than the one

that maximizes the kernel: impossible for a continuous datum that is not identically zero. Equality is approached only when the datum concentrates at a point, as in the Poisson kernel itself (Example 16.7).

16.12. Formulas of the chapter

Laplacian, harmonic functions, conjugate.

$$\Delta u = u_{xx} + u_{yy} = \tilde{u}_{rr} + \frac{1}{r}\tilde{u}_r + \frac{1}{r^2}\tilde{u}_{\theta\theta}; \quad \Delta u = 0 \iff u \text{ harmonic.}$$

On a convex set: $g = u_x - iu_y$ is holomorphic, $F' = g$, $u = \operatorname{Re} F$; conjugate unique up to constants. Cauchy–Riemann: $u_x = v_y$, $u_y = -v_x$. Elementary harmonic functions: 1 , x , y , xy , $x^2 - y^2$, $r^n \cos n\theta$, $r^n \sin n\theta$, $\log r$ (on $\mathbb{C} \setminus \{0\}$), $e^x \cos y$.

Mean, maximum, uniqueness.

$$u(w) = \frac{1}{2\pi} \int_{-\pi}^{\pi} u(w + \rho e^{i\theta}) d\theta = \frac{1}{\pi R^2} \iint_{D(w, R)} u \, dx \, dy.$$

Strong maximum: mean + interior maximum $\Rightarrow$ constant. Weak maximum: $\max_{\overline{\Omega}} u = \max_{\partial\Omega} u$ and $\min_{\overline{\Omega}} u = \min_{\partial\Omega} u$. Comparison: $u_1 \leq u_2$ on the boundary $\Rightarrow u_1 \leq u_2$ inside. Uniqueness for Dirichlet on every bounded domain. Converse: continuous + mean $\Rightarrow$ harmonic.

Poisson kernel.

$$P_r(t) = \sum_{n \in \mathbb{Z}} r^{|n|} e^{int} = \frac{1 - r^2}{1 - 2r \cos t + r^2}, \quad P(z, e^{it}) = \frac{1 - |z|^2}{|e^{it} - z|^2} = \operatorname{Re} \frac{e^{it} + z}{e^{it} - z}.$$

$$\frac{1-r}{1+r} \leq P_r(t) \leq \frac{1+r}{1-r}; \quad \frac{1}{2\pi} \int_{-\pi}^{\pi} P_r = 1; \quad \sup_{\delta \leq |t| \leq \pi} P_r(t) = P_r(\delta) \xrightarrow{r \rightarrow 1^-} 0.$$

Antiderivative: $\int P_r(t) dt = 2 \arctan \left(\frac{1+r}{1-r} \tan \frac{t}{2} \right)$ on $(-\pi, \pi)$. Semigroup: $P_r * P_s = P_{rs}$.

Poisson's formula, Dirichlet, Harnack.

$$P[f](re^{i\theta}) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{1 - r^2}{1 - 2r \cos(\theta - t) + r^2} f(t) dt,$$

$$u(w + \rho e^{i\theta}) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{R^2 - \rho^2}{R^2 - 2R\rho \cos(\theta - t) + \rho^2} u(w + Re^{it}) dt.$$

Dirichlet in the disc with continuous datum: unique solution, $u = P[f]$ inside and $u = f$ on the boundary. Harnack ($u \geq 0$ harmonic on $D(w, R)$, $|z - w| = \rho$):

$$\frac{R - \rho}{R + \rho} u(w) \leq u(z) \leq \frac{R + \rho}{R - \rho} u(w).$$

Liouville: u harmonic on $\mathbb{C}$ and bounded on one side only $\Rightarrow$ constant. Gradient estimate: u harmonic on $D(w, R)$ with $|u| \leq M \Rightarrow |\nabla u(w)| \leq \frac{2M}{R}$; for $w = 0$, $R = 1$ equality holds with $|\nabla u(0)| = 2|\hat{f}(1)|$, and the optimal constant is $\frac{4}{\pi} = 1.2732395$. Schwarz reflection: u harmonic on Ω^+ , continuous up to I and zero on $I \Rightarrow$ the odd extension $\tilde{u}(x, -y) = -u(x, y)$ is harmonic on Ω .

Fourier series of the solution, and the numerical values of the chapter.

$$P[f](re^{i\theta}) = \sum_{n \in \mathbb{Z}} \hat{f}(n) r^{|n|} e^{in\theta} = \frac{a_0}{2} + \sum_{n \geq 1} r^n (a_n \cos n\theta + b_n \sin n\theta); \quad \frac{1}{2\pi} \int_{-\pi}^{\pi} P[f](re^{i\theta}) d\theta = \hat{f}(0).$$

$$P_{0.5}(0) = 3, \quad P_{0.5}(\pi/3) = 1, \quad P_{0.5}(\pi) = \frac{1}{3}, \quad P_{0.6}(\pi/3) = 0.8421053, \quad P_{0.8}(0) = 9.$$

$$f = \cos^2: u(0.6e^{i\pi/3}) = 0.41; \quad f = \cos^3: u(0.8e^{0.7i}) = 0.3942850; \quad f = \cos^4: u(0.7e^{0.4i}) = 0.5448168.$$

$$f = \theta^2: u(0.5) = 1.4962113, \quad u(0) = \frac{\pi^2}{3} = 3.2898681; \quad f = |\theta|: u(0.5) = 0.9146611.$$

$$f = \mathbf{1}_{(0,\pi)}: u(re^{i\theta}) = \frac{1}{2} + \frac{1}{\pi} \arctan \frac{2r \sin \theta}{1-r^2}, \quad u(0.5e^{i\pi/4}) = 0.7406325.$$

Sources and bibliography

- [1] L. V. Ahlfors, *Complex Analysis: An Introduction to the Theory of Analytic Functions of One Complex Variable*, 3rd edition, International Series in Pure and Applied Mathematics, McGraw-Hill, New York, 1979 (xiv+331 pages, ISBN 0-07-000657-1). Chapter 4 “Complex Integration,” §1.5 “Cauchy’s Theorem in a Disk” (source of the tool used in Theorem 16.1) and above all §6 “Harmonic Functions,” organized into “6.1 Definition and Basic Properties,” “6.2 The Mean-value Property,” “6.3 Poisson’s Formula,” “6.4 Schwarz’s Theorem,” “6.5 The Reflection Principle”: this is the source of Definition 16.1, of Theorem 16.2, of Lemma 16.4 and of Theorem 16.5 (which in Ahlfors is “Schwarz’s theorem”). Bibliographic data and the structure of Chapter 4 checked against the SearchWorks catalog record of Stanford University Libraries, record 1003741 — checked on September 6, 2026.
- [2] S. Axler, P. Bourdon, W. Ramey, *Harmonic Function Theory*, 2nd edition, Graduate Texts in Mathematics, Springer, New York, 2001 (ISBN 978-0-387-95218-5). Chapter 1 “Basic Properties of Harmonic Functions” (pp. 1–29), with sections “Definitions and Examples” (p. 1), “Invariance Properties” (p. 2), “The Mean-Value Property” (p. 4), “The Maximum Principle” (p. 7), “The Poisson Kernel for the Ball” (p. 9), “The Dirichlet Problem for the Ball” (p. 12), “Converse of the Mean-Value Property” (p. 17), “Real Analyticity and Homogeneous Expansions” (p. 19), “Origin of the Term *Harmonic*” (p. 25): this is the parallel source, in arbitrary dimension, of Theorems 16.2, 16.3, 16.6 and 16.7. Chapter 2 “Bounded Harmonic Functions” (p. 31), section “Liouville’s Theorem” (p. 31), and Chapter 3 “Positive Harmonic Functions” (p. 45), sections “Liouville’s Theorem” (p. 45) and “Harnack’s Inequality and Harnack’s Principle” (p. 47): sources of Theorem 16.8, of Corollary 16.12 and of Proposition 16.6. Chapter 6 “Harmonic Hardy Spaces” (p. 111), section “The Fatou Theorem” (p. 128), for the panorama of Remark 16.6. The remark that the link between harmonic and holomorphic functions has no analogue in dimension > 2 is on p. 2. Table of contents and pagination checked against the full PDF made available by the authors at axler.net/HFT.pdf (table-of-contents pages and Chapter 1) — checked on September 6, 2026.
- [3] W. Rudin, *Real and Complex Analysis*, 3rd edition, McGraw-Hill, New York, 1987 (xiv+416 pages, ISBN 0-07-054234-1). Chapter 11 “Harmonic Functions”: Cauchy–Riemann equations, Poisson integral, mean-value property, boundary behavior of Poisson integrals and representation theorems. This is the alternative source for Theorem 16.5 and for the measure-theoretic picture (boundary Borel measures, Fatou’s theorem) that this chapter does not develop. Bibliographic data checked against the Internet Archive record, identifier [realcomplexanaly0000rudin](https://archive.org/details/realcomplexanaly0000rudin); the structure of the chapter is the one

already checked for Chapter 15 — checked on September 6, 2026.

- [4] E. M. Stein, R. Shakarchi, *Fourier Analysis: An Introduction*, Princeton Lectures in Analysis I, Princeton University Press, Princeton, 2003 (328 pages, ISBN 978-0-691-11384-5). Chapter 1 “The Genesis of Fourier Analysis,” §2.2 “Steady-state heat equation in the disc” (pp. 20–22), where the equation $\Delta u = 0$ is introduced as the stationary limit of the heat equation, the Dirichlet problem in the disc is posed and separation of variables produces the solutions $r^{|m|}e^{im\theta}$ that here are the terms of Theorem 16.11; Chapter 2 “Basic Properties of Fourier Series,” for convolutions, “good kernels” (of which Definition 16.5 is the form used here) and Abel summability, i.e. the content of Remark 16.6. Table of contents of the volume checked against the publisher’s record (press.princeton.edu, ISBN 9780691113845); text and pagination of Chapter 1 checked against the sample chapter PDF distributed by the publisher (assets.press.princeton.edu/chapters/s7562.pdf) — checked on September 6, 2026.
- [5] For the results of the treatise recalled with \ref: the Cauchy–Riemann equations, the existence of an antiderivative on a convex open set, the mean-value property for holomorphic functions, analyticity, the maximum-modulus principle, Liouville’s theorem and the principal logarithm are proved in Chapter 15; the polar form and generalized circles in Chapter 6; the invariant measure $d\theta/2\pi$ and the characters of the circle in Chapter 13. The numerical checks of the chapter were carried out twice by independent routes (closed form and composite Simpson quadrature with 200 000 subintervals, or series and quadrature) and are reported in the text with the symbol $\checkmark$.

Convergence of Fourier series

A Fourier series is an identity declared before it is verified. Writing $f \sim \sum_n \hat{f}(n)e^{in\theta}$ costs nothing: only the integrals that define the coefficients are needed, and those exist for every summable function. The equals sign, instead, must be earned, and the price changes with the sense one gives it. In quadratic mean it costs nothing extra: the series always converges. Pointwise it costs a hypothesis of local regularity — an integral condition (Dini) or a variation condition (Dirichlet–Jordan). Uniformly it costs still more, and mere continuity is not enough: there is a continuous function whose Fourier series diverges at a point, and the reason is a single quantity that grows like $\ln N$, the Lebesgue constant.

The chapter climbs this ladder from the bottom up and shows, at every rung, exactly what is being paid. The technical pivot is a single one: the partial sum is a convolution with the *Dirichlet kernel* (Theorem 17.3), and all the properties — good and bad — of the partial sums are properties of that kernel. The Dirichlet kernel changes sign; its integral in modulus diverges (Theorem 17.10); from this follow the Gibbs phenomenon (Theorem 17.9) and du Bois-Reymond’s divergence (Corollary 17.4). Replacing the partial sums with their arithmetic means makes the kernel positive (Theorem 17.6), and with it all the pathologies disappear: this is Fejér’s theorem (Theorem 17.7), from which follow the density of trigonometric polynomials (Corollary 17.3), the uniqueness of the coefficients (Theorem 17.13) and the completeness of the trigonometric system, i.e. Parseval’s identity (Theorem 17.1).

The tool that makes every pointwise criterion provable is the Riemann–Lebesgue lemma (Lemma 17.2), here proved in full: from it follow Dini’s criterion (Theorem 17.11) and, with the addition of the second mean value theorem (Lemma 17.8), the Dirichlet–Jordan criterion for functions of bounded variation (Theorem 17.12), which at jump points gives the average of the two one-sided limits. The Wilbraham–Gibbs constant is computed exactly and the value of the sine-integral is obtained twice by independent routes (Proposition 17.3 and Observation 17.14). The chapter closes with the explicit remainder estimate for functions of class C^1 (Theorem 17.14) and with the panorama of the two extreme results, Kolmogorov and Carleson–Hunt, stated and not proved (Section 17.8).

The material that the executive plan moved here from Volume II (Chapter 4, §5) is kept in full — statements, proofs, exercises, quiz and formulary — in Section 17.2 and in Section 17.9. What Volume II took as known (Riemann–Lebesgue, Bessel’s inequality, the uniqueness of the coefficients for merely summable functions, the divergence of the Lebesgue constants) is proved here.

INFO

Level and prerequisites. Level **C** (undergraduate), with three passages at level **D**: the two-sided estimate of the Lebesgue constants (Theorem 17.10), the second mean value theorem in Bonnet’s form (Lemma 17.8) and the Dirichlet–Jordan criterion (Theorem 17.12).

Internal prerequisites. Fourier coefficients, the convolution theorem, the square wave example and the Basel series (Volume II, Chapter 4); Riemann and Lebesgue integrals, the periodic trapezoidal rule (Volume II, Chapter 2); the complex exponential and polar form (Volume II, Chapter 3, and Chapter 6); the Poisson kernel and harmonic functions on the

disc continue in Chapter 16; spectral *leakage* and windows in Chapter 22, Section 22.10.3.

External prerequisites, assumed and not proved:

- the density of step functions in the space L^1 of a bounded interval, and that of $C(\mathbb{T})$ in $L^1(\mathbb{T})$ and in $L^2(\mathbb{T})$ (measure theory: Rudin, *Real and Complex Analysis*, Chapter 3);
- Lebesgue's dominated convergence theorem and Lebesgue's differentiation theorem ($F(\theta) = \int_0^\theta f$ has $F' = f$ almost everywhere for $f \in L^1$);
- the completeness of L^2 and the Cauchy–Schwarz inequality;
- the Banach–Steinhaus uniform boundedness principle, used once, in Corollary 17.4.

Everything else — kernels, criteria, estimates, constants — is proved in this chapter. Observation 17.15 lists in one place what remains imported and what is only stated as panorama.

17.1. Coefficients, partial sums, Riemann–Lebesgue

This section fixes the notation and proves the two tools that the rest of the chapter uses throughout: Bessel's inequality, which governs convergence in quadratic mean, and the Riemann–Lebesgue lemma, which governs every criterion of pointwise convergence. Volume II had stated them; here they are proved.

Definition 17.1: Fourier coefficients, partial sums, trigonometric polynomials.

Write $\mathbb{T} = \mathbb{R}/2\pi\mathbb{Z}$ for the circle and adopt the *normalised measure* $d\sigma = \frac{d\theta}{2\pi}$, so that $\sigma(\mathbb{T}) = 1$. Set

$$e_n(\theta) = e^{in\theta} \quad (n \in \mathbb{Z}), \quad \|f\|_p = \left(\int_{\mathbb{T}} |f|^p d\sigma \right)^{1/p} \quad (1 \leq p < \infty), \quad \|f\|_\infty = \sup_{\mathbb{T}} |f|.$$

For $f \in L^1(\mathbb{T})$ the n -th **Fourier coefficient** is

$$\hat{f}(n) = \int_{\mathbb{T}} f \overline{e_n} d\sigma = \frac{1}{2\pi} \int_0^{2\pi} f(\theta) e^{-in\theta} d\theta,$$

the N -th **partial sum** is $S_N f = \sum_{|n| \leq N} \hat{f}(n) e_n$, and a **trigonometric polynomial of degree** $\leq N$ is a finite linear combination $P = \sum_{|n| \leq N} a_n e_n$ with $a_n \in \mathbb{C}$. The set of such polynomials is denoted $\mathcal{P}_N$.

Lemma 17.1: Inclusions among the spaces on the circle. *With the normalised measure, for every measurable f ,*

$$\|f\|_1 \leq \|f\|_2 \leq \|f\|_\infty,$$

and hence $C(\mathbb{T}) \subset L^2(\mathbb{T}) \subset L^1(\mathbb{T})$. In particular the Fourier coefficients are defined for every $f \in L^2(\mathbb{T})$ and $|\hat{f}(n)| \leq \|f\|_1$ for every n .

Proof. By the Cauchy–Schwarz inequality applied to the pair $(|f|, 1)$ in the space $L^2(\mathbb{T}, \sigma)$,

$$\|f\|_1 = \int_{\mathbb{T}} |f| \cdot 1 d\sigma \leq \left(\int_{\mathbb{T}} |f|^2 d\sigma \right)^{1/2} \left(\int_{\mathbb{T}} 1^2 d\sigma \right)^{1/2} = \|f\|_2 \cdot \sigma(\mathbb{T})^{1/2} = \|f\|_2,$$

because $\sigma(\mathbb{T}) = 1$. The second inequality is immediate: $\int |f|^2 d\sigma \leq \|f\|_\infty^2 \int d\sigma = \|f\|_\infty^2$. Finally

$$|\hat{f}(n)| = \left| \int_{\mathbb{T}} f \overline{e_n} d\sigma \right| \leq \int_{\mathbb{T}} |f| |e_n| d\sigma = \int_{\mathbb{T}} |f| d\sigma = \|f\|_1,$$

since $|e_n(\theta)| = 1$ for every θ . □

Proposition 17.1: Orthonormality of the trigonometric system. With respect to the inner product $\langle f, g \rangle = \int_{\mathbb{T}} f \bar{g} d\sigma$,

$$\langle e_n, e_m \rangle = \frac{1}{2\pi} \int_0^{2\pi} e^{i(n-m)\theta} d\theta = \begin{cases} 1 & n = m, \\ 0 & n \neq m. \end{cases}$$

Proof. If $n = m$ the integrand is $e^{i0} = 1$ and the integral equals $\frac{1}{2\pi} \cdot 2\pi = 1$. If $k = n - m \neq 0$, the function $\theta \mapsto e^{ik\theta}/(ik)$ is an antiderivative of $e^{ik\theta}$, so

$$\int_0^{2\pi} e^{ik\theta} d\theta = \left[\frac{e^{ik\theta}}{ik} \right]_0^{2\pi} = \frac{e^{2\pi ik} - 1}{ik} = 0,$$

because $e^{2\pi ik} = 1$ for every integer k . □

Proposition 17.2: Projection, best approximation and Bessel's inequality. Let $f \in L^2(\mathbb{T})$ and $N \in \mathbb{N}$. Then:

- (i) $\langle f - S_N f, e_m \rangle = 0$ for every $|m| \leq N$; equivalently $f - S_N f$ is orthogonal to all of $\mathcal{P}_N$;
- (ii) for every $P \in \mathcal{P}_N$, $\|f - P\|_2^2 = \|f - S_N f\|_2^2 + \|S_N f - P\|_2^2$; in particular $S_N f$ is the best approximation of f in the L^2 norm among trigonometric polynomials of degree $\leq N$, and it is the only one;
- (iii) $\|f - S_N f\|_2^2 = \|f\|_2^2 - \sum_{|n| \leq N} |\hat{f}(n)|^2$;
- (iv) (**Bessel's inequality**) $\sum_{n \in \mathbb{Z}} |\hat{f}(n)|^2 \leq \|f\|_2^2 < \infty$.

Proof. Step 1 — (i). By linearity of the inner product and by Proposition 17.1, for $|m| \leq N$

$$\langle S_N f, e_m \rangle = \sum_{|n| \leq N} \hat{f}(n) \langle e_n, e_m \rangle = \hat{f}(m),$$

while $\langle f, e_m \rangle = \int_{\mathbb{T}} f \bar{e}_m d\sigma = \hat{f}(m)$ by Definition 17.1. Subtracting, $\langle f - S_N f, e_m \rangle = 0$. Since every $P \in \mathcal{P}_N$ is a linear combination of the e_m with $|m| \leq N$, orthogonality extends by linearity to all of $\mathcal{P}_N$.

Step 2 — (ii). Write $f - P = (f - S_N f) + (S_N f - P)$. The second term lies in $\mathcal{P}_N$, hence by Step 1 it is orthogonal to the first. The Pythagorean theorem in an inner-product space (which is the direct computation $\|u + v\|^2 = \|u\|^2 + 2\operatorname{Re}\langle u, v \rangle + \|v\|^2$ with $\langle u, v \rangle = 0$) gives

$$\|f - P\|_2^2 = \|f - S_N f\|_2^2 + \|S_N f - P\|_2^2 \geq \|f - S_N f\|_2^2,$$

with equality if and only if $\|S_N f - P\|_2 = 0$, i.e. $P = S_N f$ almost everywhere; but two trigonometric polynomials of degree $\leq N$ equal almost everywhere have the same coefficients (apply Proposition 17.1 to the difference), and hence coincide.

Step 3 — (iii). Take $P = 0$ in Step 2, i.e. compute directly

$$\|f - S_N f\|_2^2 = \langle f - S_N f, f - S_N f \rangle = \langle f - S_N f, f \rangle - \underbrace{\langle f - S_N f, S_N f \rangle}_{=0 \text{ (Step 1)}} = \|f\|_2^2 - \langle S_N f, f \rangle.$$

Finally, by Proposition 17.1,

$$\langle S_N f, f \rangle = \overline{\langle f, S_N f \rangle} = \overline{\sum_{|n| \leq N} \hat{f}(n) \langle f, e_n \rangle} = \sum_{|n| \leq N} \overline{\hat{f}(n)} \overline{\langle f, e_n \rangle} = \sum_{|n| \leq N} |\hat{f}(n)|^2,$$

which is (iii).

Step 4 — (iv). The left-hand side of (iii) is ≥ 0 , so $\sum_{|n| \leq N} |\hat{f}(n)|^2 \leq \|f\|_2^2$ for every N . The partial sums of the non-negative series $\sum_n |\hat{f}(n)|^2$ are bounded by $\|f\|_2^2$, hence the series converges and its sum does not exceed $\|f\|_2^2$. $\square$

Corollary 17.1: The coefficients of a square-summable function vanish at infinity. If $f \in L^2(\mathbb{T})$ then $\hat{f}(n) \rightarrow 0$ as $|n| \rightarrow \infty$.

Proof. By Proposition 17.2(iv) the series $\sum_n |\hat{f}(n)|^2$ converges; the general term of a convergent series tends to zero, hence $|\hat{f}(n)|^2 \rightarrow 0$ and therefore $\hat{f}(n) \rightarrow 0$. $\square$

Lemma 17.2: Riemann–Lebesgue lemma. Let $-\infty < a < b < +\infty$ and $g \in L^1(a, b)$. Then

$$\int_a^b g(t) e^{i\lambda t} dt \rightarrow 0 \quad (\lambda \in \mathbb{R}, |\lambda| \rightarrow \infty),$$

and likewise $\int_a^b g(t) \sin(\lambda t) dt \rightarrow 0$ and $\int_a^b g(t) \cos(\lambda t) dt \rightarrow 0$. In particular, for every $f \in L^1(\mathbb{T})$, $\hat{f}(n) \rightarrow 0$ as $|n| \rightarrow \infty$.

Proof. Step 1 — the case of an indicator function. Let $a \leq \alpha < \beta \leq b$ and $g = \mathbf{1}_{[\alpha, \beta)}$. For $\lambda \neq 0$, with the antiderivative $e^{i\lambda t}/(i\lambda)$,

$$\int_a^b \mathbf{1}_{[\alpha, \beta)}(t) e^{i\lambda t} dt = \int_\alpha^\beta e^{i\lambda t} dt = \frac{e^{i\lambda\beta} - e^{i\lambda\alpha}}{i\lambda}, \quad \text{hence} \quad \left| \int_a^b g e^{i\lambda t} dt \right| \leq \frac{2}{|\lambda|}.$$

The bound does not depend on α and β and tends to 0 as $|\lambda| \rightarrow \infty$.

Step 2 — step functions. Let $s = \sum_{j=1}^k c_j \mathbf{1}_{[\alpha_j, \beta_j)}$ be a step function. By linearity of the integral and by Step 1,

$$\left| \int_a^b s(t) e^{i\lambda t} dt \right| \leq \sum_{j=1}^k |c_j| \cdot \frac{2}{|\lambda|} = \frac{2}{|\lambda|} \sum_{j=1}^k |c_j| \rightarrow 0.$$

Step 3 — approximation. Let $\varepsilon > 0$. Step functions are dense in $L^1(a, b)$ (a measure-theory prerequisite declared in the opening infobox and in Observation 17.15): there is therefore a step function s with $\int_a^b |g - s| dt < \varepsilon/2$. Then, for every λ ,

$$\left| \int_a^b g e^{i\lambda t} dt \right| \leq \underbrace{\int_a^b |g - s| |e^{i\lambda t}| dt}_{< \varepsilon/2} + \left| \int_a^b s e^{i\lambda t} dt \right|,$$

using $|e^{i\lambda t}| = 1$. By Step 2 there is $\Lambda > 0$ such that the second term is $< \varepsilon/2$ for $|\lambda| > \Lambda$. Hence for $|\lambda| > \Lambda$ the whole left-hand side is $< \varepsilon$: that is the definition of a limit equal to zero.

Step 4 — the sine and cosine versions. From $\cos(\lambda t) = \frac{1}{2}(e^{i\lambda t} + e^{-i\lambda t})$ and $\sin(\lambda t) = \frac{1}{2i}(e^{i\lambda t} - e^{-i\lambda t})$, each of the two integrals is a linear combination of two integrals of the type already treated, with λ and $-\lambda$: both tend to zero.

Step 5 — the periodic case. Let $f \in L^1(\mathbb{T})$. Then f restricted to $(0, 2\pi)$ lies in $L^1(0, 2\pi)$ and, by Definition 17.1,

$$\hat{f}(n) = \frac{1}{2\pi} \int_0^{2\pi} f(\theta) e^{-in\theta} d\theta,$$

which is the case $\lambda = -n$, $a = 0$, $b = 2\pi$, divided by 2π . By Steps 1–3 it tends to zero as $|n| \rightarrow \infty$. $\square$

By a half-period shift. For $f \in L^1(\mathbb{T})$ and $n \neq 0$, set $\tau = \pi/n$. Since $e^{-in(\theta+\tau)} = e^{-in\theta}e^{-i\pi} = -e^{-in\theta}$, the substitution $\theta \mapsto \theta + \tau$ in the integral (legitimate by periodicity) gives

$$\hat{f}(n) = \frac{1}{2\pi} \int_0^{2\pi} f(\theta + \tau) e^{-in(\theta+\tau)} d\theta = -\frac{1}{2\pi} \int_0^{2\pi} f(\theta + \tau) e^{-in\theta} d\theta.$$

Adding this identity to the original one and dividing by 2,

$$\hat{f}(n) = \frac{1}{4\pi} \int_0^{2\pi} [f(\theta) - f(\theta + \pi/n)] e^{-in\theta} d\theta, \quad \text{hence} \quad |\hat{f}(n)| \leq \frac{1}{2} \|f - f(\cdot + \pi/n)\|_1.$$

Continuity of translations in L^1 — that is, $\|f - f(\cdot + \tau)\|_1 \rightarrow 0$ as $\tau \rightarrow 0$, itself a consequence of the density of step functions — concludes the proof. This variant has the merit of producing an *estimate*, not merely a limit: if f is α -Hölder, $\|f - f(\cdot + \tau)\|_1 \leq C|\tau|^\alpha$ and hence $|\hat{f}(n)| \leq \frac{1}{2} C(\pi/|n|)^\alpha$. $\square$

Remark 17.1: Why exactly this lemma is needed. Every criterion of pointwise convergence in this chapter has the same shape: one writes $S_N f(\theta_0) - L$ as an integral $\int_0^\pi g(t) \sin((N + \frac{1}{2})t) dt$ (Step 4 of the proof of Theorem 17.4), and then asks that g lie in L^1 . The whole work of each criterion is exactly there: proving the integrability of g . Dini does it with an integral hypothesis, Dirichlet–Jordan with a variation hypothesis, Theorem 17.4 with the one-sided derivatives. The Riemann–Lebesgue lemma is the common machine that, once that integrability is established, produces the conclusion.

17.2. Convergence of the Fourier series

Theorem 17.1: Convergence in L^2 and completeness of the trigonometric system. For every $f \in L^2(\mathbb{T})$ the partial sums $S_N f(\theta) = \sum_{|n| \leq N} \hat{f}(n) e^{in\theta}$ converge to f in the L^2 norm:

$$\|f - S_N f\|_2 \rightarrow 0 \quad (N \rightarrow \infty).$$

Equivalently, the system $\{e_n\}_{n \in \mathbb{Z}}$ is complete in $L^2(\mathbb{T})$, and Bessel's inequality becomes an equality (Parseval's identity, Theorem (Volume II, Chapter 4)).

Proof. Step 1 — reduction to the density of trigonometric polynomials. By Theorem (Volume II, Chapter 4)(ii), $S_N f$ is the best approximation of f in the L^2 norm among all trigonometric polynomials of degree $\leq N$. Hence, if for every $\varepsilon > 0$ there exists *some* trigonometric polynomial P (of some degree M) with $\|f - P\|_2 < \varepsilon$, then for every $N \geq M$

$$\|f - S_N f\|_2 \leq \|f - P\|_2 < \varepsilon,$$

and the claim follows. It remains to prove that trigonometric polynomials are *dense* in $L^2(\mathbb{T})$.

Step 2 — density of continuous functions. It is a standard result of measure theory that $C(\mathbb{T})$ is dense in $L^2(\mathbb{T})$: given $f \in L^2$ and $\varepsilon > 0$, there exists g continuous and 2π -periodic with $\|f - g\|_2 < \varepsilon/2$ (see Rudin, *Real and Complex Analysis*, Chapter 3).

Step 3 — density of trigonometric polynomials in $C(\mathbb{T})$. By Fejér's theorem (Theorem 17.7, proved later in this same section without using the present theorem, hence without circularity) the Cesàro means $\sigma_N g$ converge to g *uniformly*. Since on a space of total measure 1 the L^2 norm is dominated by the uniform norm,

$$\|g - \sigma_N g\|_2 \leq \|g - \sigma_N g\|_\infty \rightarrow 0,$$

there exists N with $\|g - \sigma_N g\|_2 < \varepsilon/2$, and $\sigma_N g$ is a trigonometric polynomial.

Step 4 — conclusion. By the triangle inequality, $\|f - \sigma_N g\|_2 \leq \|f - g\|_2 + \|g - \sigma_N g\|_2 < \varepsilon$: trigonometric polynomials are dense in $L^2(\mathbb{T})$, and Step 1 concludes.

Step 5 — from Bessel to Parseval. By Theorem (Volume II, Chapter 4)(iii),

$$\|f - S_N f\|_2^2 = \|f\|_2^2 - \sum_{|n| \leq N} |\hat{f}(n)|^2.$$

Passing to the limit as $N \rightarrow \infty$, the left-hand side tends to 0, hence $\sum_{n \in \mathbb{Z}} |\hat{f}(n)|^2 = \|f\|_2^2$. $\square$

Corollary 17.2: Uniqueness of the Fourier coefficients. If $f, g \in L^2(\mathbb{T})$ have the same Fourier coefficients, then $f = g$ almost everywhere. In particular, if $\hat{f}(n) = 0$ for every $n \in \mathbb{Z}$, then $f = 0$ almost everywhere; if moreover f is continuous, $f \equiv 0$.

Proof. Set $h = f - g$; by linearity $\hat{h}(n) = 0$ for every n . By Parseval's identity (Theorem 17.1, Step 5),

$$\|h\|_2^2 = \sum_{n \in \mathbb{Z}} |\hat{h}(n)|^2 = 0,$$

hence $h = 0$ almost everywhere. If h is continuous and zero almost everywhere, then it is zero everywhere: if $h(\theta_0) \neq 0$ for some θ_0 , by continuity h would be nonzero on a neighbourhood of θ_0 , which has positive measure. $\square$

Remark 17.2: Three regimes of convergence. L^2 convergence (Theorem 17.1) is the most general and robust. Under stronger hypotheses one gets finer results: if $f \in C^1(\mathbb{T})$, the series converges uniformly (and hence pointwise) to f ; if f is merely continuous, pointwise convergence may fail at individual points (a phenomenon tied to the Dirichlet kernel), but the Cesàro mean of the partial sums always converges uniformly (Fejér's theorem).

17.2.1 The Dirichlet kernel and the Gibbs phenomenon

Definition 17.2: Dirichlet kernel.

$$D_N(\theta) = \sum_{n=-N}^N e^{in\theta}.$$

Theorem 17.2: Closed form of the Dirichlet kernel. For $\theta \not\equiv 0 \pmod{2\pi}$:

$$D_N(\theta) = \frac{\sin\left((N + \frac{1}{2})\theta\right)}{\sin(\theta/2)}.$$

Proof. With $x = e^{i\theta}$, $D_N(\theta) = \sum_{n=-N}^N x^n = x^{-N} \sum_{k=0}^{2N} x^k = x^{-N} \frac{x^{2N+1} - 1}{x - 1}$ (geometric sum, Corollary 3.2 generalised to ratio $x \neq 1$) $= \frac{x^{N+1} - x^{-N}}{x - 1}$. Multiplying numerator and denominator by $x^{-1/2}$:

$$D_N(\theta) = \frac{x^{N+1/2} - x^{-(N+1/2)}}{x^{1/2} - x^{-1/2}} = \frac{2i \sin((N + \frac{1}{2})\theta)}{2i \sin(\theta/2)} = \frac{\sin((N + \frac{1}{2})\theta)}{\sin(\theta/2)}.$$

$\square$

Theorem 17.3: Partial sums as convolution with the Dirichlet kernel.

$$S_N f(\theta) = \frac{1}{2\pi} \int_0^{2\pi} f(\varphi) D_N(\theta - \varphi) d\varphi.$$

Proof. Substituting Definition (Volume II, Chapter 4) into $S_N f(\theta) = \sum_{n=-N}^N \hat{f}(n) e^{in\theta}$ and exchanging the finite sum and the integral:

$$\begin{aligned} S_N f(\theta) &= \sum_{n=-N}^N \left(\frac{1}{2\pi} \int_0^{2\pi} f(\varphi) e^{-in\varphi} d\varphi \right) e^{in\theta} = \frac{1}{2\pi} \int_0^{2\pi} f(\varphi) \sum_{n=-N}^N e^{in(\theta-\varphi)} d\varphi \\ &= \frac{1}{2\pi} \int_0^{2\pi} f(\varphi) D_N(\theta - \varphi) d\varphi. \end{aligned}$$

□

Remark 17.3: The Gibbs phenomenon. The Dirichlet kernel is not positive (it oscillates), unlike the Fejér kernel cited in Observation 17.2: this is precisely why $S_N f$ can behave worse than f near a discontinuity. For a function with a jump (for example the square wave), the partial sum $S_N f$ exhibits an overshoot just before and after the jump, of an amplitude that **does not tend to zero** as N grows: it stabilises around 8.95% of the height of the jump (the Wilbraham–Gibbs constant, tied to the value of the sine integral $\text{Si}(\pi) = \int_0^\pi \frac{\sin t}{t} dt$), while its position moves ever closer to the jump point. This is a failure of uniform convergence, not a computational error: Figure 17.1 shows it for the square wave $\text{sq}(\theta) \sim \frac{4}{\pi} \sum_{k \text{ odd}} \frac{\sin k\theta}{k}$.

Figure 17.1: Partial sums of the square wave with 5 terms (dashed) and 10 terms (solid): the overshoot near the jump at $\theta = \pi$ does not shrink going from 5 to 10 terms, it only compresses toward the discontinuity point — the Gibbs phenomenon.

17.2.2 Pointwise convergence: the Dirichlet–Jordan theorem

Theorem 17.4: Pointwise convergence (Dirichlet–Jordan). Let $f \in L^1(\mathbb{T})$ and let $\theta_0 \in \mathbb{T}$ be a point at which the one-sided limits $f(\theta_0^\pm)$ exist and are finite, together with the one-sided derivatives, i.e. the following exist and are finite:

$$\lim_{t \rightarrow 0^+} \frac{f(\theta_0 + t) - f(\theta_0^+)}{t}, \quad \lim_{t \rightarrow 0^+} \frac{f(\theta_0 - t) - f(\theta_0^-)}{t}.$$

Then

$$S_N f(\theta_0) \longrightarrow \frac{f(\theta_0^+) + f(\theta_0^-)}{2} \quad (N \rightarrow \infty).$$

In particular, if f is continuous and differentiable at θ_0 , the Fourier series converges there to $f(\theta_0)$; at a jump point it converges to the average of the two one-sided limits.

Proof. Step 1 — normalisation of the kernel. By Theorem (Volume II, Chapter 4), integrating the Definition 17.2 term by term,

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} D_N(t) dt = \sum_{|n| \leq N} \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{int} dt = 1,$$

since only the term $n = 0$ survives. Moreover D_N is *even* (a sum of e^{int} over symmetric indices, or, by Theorem 17.2, a ratio of two odd functions), hence

$$\frac{1}{2\pi} \int_0^{\pi} D_N(t) dt = \frac{1}{2}.$$

Step 2 — symmetrisation. By Theorem 17.3, with the substitution $\varphi = \theta_0 - t$ and using periodicity,

$$S_N f(\theta_0) = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(\theta_0 - t) D_N(t) dt.$$

Splitting the integral over $[-\pi, 0]$ and $[0, \pi]$ and substituting $t \mapsto -t$ in the first, with D_N even:

$$S_N f(\theta_0) = \frac{1}{2\pi} \int_0^{\pi} [f(\theta_0 - t) + f(\theta_0 + t)] D_N(t) dt.$$

Step 3 — subtracting the expected limit. Set $L = \frac{1}{2}(f(\theta_0^+) + f(\theta_0^-))$; by Step 1, $\frac{1}{2\pi} \int_0^{\pi} 2L D_N(t) dt = L$, hence

$$S_N f(\theta_0) - L = \frac{1}{2\pi} \int_0^{\pi} \underbrace{[f(\theta_0 - t) + f(\theta_0 + t) - 2L]}_{=: \psi(t)} D_N(t) dt.$$

Step 4 — the auxiliary function is integrable. By Theorem 17.2, $D_N(t) = \sin((N + \frac{1}{2})t) / \sin(t/2)$; set therefore

$$g(t) = \frac{\psi(t)}{\sin(t/2)}, \quad t \in (0, \pi],$$

so that $S_N f(\theta_0) - L = \frac{1}{2\pi} \int_0^{\pi} g(t) \sin((N + \frac{1}{2})t) dt$. We verify that $g \in L^1(0, \pi)$. Write

$$\psi(t) = [f(\theta_0 + t) - f(\theta_0^+)] + [f(\theta_0 - t) - f(\theta_0^-)].$$

By the hypothesis on the one-sided derivatives, each bracket is $O(t)$ as $t \rightarrow 0^+$; since $\sin(t/2) \sim t/2$, the ratio $g(t)$ stays *bounded* on a right neighbourhood of 0. On $[\delta, \pi]$, instead, $\sin(t/2) \geq \sin(\delta/2) > 0$ and g is integrable because ψ is (a sum of translates of $f \in L^1$). Hence $g \in L^1(0, \pi)$.

Step 5 — Riemann–Lebesgue. Expanding $\sin((N + \frac{1}{2})t) = \sin(Nt) \cos(t/2) + \cos(Nt) \sin(t/2)$,

$$S_N f(\theta_0) - L = \frac{1}{2\pi} \int_0^{\pi} [g(t) \cos \frac{t}{2}] \sin(Nt) dt + \frac{1}{2\pi} \int_0^{\pi} [g(t) \sin \frac{t}{2}] \cos(Nt) dt.$$

Both functions in square brackets belong to $L^1(0, \pi)$ (the product of an L^1 function and a bounded one). Extending them oddly, resp. evenly, to $(-\pi, \pi)$, the two integrals are — up to constants — Fourier coefficients of index N of L^1 functions: by Corollary (Volume II, Chapter 4) both tend to zero as $N \rightarrow \infty$. Hence $S_N f(\theta_0) \rightarrow L$. $\square$

Remark 17.4: The value at jump points. Theorem 17.4 answers a question intuition leaves open: at a discontinuity point the series does not "choose" one of the two values, but converges to their average. For the square wave of Example (Volume II, Chapter 4), at $\theta = 0$ the series equals $\frac{4}{\pi} \sum_k \sin 0 / (2k + 1) = 0$, which is exactly $\frac{1}{2}(1 + (-1)) = 0$. ✓ The same happens at $\theta = \pi$. Note that this does not contradict the Gibbs phenomenon: convergence at the jump point is perfect, it is uniform convergence on a neighbourhood that fails.

17.2.3 Uniform convergence

Theorem 17.5: Absolute and uniform convergence. Let $f \in L^2(\mathbb{T})$ with coefficients $c_n = \hat{f}(n)$.

- (i) If $\sum_{n \in \mathbb{Z}} |c_n| < \infty$, then the Fourier series converges absolutely and uniformly on $\mathbb{T}$, its sum is continuous and coincides with f almost everywhere (everywhere, if f is continuous).
- (ii) If f is continuous, 2π -periodic and piecewise C^1 , then $\sum_n |c_n| < \infty$ and hence the series converges uniformly to f .

Proof. (i) Since $|c_n e^{in\theta}| = |c_n|$ for every θ , the hypothesis $\sum |c_n| < \infty$ allows the Weierstrass criterion to be applied: the series converges totally, hence absolutely and uniformly on $\mathbb{T}$. The uniform limit of a sequence of continuous functions (the partial sums are trigonometric polynomials, hence continuous) is continuous; call it g . Since uniform convergence on a domain of finite measure implies convergence in L^2 , one has $S_N f \rightarrow g$ in L^2 ; but by Theorem 17.1, $S_N f \rightarrow f$ in L^2 . By uniqueness of the L^2 limit, $f = g$ almost everywhere; if f is continuous, two continuous functions equal almost everywhere coincide everywhere (Corollary 17.2).

(ii) Let $f' \in L^2(\mathbb{T})$ be the derivative (defined almost everywhere, and in L^2 because f is piecewise C^1 with finitely many pieces). Integrating by parts over a period, with f continuous and periodic so that the boundary terms cancel:

$$\hat{f}'(n) = \frac{1}{2\pi} \int_0^{2\pi} f'(\theta) e^{-in\theta} d\theta = \frac{1}{2\pi} \underbrace{[f(\theta) e^{-in\theta}]_0^{2\pi}}_{=0} + \frac{in}{2\pi} \int_0^{2\pi} f(\theta) e^{-in\theta} d\theta = in c_n.$$

Hence $|c_n| = |\hat{f}'(n)|/|n|$ for $n \neq 0$. Applying the Cauchy–Schwarz inequality to the sequence:

$$\sum_{n \neq 0} |c_n| = \sum_{n \neq 0} \frac{1}{|n|} |\hat{f}'(n)| \leq \left(\sum_{n \neq 0} \frac{1}{n^2} \right)^{1/2} \left(\sum_{n \neq 0} |\hat{f}'(n)|^2 \right)^{1/2}.$$

The first series equals $2 \cdot \pi^2/6 = \pi^2/3$ (Example (Volume II, Chapter 4), Step 5); the second is finite by Bessel's inequality (Theorem (Volume II, Chapter 4)(iv)) applied to $f' \in L^2$. Hence $\sum_n |c_n| < \infty$ and (i) applies. $\square$

Remark 17.5: Regularity and decay: the practical rule. The proof of (ii) contains the key relation

$$\hat{f}'(n) = in \hat{f}(n),$$

which, iterated, gives $\widehat{f^{(k)}}(n) = (in)^k \hat{f}(n)$. Since by Riemann–Lebesgue $\widehat{f^{(k)}}(n) \rightarrow 0$, it follows that if $f \in C^k(\mathbb{T})$ then

$$\hat{f}(n) = o\left(\frac{1}{|n|^k}\right).$$

The more regular f is, the faster its coefficients decay — and this is exactly the principle that in Chapter 2 governed the order of convergence of the periodic trapezoidal rule (Theorem, Volume II, Chapter 2). The two statements are, on closer inspection, the same theorem read from two sides: there one estimated the aliasing error $\sum_{m \geq 1} c_m N$, here the decay of the c_n .

17.2.4 The Fejér kernel and Cesàro means

The Dirichlet kernel is not positive, and all the pathologies stem from this: the Gibbs phenomenon, the possible pointwise divergence for merely continuous functions. Replacing the partial sums with their *arithmetic means* yields a positive kernel, and with it a convergence theorem without exceptions.

Definition 17.3: Cesàro means and the Fejér kernel. Set

$$\sigma_N f = \frac{1}{N+1} \sum_{n=0}^N S_n f, \quad F_N(\theta) = \frac{1}{N+1} \sum_{n=0}^N D_n(\theta).$$

$\sigma_N f$ is called the **Cesàro mean** of order N and F_N the **Fejér kernel**.

Theorem 17.6: Closed form and properties of the Fejér kernel. For $\theta \not\equiv 0 \pmod{2\pi}$:

$$F_N(\theta) = \frac{1}{N+1} \left(\frac{\sin((N+1)\theta/2)}{\sin(\theta/2)} \right)^2 = \sum_{|n| \leq N} \left(1 - \frac{|n|}{N+1} \right) e^{in\theta},$$

and the three properties of an **approximate identity** hold:

- (a) $F_N \geq 0$ everywhere;
- (b) $\frac{1}{2\pi} \int_{-\pi}^{\pi} F_N(\theta) d\theta = 1$ for every N ;
- (c) for every $\delta \in (0, \pi)$, $\sup_{\delta \leq |\theta| \leq \pi} F_N(\theta) \rightarrow 0$ as $N \rightarrow \infty$.

Moreover $\sigma_N f = f * F_N$, i.e. $\sigma_N f(\theta) = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(\theta - t) F_N(t) dt$.

Proof. Step 1 — closed form. By Theorem 17.2, $D_n(\theta) \sin(\theta/2) = \sin((n + \frac{1}{2})\theta)$. Multiply by $2 \sin(\theta/2)$ and use the product-to-sum formula $2 \sin A \sin B = \cos(A - B) - \cos(A + B)$ with $A = (n + \frac{1}{2})\theta$, $B = \theta/2$:

$$2 \sin^2 \frac{\theta}{2} D_n(\theta) = \cos(n\theta) - \cos((n+1)\theta).$$

Summing for $n = 0, \dots, N$, the right-hand sum is *telescoping*:

$$2 \sin^2 \frac{\theta}{2} \sum_{n=0}^N D_n(\theta) = \cos 0 - \cos((N+1)\theta) = 1 - \cos((N+1)\theta) = 2 \sin^2 \frac{(N+1)\theta}{2},$$

having used $1 - \cos u = 2 \sin^2(u/2)$. Dividing by $2 \sin^2(\theta/2)$ and by $N+1$ gives the closed form.

Step 2 — spectral form. Each $D_n = \sum_{|k| \leq n} e_k$, so when summing $D_0, \dots, D_N$ the mode e_k appears once for each $n \geq |k|$, i.e. $N+1 - |k|$ times. Dividing by $N+1$:

$$F_N = \sum_{|k| \leq N} \frac{N+1 - |k|}{N+1} e_k = \sum_{|k| \leq N} \left(1 - \frac{|k|}{N+1} \right) e_k.$$

Step 3 — (a) positivity. Immediate from the closed form: it is a square divided by $N+1 > 0$. (At the points $\theta \equiv 0$ the value is $N+1$ by continuity, still positive.)

Step 4 — (b) normalisation. From the spectral form, integrating term by term and using Theorem (Volume II, Chapter 4), only the mode $k=0$ survives, whose coefficient is 1.

Step 5 — (c) concentration. For $\delta \leq |\theta| \leq \pi$, $\sin^2(\theta/2) \geq \sin^2(\delta/2) > 0$, while the numerator is ≤ 1 . Hence

$$0 \leq F_N(\theta) \leq \frac{1}{(N+1)\sin^2(\delta/2)} \rightarrow 0,$$

uniformly on $\{\delta \leq |\theta| \leq \pi\}$.

Step 6 — convolution. Averaging over $n = 0, \dots, N$ the identity of Theorem 17.3 and exchanging the finite sum and the integral gives $\sigma_N f = f * F_N$. $\square$

Theorem 17.7: Fejér's theorem. Let $f : \mathbb{T} \rightarrow \mathbb{C}$ be continuous. Then $\sigma_N f \rightarrow f$ uniformly on $\mathbb{T}$. More generally, if $f \in L^1(\mathbb{T})$ and θ_0 is a point at which the one-sided limits exist, $\sigma_N f(\theta_0) \rightarrow \frac{1}{2}(f(\theta_0^+) + f(\theta_0^-))$.

Proof. We prove the uniform case; the other is identical, with the symmetrisation of Step 2 of the proof of Theorem 17.4.

Step 1 — representation of the error. By Theorem 17.6(b),

$$\sigma_N f(\theta) - f(\theta) = \frac{1}{2\pi} \int_{-\pi}^{\pi} [f(\theta - t) - f(\theta)] F_N(t) dt,$$

having written $f(\theta) = \frac{1}{2\pi} \int f(\theta) F_N(t) dt$.

Step 2 — uniform continuity. f is continuous on the compact set $\mathbb{T}$, hence uniformly continuous and bounded: let $M = \sup |f|$. Given $\varepsilon > 0$, there exists $\delta > 0$ such that

$$|t| < \delta \implies |f(\theta - t) - f(\theta)| < \frac{\varepsilon}{2} \quad \text{for every } \theta.$$

Step 3 — splitting the integral. We separate $|t| < \delta$ from $\delta \leq |t| \leq \pi$ and bound in modulus, using $F_N \geq 0$ (property (a)):

$$|\sigma_N f(\theta) - f(\theta)| \leq \underbrace{\frac{1}{2\pi} \int_{|t| < \delta} \frac{\varepsilon}{2} F_N(t) dt}_{(I)} + \underbrace{\frac{1}{2\pi} \int_{\delta \leq |t| \leq \pi} 2M F_N(t) dt}_{(II)}.$$

Step 4 — bounding the two pieces. For (I), extending the integral to the whole period and using (b):

$$(I) \leq \frac{\varepsilon}{2} \cdot \frac{1}{2\pi} \int_{-\pi}^{\pi} F_N = \frac{\varepsilon}{2}.$$

For (II), using the concentration property (c): there exists N_0 such that for $N \geq N_0$, $F_N(t) \leq \varepsilon/(4M+1)$ on $\delta \leq |t| \leq \pi$, and hence

$$(II) \leq 2M \cdot \frac{\varepsilon}{4M+1} < \frac{\varepsilon}{2}.$$

Step 5 — conclusion. For $N \geq N_0$ and for every θ , $|\sigma_N f(\theta) - f(\theta)| < \varepsilon$: the convergence is uniform. $\square$

Corollary 17.3: Weierstrass's trigonometric approximation theorem. Trigonometric polynomials are dense in $C(\mathbb{T})$ with respect to the uniform norm: for every con-

tinuous, 2π -periodic f and every $\varepsilon > 0$ there is a trigonometric polynomial P with $\sup_{\mathbb{T}} |f - P| < \varepsilon$. They are consequently dense also in $L^p(\mathbb{T})$ for every $1 \leq p < \infty$.

Proof. By Theorem 17.7, $\sigma_N f \rightarrow f$ uniformly, and $\sigma_N f$ is a trigonometric polynomial of degree $\leq N$ by Theorem 17.6 (spectral form). It suffices to choose N large enough. For density in L^p : $C(\mathbb{T})$ is dense in $L^p(\mathbb{T})$ for $p < \infty$, and on a space of total measure 1 the L^p norm is dominated by the uniform norm, hence uniform approximation implies approximation in L^p . $\square$

Remark 17.6: Why Fejér saves what Dirichlet loses. The comparison between the two kernels is instructive and explains everything:

	Dirichlet D_N	Fejér F_N
Sign	oscillates, changes sign	≥ 0 always
Mean	1	1
$\frac{1}{2\pi} \int K_N $	$\sim \frac{4}{\pi^2} \ln N \rightarrow \infty$	$= 1$, bounded
Convergence	can fail for continuous f	always uniform if f continuous
Gibbs	present	absent

The quantity $L_N = \frac{1}{2\pi} \int_{-\pi}^{\pi} |D_N|$ is called the **Lebesgue constant**; the fact that it diverges (logarithmically) is the structural reason why there exists a continuous function whose Fourier series diverges at a point — a result of du Bois-Reymond (1876). The Fejér kernel, being positive, has Lebesgue constant 1: it is an approximate identity in the proper sense, and this is why the pathologies are absent.

17.2.5 The Poisson kernel and Abel summation

Definition 17.4: Poisson kernel. For $0 \leq r < 1$ set

$$P_r(\theta) = \sum_{n \in \mathbb{Z}} r^{|n|} e^{in\theta}.$$

Theorem 17.8: Closed form of the Poisson kernel and Abel summation. For $0 \leq r < 1$:

$$P_r(\theta) = \frac{1 - r^2}{1 - 2r \cos \theta + r^2} \geq 0, \quad \frac{1}{2\pi} \int_{-\pi}^{\pi} P_r(\theta) d\theta = 1,$$

and for every $\delta \in (0, \pi)$, $\sup_{\delta \leq |\theta| \leq \pi} P_r(\theta) \rightarrow 0$ as $r \rightarrow 1^-$. Consequently, if f is continuous on $\mathbb{T}$,

$$u(r, \theta) := (f * P_r)(\theta) = \sum_{n \in \mathbb{Z}} r^{|n|} \hat{f}(n) e^{in\theta} \longrightarrow f(\theta) \quad \text{uniformly as } r \rightarrow 1^-,$$

By Theorem 16.6 of Chapter 16, u is moreover the unique harmonic function in the disc, continuous up to the boundary, with boundary value f (solution of the Dirichlet problem); uniqueness is not proved here, only the uniform convergence just established.

Proof. Step 1 — closed form. Split the sum into $n \geq 0$ and $n \leq -1$; both are geometric series of ratio with modulus $r < 1$, hence convergent:

$$P_r(\theta) = \sum_{n \geq 0} (re^{i\theta})^n + \sum_{m \geq 1} (re^{-i\theta})^m = \frac{1}{1 - re^{i\theta}} + \frac{re^{-i\theta}}{1 - re^{-i\theta}}.$$

Reducing to a common denominator $(1 - re^{i\theta})(1 - re^{-i\theta}) = 1 - 2r \cos \theta + r^2$ (by Theorem (Volume II, Chapter 3) of Chapter 3), the numerator is

$$(1 - re^{-i\theta}) + re^{-i\theta}(1 - re^{i\theta}) = 1 - re^{-i\theta} + re^{-i\theta} - r^2 = 1 - r^2.$$

Step 2 — positivity and normalisation. The numerator $1 - r^2 > 0$; the denominator is $|1 - re^{i\theta}|^2 > 0$ because $r < 1$. For the normalisation, integrating the definition term by term (legitimate by uniform convergence in θ for fixed r) and using Theorem (Volume II, Chapter 4), only the term $n = 0$ survives, which equals $r^0 = 1$.

Step 3 — concentration. For $\delta \leq |\theta| \leq \pi$, $\cos \theta \leq \cos \delta$, hence

$$1 - 2r \cos \theta + r^2 \geq 1 - 2r \cos \delta + r^2 = (1 - r)^2 + 2r(1 - \cos \delta) \geq 2r(1 - \cos \delta),$$

and therefore

$$P_r(\theta) \leq \frac{1 - r^2}{2r(1 - \cos \delta)} \rightarrow 0 \quad (r \rightarrow 1^-).$$

Step 4 — convergence. The three properties of Steps 2 and 3 are exactly those of the Fejér kernel: the proof of Theorem 17.7 repeats word for word, with $r \rightarrow 1^-$ in place of $N \rightarrow \infty$, and gives the uniform convergence of $f * P_r$ to f .

Step 5 — spectral form and harmonicity. Since $\widehat{P_r}(n) = r^{|n|}$, the convolution theorem (Theorem, Volume II, Chapter 4) gives $\widehat{f * P_r}(n) = r^{|n|}\widehat{f}(n)$, which is the series in the statement. Writing $z = re^{i\theta}$, one has $r^{|n|}e^{in\theta} = z^n$ for $n \geq 0$ and $= \bar{z}^{|n|}$ for $n < 0$: hence u is the sum of a holomorphic function and the conjugate of a holomorphic function on $|z| < 1$, and is therefore harmonic (the real and imaginary parts of holomorphic functions are harmonic). $\square$

***Remark 17.7: Three approximate identities, one idea.** Dirichlet, Fejér and Poisson are three summation kernels for the same series. The common structure — normalisation to 1, concentration around the origin, and (for the last two) positivity — is that of an **approximate identity**: convolving with it reproduces the function in the limit. The difference lies entirely in the sign:*

- D_N oscillates $\Rightarrow$ faithful reconstruction in quadratic mean, but with Gibbs and possible pointwise divergences;
- $F_N \geq 0 \Rightarrow$ uniform reconstruction without Gibbs, at the price of a damping of the high coefficients (the factor $1 - |n|/(N + 1)$), i.e. a slight loss of detail;
- $P_r \geq 0 \Rightarrow$ like Fejér, with damping $r^{|n|}$; it is the “continuous” version and is the one that solves the Dirichlet problem in the disc.

In signal processing these factors are called windows: the Fejér factor is the triangular (Bartlett) window, and the trade-off between resolution and the absence of spurious oscillations is exactly the one discussed in Section 22.10.3 regarding spectral leakage.

17.2.6 The Gibbs phenomenon: the exact constant

Theorem 17.9: The Wilbraham–Gibbs constant. Let f be the square wave of Example (Volume II, Chapter 4), with a jump of amplitude 2 at $\theta = 0$, and let $S_N f$ be its partial sum with $N = 2m - 1$. Then the first maximum of $S_N f$ to the right of the origin is at $\theta_m = \pi/(2m)$, and

$$\lim_{m \rightarrow \infty} S_{2m-1} f(\theta_m) = \frac{2}{\pi} \int_0^\pi \frac{\sin u}{u} du = \frac{2}{\pi} \text{Si}(\pi) = 1.178979744 \dots$$

The overshoot beyond the limiting value 1 is thus 17.898% of the half-amplitude of the jump, i.e. 8.949% of the total amplitude, and does not tend to zero as N grows.

Proof. Step 1 — the derivative of the partial sum. From Example (Volume II, Chapter 4),

$$S_{2m-1} f(\theta) = \frac{4}{\pi} \sum_{j=1}^m \frac{\sin((2j-1)\theta)}{2j-1}, \quad \text{hence} \quad \frac{d}{d\theta} S_{2m-1} f(\theta) = \frac{4}{\pi} \sum_{j=1}^m \cos((2j-1)\theta).$$

Step 2 — closed form of the sum of odd cosines. Multiplying by $2 \sin \theta$ and using $2 \cos A \sin B = \sin(A+B) - \sin(A-B)$ with $A = (2j-1)\theta$, $B = \theta$:

$$2 \sin \theta \sum_{j=1}^m \cos((2j-1)\theta) = \sum_{j=1}^m [\sin(2j\theta) - \sin((2j-2)\theta)] = \sin(2m\theta),$$

by telescoping (the term $j = 1$ contributes $\sin 2\theta - \sin 0$). Hence

$$\frac{d}{d\theta} S_{2m-1} f(\theta) = \frac{2}{\pi} \cdot \frac{\sin(2m\theta)}{\sin \theta}.$$

Step 3 — the first critical point. For $\theta \in (0, \pi)$ the denominator is positive, so the first zero of the derivative to the right of 0 occurs when $2m\theta = \pi$, i.e. $\theta_m = \pi/(2m)$. Since the derivative is positive on $(0, \theta_m)$ (where $0 < 2m\theta < \pi$), the point θ_m is a maximum.

Step 4 — value at the maximum. Since $S_{2m-1} f(0) = 0$, integrating the derivative:

$$S_{2m-1} f(\theta_m) = \frac{2}{\pi} \int_0^{\pi/(2m)} \frac{\sin(2mt)}{\sin t} dt.$$

Substituting $u = 2mt$, $dt = du/(2m)$:

$$S_{2m-1} f(\theta_m) = \frac{2}{\pi} \int_0^\pi \sin u \cdot \frac{1}{2m \sin(u/(2m))} du.$$

Step 5 — passing to the limit. As $m \rightarrow \infty$, for fixed $u \in (0, \pi]$,

$$2m \sin \frac{u}{2m} \rightarrow u,$$

since $\sin x/x \rightarrow 1$. Moreover the integrand is uniformly dominated: from the concavity of $\sin$ on $[0, \pi/2]$, $\sin x \geq \frac{2}{\pi}x$ for $x \in [0, \pi/2]$, hence $2m \sin(u/(2m)) \geq \frac{2}{\pi}u$ and the integrand is bounded by $\frac{\pi}{2} \cdot \frac{\sin u}{u} \leq \frac{\pi}{2}$, which is integrable on $[0, \pi]$. By the dominated convergence theorem,

$$\lim_{m \rightarrow \infty} S_{2m-1} f(\theta_m) = \frac{2}{\pi} \int_0^\pi \frac{\sin u}{u} du.$$

Step 6 — the numerical value. The integral is the sine integral $\text{Si}(\pi) = 1.851937052 \dots$, hence the limit equals

$$\frac{2}{\pi} \cdot 1.851937052 = 1.178979744 \dots$$

The overshoot beyond the value 1 is 0.178979744, i.e. 17.898% of 1 (half-amplitude of the jump) and 8.949% of 2 (total amplitude). $\square$

Remark 17.8: What the Gibbs phenomenon is not. Three clarifications that Theorem 17.9 makes rigorous:

- **It is not a computational or truncation error that can be fixed:** the amplitude of the overshoot has a positive limit, and no increase of N reduces it.
- **It does not contradict pointwise convergence:** by Theorem 17.4, at every fixed point the series converges. The overshoot moves toward the jump ($\theta_m = \pi/(2m) \rightarrow 0$) without ever settling on a point: it is uniform convergence that fails, not pointwise convergence.
- **It is not unavoidable:** replacing the partial sums with the Fejér means (Theorem 17.7) the phenomenon disappears, because the Fejér kernel is positive. The price is a slowdown of convergence where f is regular.

Historically the phenomenon was described by Henry Wilbraham in 1848 and rediscovered, independently and with greater resonance, by J. Willard Gibbs in 1899 in a letter to Nature: hence the double name.

Remark 17.9: The two extremes of the theory: Kolmogorov and Carleson. Two deep results delimit what one can hope for from pointwise convergence, and they are cited here without proof because they lie well beyond the level of this chapter.

- **Kolmogorov (1926).** There exists $f \in L^1(\mathbb{T})$ whose Fourier series diverges at every point. Mere integrability is not enough.
- **Carleson (1966).** For every $f \in L^2(\mathbb{T})$ the Fourier series converges to f almost everywhere. The result, extended by Hunt (1968) to L^p with $p > 1$, resolved positively a conjecture that had been open for half a century.

Between the two extremes sits the theorem of du Bois-Reymond cited in Observation 17.6: there exists a continuous function whose series diverges at a point. The operational moral, for anyone computing, is the one already stated: for piecewise C^1 functions, pointwise convergence is guaranteed everywhere (Theorem 17.4), and for continuous functions reliable reconstruction goes through the Fejér means.

17.3. The Lebesgue constants and logarithmic divergence

Observation 17.6 announced that the integral of the *modulus* of the Dirichlet kernel diverges like $\ln N$, and Exercise 17.2 derived the lower bound. Here the question is settled in both directions: an upper bound of the same order is proved, so that L_N is *exactly* of order $\ln N$, and the structural consequence is drawn — the existence of a continuous function whose series diverges at a point.

Definition 17.5: Lebesgue constant. For $N \in \mathbb{N}$ set

$$L_N = \frac{1}{2\pi} \int_{-\pi}^{\pi} |D_N(\theta)| d\theta = \|D_N\|_1,$$

with D_N the Dirichlet kernel of Definition 17.2.

Lemma 17.3: Gap between the cosecant and its asymptote. Set, for $t \in (0, \pi]$,

$$g(t) = \frac{1}{\sin(t/2)} - \frac{2}{t}.$$

Then

$$0 \leq g(t) \leq \frac{\pi t}{24} \leq \frac{\pi^2}{24} < 0.412.$$

Proof. **Step 1 — three elementary inequalities.** For $x \geq 0$,

$$(a) \sin x \leq x, \quad (b) \sin x \geq x - \frac{x^3}{6}, \quad (c) \sin x \geq \frac{2}{\pi}x \text{ for } x \in \left[0, \frac{\pi}{2}\right].$$

For (a): the function $h(x) = x - \sin x$ has $h(0) = 0$ and $h'(x) = 1 - \cos x \geq 0$, hence it is non-decreasing and so $h \geq 0$. For (b): let $m(x) = \cos x - 1 + \frac{x^2}{2}$; then $m(0) = 0$ and $m'(x) = x - \sin x \geq 0$ by (a), hence $m \geq 0$, i.e. $\cos x \geq 1 - \frac{x^2}{2}$. Now let $k(x) = \sin x - x + \frac{x^3}{6}$: one has $k(0) = 0$ and $k'(x) = \cos x - 1 + \frac{x^2}{2} = m(x) \geq 0$, hence $k \geq 0$. For (c): on $[0, \pi]$, $(\sin)'' = -\sin \leq 0$, so $\sin$ is concave on $[0, \pi]$; a concave function on an interval lies *above* the chord joining its endpoints, and the chord between $(0, 0)$ and $(\pi/2, 1)$ is the line $x \mapsto 2x/\pi$.

Step 2 — rewriting g . Reducing to a common denominator,

$$g(t) = \frac{t - 2\sin(t/2)}{t \sin(t/2)}, \quad t \in (0, \pi].$$

The denominator is positive, because $t > 0$ and $t/2 \in (0, \pi/2]$ where the sine is positive.

Step 3 — the numerator is non-negative and $O(t^3)$. From (a) with $x = t/2$ it follows that $2\sin(t/2) \leq t$, so the numerator is ≥ 0 and hence $g \geq 0$. From (b) with $x = t/2$ it follows that

$$2\sin \frac{t}{2} \geq 2\left(\frac{t}{2} - \frac{t^3}{48}\right) = t - \frac{t^3}{24}, \quad \text{i.e.} \quad t - 2\sin \frac{t}{2} \leq \frac{t^3}{24}.$$

Step 4 — lower bound for the denominator. From (c) with $x = t/2 \in (0, \pi/2]$ it follows that $\sin(t/2) \geq t/\pi$, hence $t \sin(t/2) \geq t^2/\pi$.

Step 5 — conclusion. Combining Steps 3 and 4,

$$0 \leq g(t) \leq \frac{t^3/24}{t^2/\pi} = \frac{\pi t}{24} \leq \frac{\pi \cdot \pi}{24} = \frac{\pi^2}{24} = 0.41123\dots$$

□

Theorem 17.10: Logarithmic growth of the Lebesgue constants. For every $N \geq 1$,

$$\frac{4}{\pi^2}(\ln N - 1) \leq L_N \leq \frac{2}{\pi}\left(1 + \ln\left((N + \frac{1}{2})\pi\right)\right) + \frac{\pi^2}{24}.$$

In particular $L_N \rightarrow \infty$ and L_N is exactly of order $\ln N$: the ratio $L_N/\ln N$ stays, for $N \geq 3$, between two positive constants.

Proof. **Step 1 — reduction to an integral on $[0, \pi]$.** By Theorem 17.2, $D_N(\theta) = \sin(M\theta)/\sin(\theta/2)$ with $M = N + \frac{1}{2}$. The numerator and denominator are odd functions, hence $|D_N|$ is even and

$$L_N = \frac{1}{2\pi} \int_{-\pi}^{\pi} |D_N| = \frac{1}{\pi} \int_0^{\pi} \frac{|\sin(M\theta)|}{\sin(\theta/2)} d\theta.$$

Step 2 — lower bound. By Step 1 (a) of Lemma 17.3 with $x = \theta/2$, $\sin(\theta/2) \leq \theta/2$, hence $1/\sin(\theta/2) \geq 2/\theta$ and

$$L_N \geq \frac{2}{\pi} \int_0^{\pi} \frac{|\sin(M\theta)|}{\theta} d\theta = \frac{2}{\pi} \int_0^{M\pi} \frac{|\sin u|}{u} du \geq \frac{2}{\pi} \int_0^{N\pi} \frac{|\sin u|}{u} du,$$

having set $u = M\theta$ and used $M\pi \geq N\pi$ with a non-negative integrand. Splitting $[0, N\pi]$ into the intervals $[k\pi, (k+1)\pi]$ and bounding $1/u$ from below by its minimum $1/((k+1)\pi)$ on each,

$$\int_0^{N\pi} \frac{|\sin u|}{u} du \geq \sum_{k=1}^{N-1} \frac{1}{(k+1)\pi} \int_{k\pi}^{(k+1)\pi} |\sin u| du = \frac{2}{\pi} \sum_{k=1}^{N-1} \frac{1}{k+1} = \frac{2}{\pi} \sum_{j=2}^N \frac{1}{j},$$

since $\int_{k\pi}^{(k+1)\pi} |\sin u| du = 2$ for every k . Finally, comparing the sum with the integral of the decreasing function $1/x$,

$$\sum_{j=2}^N \frac{1}{j} \geq \int_2^{N+1} \frac{dx}{x} = \ln \frac{N+1}{2} \geq \ln N - \ln 2 \geq \ln N - 1,$$

and combining gives $L_N \geq \frac{4}{\pi^2}(\ln N - 1)$.

Step 3 — upper bound. By Lemma 17.3, $\frac{1}{\sin(\theta/2)} = \frac{2}{\theta} + g(\theta)$ with $0 \leq g \leq \pi^2/24$. Hence

$$L_N \leq \frac{2}{\pi} \int_0^\pi \frac{|\sin(M\theta)|}{\theta} d\theta + \frac{1}{\pi} \int_0^\pi |\sin(M\theta)| g(\theta) d\theta.$$

The second term is bounded by $\frac{1}{\pi} \cdot 1 \cdot \frac{\pi^2}{24} \cdot \pi = \frac{\pi^2}{24}$, because $|\sin| \leq 1$ and the interval has length π . For the first, with $u = M\theta$,

$$\int_0^\pi \frac{|\sin(M\theta)|}{\theta} d\theta = \int_0^{M\pi} \frac{|\sin u|}{u} du \leq \int_0^1 1 du + \int_1^{M\pi} \frac{du}{u} = 1 + \ln(M\pi),$$

where $|\sin u|/u \leq 1$ for $u \in (0, 1]$ was used (which is (a) of Step 1 of Lemma 17.3) together with $|\sin u| \leq 1$ for $u \geq 1$; note that $M\pi = (N + \frac{1}{2})\pi > 1$ for every $N \geq 0$. The bound in the statement follows.

Step 4 — the order of magnitude. From below: for $N \geq 8$, $\ln N \geq 2$, hence $\ln N - 1 \geq \frac{1}{2} \ln N$ and so $L_N \geq \frac{2}{\pi^2} \ln N$; for $N \in \{3, \dots, 7\}$ it suffices to note that $L_N \geq L_3 > 0$ and $\ln N \leq \ln 7$, so that $L_N/\ln N \geq L_3/\ln 7 > 0$. From above: for $N \geq 1$, $(N + \frac{1}{2})\pi \leq 2\pi N$, hence $\ln((N + \frac{1}{2})\pi) \leq \ln N + \ln(2\pi)$ and

$$L_N \leq \frac{2}{\pi} \ln N + C, \quad C = \frac{2}{\pi}(1 + \ln 2\pi) + \frac{\pi^2}{24} = 2.2179\dots,$$

so that $L_N/\ln N \leq \frac{2}{\pi} + C/\ln 3$ for $N \geq 3$. The ratio $L_N/\ln N$ thus stays between two positive constants for every $N \geq 3$. $\square$

***Remark 17.10: Numerical check of the two estimates.** The constants L_N were computed by composite Simpson quadrature ($2 \cdot 10^5$ subintervals on $[0, \pi]$, integrand $|\sin(M\theta)|/\sin(\theta/2)$) and compared with the two sides of Theorem 17.10 and with the asymptotic $\frac{4}{\pi^2} \ln N + 1.2703$ mentioned in Exercise 17.2:*

N	lower bound	L_N	upper bound	$\frac{4}{\pi^2} \ln N + 1.2703$
1	—	1.435991	2.034738	1.270300

The two outer columns always bracket L_N : ✓. One also sees that the asymptotic is already excellent at $N = 1\,000$ (gap $2.6 \cdot 10^{-4}$), while the bounds proved here, though of the right order, have worse constants: the lower bound loses the factor $\pi/2$ in the step $\sin(\theta/2) \leq \theta/2$, the upper bound loses it in the crude $|\sin u| \leq 1$. The sharp asymptotic $L_N = \frac{4}{\pi^2} \ln N + O(1)$ is imported from Zygmund, *Trigonometric Series, Chapter II*: it is not needed for anything that follows, for which the divergence alone suffices.

Figure 17.2: The Lebesgue constants L_N (points, computed by quadrature) as a function of $\ln N$, with the asymptotic line $\frac{4}{\pi^2} \ln N + 1.2703$ (dashed). Abscissa: $x = 0.8 \ln N$ centimetres; ordinate: $y = 1.2(L_N - 1)$ centimetres. The growth is linear in $\ln N$: this is the content of Theorem 17.10.

Lemma 17.4: *The norm of the “partial sum at the origin” functional. Consider $\Lambda_N : C(\mathbb{T}) \rightarrow \mathbb{C}$, $\Lambda_N(f) = S_N f(0)$, on the space of continuous, 2π -periodic functions with the uniform norm. Then Λ_N is linear,*

$$\Lambda_N(f) = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(\varphi) D_N(\varphi) d\varphi, \quad |\Lambda_N(f)| \leq L_N \|f\|_{\infty},$$

and its operator norm equals exactly $\|\Lambda_N\| = L_N$.

Proof. Step 1 — the integral formula. By Theorem 17.3 with $\theta = 0$, $S_N f(0) = \frac{1}{2\pi} \int_0^{2\pi} f(\varphi) D_N(-\varphi) d\varphi$; since D_N is even (Step 1 of the proof of Theorem 17.4) and the functions involved are 2π -periodic, the integral on $[0, 2\pi]$ equals the one on $[-\pi, \pi]$ and the formula follows. Linearity is that of the integral.

Step 2 — the bound. Bringing the modulus inside the integral,

$$|\Lambda_N(f)| \leq \frac{1}{2\pi} \int_{-\pi}^{\pi} |f| |D_N| \leq \|f\|_{\infty} \cdot \frac{1}{2\pi} \int_{-\pi}^{\pi} |D_N| = L_N \|f\|_{\infty},$$

hence $\|\Lambda_N\| \leq L_N$.

Step 3 — the bound is attained. D_N is a trigonometric polynomial, hence continuous, and by Theorem 17.2 it vanishes on $[-\pi, \pi]$ only where $\sin(M\theta) = 0$ with $M = N + \frac{1}{2}$, i.e. at the points $\theta = k\pi/M$: finitely many. Let Z be the (finite) set formed by these points and by $\pm\pi$, and let $h = \operatorname{sgn} D_N$, which equals ± 1 outside Z . For every integer $j \geq 1$ define $f_j : \mathbb{T} \rightarrow [-1, 1]$ continuous as follows: $f_j = h$ outside the intervals $I_z = (z - \frac{1}{j}, z + \frac{1}{j})$ centred at the points $z \in Z$, $f_j(z) = 0$ for $z \in Z$, and f_j affine on each of the two halves of every I_z (for j large enough the I_z are pairwise disjoint). The condition $f_j(\pm\pi) = 0$ makes f_j well defined and continuous on $\mathbb{T}$, and $\|f_j\|_\infty \leq 1$.

Step 4 — passing to the limit. As $j \rightarrow \infty$, $f_j(\theta) \rightarrow h(\theta)$ for every $\theta \notin Z$, i.e. almost everywhere, and $|f_j D_N| \leq |D_N| \in L^1(-\pi, \pi)$. By the dominated convergence theorem,

$$\Lambda_N(f_j) = \frac{1}{2\pi} \int_{-\pi}^{\pi} f_j D_N \rightarrow \frac{1}{2\pi} \int_{-\pi}^{\pi} h D_N = \frac{1}{2\pi} \int_{-\pi}^{\pi} |D_N| = L_N.$$

Since $\|f_j\|_\infty \leq 1$, $\|\Lambda_N\| \geq |\Lambda_N(f_j)|$ for every j , hence $\|\Lambda_N\| \geq L_N$. With Step 2, $\|\Lambda_N\| = L_N$. $\square$

Corollary 17.4: *There exists a continuous function whose Fourier series diverges at a point (du Bois-Reymond). There exists $f \in C(\mathbb{T})$ such that $\sup_N |S_N f(0)| = +\infty$; in particular the Fourier series of f does not converge at $\theta = 0$, even though f is continuous. Consequently continuity alone implies neither the pointwise nor the uniform convergence of the partial sums.*

Proof. The space $C(\mathbb{T})$ with the uniform norm is complete (the uniform limit of continuous functions is continuous), hence it is a Banach space. The family $\{\Lambda_N\}_{N \in \mathbb{N}}$ of Lemma 17.4 consists of continuous linear functionals with $\sup_N \|\Lambda_N\| = \sup_N L_N = +\infty$ by Theorem 17.10. The Banach–Steinhaus uniform boundedness principle — assumed here as an external prerequisite, see Observation 17.15 — states that a family of continuous linear operators on a Banach space that is pointwise bounded is uniformly bounded in norm. By the contrapositive, since the family is not uniformly bounded in norm, it is not pointwise bounded: there exists $f \in C(\mathbb{T})$ with $\sup_N |\Lambda_N(f)| = \sup_N |S_N f(0)| = +\infty$. An unbounded numerical sequence does not converge, hence $S_N f(0)$ does not converge; and since uniform convergence would imply pointwise convergence at 0, uniform convergence cannot occur either. $\square$

Figure 17.3: The Dirichlet kernel D_5 (solid) and the Fejér kernel F_5 (dashed) on $[-\pi, \pi]$. Scale: abscissa $x = 1.5\theta$ centimetres, ordinate $y = 0.3K$ centimetres. Control values computed by hand: $D_5(0) = 2 \cdot 5 + 1 = 11$ and $F_5(0) = 5 + 1 = 6$ (the heights marked on the axis); $D_5(\pi/6) = \sin(11\pi/12)/\sin(\pi/12) = 1$ because $\sin(11\pi/12) = \sin(\pi/12)$; $D_5(\pi) = \sin(11\pi/2) = -1$; $F_5(\pi/2) = (\sin(3\pi/2)/\sin(\pi/4))^2/6 = 2/6 = 1/3$; $F_5(\pi/3) = 0$ because $\sin(\pi) = 0$. D_5 changes sign, F_5 does not: that is the whole difference between the two worlds.

17.4. Criteria for pointwise convergence: Dini and Dirichlet–Jordan

Theorem 17.4 gave a first pointwise criterion, based on the existence of the one-sided derivatives. That hypothesis is convenient but is neither the weakest nor the most natural: there are two classical conditions, independent of one another, that both contain it. The first is *integral* (Dini), the second is a *variation* condition (Dirichlet–Jordan). Both rest on the same scheme, which it is worth isolating once and for all.

Definition 17.6: Symmetrised difference. Let $f \in L^1(\mathbb{T})$, $\theta_0 \in \mathbb{T}$ and $L \in \mathbb{C}$. Set, for $t \in (0, \pi]$,

$$\psi(t) = \psi_{\theta_0, L}(t) = f(\theta_0 + t) + f(\theta_0 - t) - 2L.$$

Lemma 17.5: Reduction of the pointwise criteria to a single integral. With the notation of Definition 17.6 and $M = N + \frac{1}{2}$,

$$S_N f(\theta_0) - L = \frac{1}{2\pi} \int_0^\pi \psi(t) \frac{\sin(Mt)}{\sin(t/2)} dt,$$

and $\psi \in L^1(0, \pi)$.

Proof. Step 1 — convolution and symmetrisation. This is exactly the content of Steps 1–3 of the proof of Theorem 17.4, which use no hypothesis on f beyond $f \in L^1(\mathbb{T})$: the normalisation $\frac{1}{2\pi} \int_0^\pi D_N = \frac{1}{2}$ gives $\frac{1}{2\pi} \int_0^\pi 2L D_N(t) dt = L$, and the symmetrisation gives

$$S_N f(\theta_0) - L = \frac{1}{2\pi} \int_0^\pi \psi(t) D_N(t) dt.$$

Substituting the closed form of Theorem 17.2 gives the formula in the statement.

Step 2 — summability of ψ . The functions $t \mapsto f(\theta_0 \pm t)$ are translates and reflections of f , hence lie in $L^1(0, \pi)$ with $\int_0^\pi |f(\theta_0 \pm t)| dt \leq \int_{-\pi}^\pi |f| < \infty$; the constant $2L$ is integrable on a bounded interval. Hence $\psi \in L^1(0, \pi)$ as a sum of three summable functions. $\square$

Theorem 17.11: Dini’s criterion. Let $f \in L^1(\mathbb{T})$, $\theta_0 \in \mathbb{T}$, $L \in \mathbb{C}$, and suppose the **Dini condition** holds:

$$\int_0^\pi \frac{|\psi(t)|}{t} dt < \infty, \quad \psi(t) = f(\theta_0 + t) + f(\theta_0 - t) - 2L.$$

Then $S_N f(\theta_0) \rightarrow L$ as $N \rightarrow \infty$.

Proof. Step 1 — the function to integrate. By Lemma 17.5,

$$S_N f(\theta_0) - L = \frac{1}{2\pi} \int_0^\pi G(t) \sin(Mt) dt, \quad G(t) = \frac{\psi(t)}{\sin(t/2)}.$$

Step 2 — G is summable. By Lemma 17.3, $\frac{1}{\sin(t/2)} = \frac{2}{t} + g(t)$ with $0 \leq g \leq \pi^2/24$; hence

$$|G(t)| \leq 2 \frac{|\psi(t)|}{t} + \frac{\pi^2}{24} |\psi(t)|.$$

The first term is summable on $(0, \pi)$ by the Dini condition, the second because $\psi \in L^1(0, \pi)$ by Lemma 17.5. Hence $G \in L^1(0, \pi)$.

Step 3 — Riemann–Lebesgue with a half-integer frequency. Since $M = N + \frac{1}{2}$ is not an integer, one expands

$$\sin(Mt) = \sin(Nt) \cos \frac{t}{2} + \cos(Nt) \sin \frac{t}{2},$$

so that

$$\int_0^\pi G(t) \sin(Mt) dt = \int_0^\pi \left[G(t) \cos \frac{t}{2} \right] \sin(Nt) dt + \int_0^\pi \left[G(t) \sin \frac{t}{2} \right] \cos(Nt) dt.$$

The two functions in square brackets lie in $L^1(0, \pi)$, being products of $G \in L^1$ with functions bounded by 1. By Lemma 17.2, with $\lambda = N$, both integrals tend to zero as $N \rightarrow \infty$. Hence $S_N f(\theta_0) - L \rightarrow 0$. $\square$

Corollary 17.5: Convergence at points of one-sided Hölder continuity. Let $f \in L^1(\mathbb{T})$ and let θ_0 be a point at which the one-sided limits $f(\theta_0^\pm)$ exist and are finite, and at which, for some $\delta, C > 0$ and $\alpha \in (0, 1]$,

$$|f(\theta_0 \pm t) - f(\theta_0^\pm)| \leq C t^\alpha \quad \text{for } 0 < t < \delta.$$

Then $S_N f(\theta_0) \rightarrow \frac{1}{2}(f(\theta_0^+) + f(\theta_0^-))$. In particular, if f is Lipschitz in a neighbourhood of θ_0 , or differentiable at θ_0 , the series converges there to $f(\theta_0)$.

Proof. Take $L = \frac{1}{2}(f(\theta_0^+) + f(\theta_0^-))$, so that

$$\psi(t) = [f(\theta_0 + t) - f(\theta_0^+)] + [f(\theta_0 - t) - f(\theta_0^-)], \quad |\psi(t)| \leq 2Ct^\alpha \quad (0 < t < \delta).$$

Then, splitting the integral of the Dini condition,

$$\int_0^\delta \frac{|\psi(t)|}{t} dt \leq 2C \int_0^\delta t^{\alpha-1} dt = \frac{2C\delta^\alpha}{\alpha} < \infty, \quad \int_\delta^\pi \frac{|\psi(t)|}{t} dt \leq \frac{1}{\delta} \int_0^\pi |\psi| < \infty,$$

the first because $\alpha > 0$ makes $t^{\alpha-1}$ integrable at 0, the second because $\psi \in L^1(0, \pi)$ (Lemma 17.5). The Dini condition holds and Theorem 17.11 concludes. If f is differentiable at θ_0 then it is continuous there and $|f(\theta_0 \pm t) - f(\theta_0)| \leq Ct$ for small t , i.e. the case $\alpha = 1$ with $L = f(\theta_0)$. $\square$

Remark 17.11: Dini's criterion contains the one-sided-derivative criterion. Theorem 17.4, inherited from Volume II, is the case $\alpha = 1$ of Corollary 17.5: the existence of finite one-sided derivatives implies $|f(\theta_0 \pm t) - f(\theta_0^\pm)| \leq Ct$ for small t , which is the Dini condition. It is worth pointing out a small historical inaccuracy in the name: that statement is due to **Dini**, not to Dirichlet and Jordan. The properly named Dirichlet–Jordan criterion is the one in Theorem 17.12, which assumes bounded variation and not differentiability. Neither one contains the other: there exist functions of bounded variation that fail Dini's condition at a point, and functions that satisfy Dini's condition without being of bounded variation on any neighbourhood.

17.4.1 Functions of bounded variation

Definition 17.7: Total variation and functions of bounded variation. Let $u : [a, b] \rightarrow \mathbb{R}$. The **total variation** of u on $[a, b]$ is

$$V_a^b(u) = \sup \left\{ \sum_{i=1}^n |u(x_i) - u(x_{i-1})| : n \in \mathbb{N}, a = x_0 < x_1 < \cdots < x_n = b \right\} \in [0, +\infty].$$

If $V_a^b(u) < \infty$, u is said to be of **bounded variation** on $[a, b]$, written $u \in BV[a, b]$. A complex-valued function is of bounded variation when both its real and imaginary parts are.

Lemma 17.6: Jordan decomposition and one-sided limits. Let $u : [a, b] \rightarrow \mathbb{R}$. Then:

- (i) if $u = p - q$ with p, q non-decreasing, then $u \in BV[a, b]$;
- (ii) if $u \in BV[a, b]$, setting $V(x) = V_a^x(u)$ (with $V(a) = 0$), the functions $p = \frac{V+u}{2}$ and $q = \frac{V-u}{2}$ are non-decreasing and $u = p - q$;
- (iii) every $u \in BV[a, b]$ has finite one-sided limits at every point (right-sided at a , left-sided at b).

Proof. **Step 1 — (i).** For every partition, the triangle inequality gives

$$\sum_i |u(x_i) - u(x_{i-1})| \leq \sum_i (p(x_i) - p(x_{i-1})) + \sum_i (q(x_i) - q(x_{i-1})) = (p(b) - p(a)) + (q(b) - q(a)),$$

because the two sums telescope and their terms are non-negative. The bound does not depend on the partition, hence $V_a^b(u) < \infty$.

Step 2 — additivity of the variation. For $a \leq x \leq y \leq b$, $V_a^y(u) = V_a^x(u) + V_x^y(u)$. Indeed: joining a partition of $[a, x]$ and one of $[x, y]$ gives a partition of $[a, y]$, and the corresponding sum is the sum of the two, hence $V_a^y \geq V_a^x + V_x^y$; conversely, given a partition of $[a, y]$, adding the point x does not decrease the sum (again by the triangle inequality) and splits it into the two sums relative to $[a, x]$ and $[x, y]$, hence $V_a^y \leq V_a^x + V_x^y$.

Step 3 — (ii). For $x < y$, Step 2 gives $V(y) - V(x) = V_x^y(u) \geq |u(y) - u(x)| \geq \pm(u(y) - u(x))$, where the first inequality is the trivial partition $\{x, y\}$. Hence

$$(V \pm u)(y) - (V \pm u)(x) \geq 0,$$

i.e. $V + u$ and $V - u$ are non-decreasing; dividing by 2 gives p and q , and $p - q = u$.

Step 4 — (iii). A monotone bounded function on $[a, b]$ has finite one-sided limits at every point: for φ non-decreasing, $\varphi(x_0^-) = \sup_{x < x_0} \varphi(x)$ and $\varphi(x_0^+) = \inf_{x > x_0} \varphi(x)$ exist and are finite because φ is bounded between $\varphi(a)$ and $\varphi(b)$. By (ii), $u = p - q$ is a difference of two non-decreasing functions, each between its own value at a and its own value at b , hence bounded; the one-sided limits of u therefore exist and are finite, as differences of finite limits. $\square$

Lemma 17.7: The variation vanishes where the function is continuous. Let $u \in BV[0, \delta]$ with u right-continuous at 0, i.e. $u(0^+) = u(0)$. Then $V(t) = V_0^t(u) \rightarrow 0$ as $t \rightarrow 0^+$.

Proof. Let $\varepsilon > 0$. By definition of supremum there is a partition $0 = t_0 < t_1 < \cdots < t_n = \delta$ with

$$\sum_{i=1}^n |u(t_i) - u(t_{i-1})| > V(\delta) - \varepsilon.$$

Refining the partition does not decrease the sum (triangle inequality, as in Step 2 of the proof of Lemma 17.6), so one may further assume that t_1 is small enough that $|u(t_1) - u(0)| < \varepsilon$:

it suffices to add to the partition a point t^* with that property, which is possible because $u(0^+) = u(0)$, and rename. Now, by Step 2 of Lemma 17.6, $\sum_{i \geq 2} |u(t_i) - u(t_{i-1})| \leq V_{t_1}^\delta(u) = V(\delta) - V(t_1)$, hence

$$V(\delta) - \varepsilon < \underbrace{|u(t_1) - u(0)|}_{< \varepsilon} + (V(\delta) - V(t_1)),$$

whence $V(t_1) < 2\varepsilon$. Since V is non-decreasing (Step 2 of Lemma 17.6) and $V \geq 0$, $0 \leq V(t) \leq V(t_1) < 2\varepsilon$ for every $t \in (0, t_1]$. By the arbitrariness of ε , $V(0^+) = 0$. $\square$

Lemma 17.8: Second mean value theorem, Bonnet's form. Let $v : [a, b] \rightarrow \mathbb{R}$ be non-increasing and non-negative and $h \in L^1(a, b)$, and set $H(x) = \int_a^x h(t) dt$. Then there exists $\xi \in [a, b]$ with

$$\int_a^b v(t)h(t) dt = v(a)H(\xi), \quad \text{and in particular} \quad \left| \int_a^b v h \right| \leq v(a) \max_{[a,b]} |H|.$$

Proof. Step 1 — H is continuous. If $x_k \rightarrow x$ in $[a, b]$, then $\mathbf{1}_{[a, x_k]}h \rightarrow \mathbf{1}_{[a, x]}h$ almost everywhere (outside the single point x) and $|\mathbf{1}_{[a, x_k]}h| \leq |h| \in L^1$; by dominated convergence $H(x_k) \rightarrow H(x)$. Hence H is continuous on the compact set $[a, b]$ and attains there a minimum m and a maximum M ; note $H(a) = 0$, hence $m \leq 0 \leq M$.

Step 2 — approximation by step functions and Abel summation. For $n \geq 1$ consider the uniform partition $x_k = a + k\frac{b-a}{n}$, $k = 0, \dots, n$, and the step function

$$v_n = \sum_{k=1}^n v(x_{k-1}) \mathbf{1}_{[x_{k-1}, x_k]}.$$

Then, setting $H_k = H(x_k)$ and $c_k = v(x_{k-1})$, and recalling $H_0 = H(a) = 0$,

$$\int_a^b v_n h = \sum_{k=1}^n c_k (H_k - H_{k-1}) = c_n H_n + \sum_{k=1}^{n-1} (c_k - c_{k+1}) H_k,$$

which is Abel summation: separate the two sums $\sum c_k H_k$ and $\sum c_k H_{k-1}$, shift the index of the second, and collect terms.

Step 3 — the value is a weighted average. The coefficients $c_n = v(x_{n-1}) \geq 0$ and $c_k - c_{k+1} = v(x_{k-1}) - v(x_k) \geq 0$ (because v is non-increasing and non-negative) have telescoping sum

$$c_n + \sum_{k=1}^{n-1} (c_k - c_{k+1}) = c_1 = v(a).$$

Hence $\int_a^b v_n h$ is a combination, with non-negative coefficients summing to $v(a)$, of values of H , and therefore

$$v(a)m \leq \int_a^b v_n h \leq v(a)M \quad \text{for every } n.$$

Step 4 — passing to the limit. A monotone function has at most countably many discontinuities: for every j the points where the jump exceeds $1/j$ are at most $j(v(a) - v(b))$, because the jumps are pairwise disjoint and their sum does not exceed the total variation $v(a) - v(b)$; the set of discontinuities is therefore a countable union of finite sets. At every point x of continuity of v , $v_n(x) = v(x_{k-1})$ with $x_{k-1} \leq x < x_k$ and $x - x_{k-1} \leq \frac{b-a}{n} \rightarrow 0$, hence $v_n(x) \rightarrow v(x)$: the convergence is almost everywhere. Moreover $|v_n h| \leq v(a)|h| \in L^1$. By dominated convergence $\int_a^b v_n h \rightarrow \int_a^b v h$, and by Step 3

$$v(a)m \leq \int_a^b v h \leq v(a)M.$$

Step 5 — the point ξ . If $v(a) = 0$, then $0 \leq v \leq v(a) = 0$ gives $v \equiv 0$ and the equality holds for any ξ . If $v(a) > 0$, the number $\frac{1}{v(a)} \int_a^b v h$ lies in $[m, M]$; since H is continuous on $[a, b]$ and attains the values m and M , the intermediate value theorem provides $\xi \in [a, b]$ with $H(\xi) = \frac{1}{v(a)} \int_a^b v h$, which is the claim. The final bound follows from $|H(\xi)| \leq \max |H|$. $\square$

Lemma 17.9: Uniform boundedness of the sine integral. Set $\text{Si}(x) = \int_0^x \frac{\sin u}{u} du$ for $x \geq 0$ (the integrand extends continuously to 1 at $u = 0$). Then

$$0 \leq \text{Si}(x) \leq \text{Si}(\pi) = 1.851937052 \dots \quad \text{for every } x \geq 0,$$

and consequently, for every $\lambda > 0$ and $0 \leq c_1 \leq c_2$,

$$\left| \int_{c_1}^{c_2} \frac{\sin(\lambda t)}{t} dt \right| = |\text{Si}(\lambda c_2) - \text{Si}(\lambda c_1)| \leq \text{Si}(\pi) < 1.852.$$

Proof. Step 1 — an alternating series. Set $a_k = \int_{k\pi}^{(k+1)\pi} \frac{\sin u}{u} du$ for $k \geq 0$. Substituting $u = v + k\pi$ and using $\sin(v + k\pi) = (-1)^k \sin v$,

$$a_k = (-1)^k b_k, \quad b_k = \int_0^\pi \frac{\sin v}{v + k\pi} dv > 0.$$

The sequence b_k is strictly decreasing, because the integrand decreases pointwise in k and is positive on $(0, \pi)$; moreover $b_k \leq \frac{\pi}{k\pi} = \frac{1}{k} \rightarrow 0$.

Step 2 — the partial sums lie in $[0, b_0]$. By construction $\text{Si}(n\pi) = \sum_{k=0}^{n-1} (-1)^k b_k$. For an alternating series with decreasing positive terms, the even-index partial sums increase, the odd-index ones decrease, and every even-index partial sum is $\leq$ every odd-index one; the smallest is $\text{Si}(0) = 0$ and the largest is $b_0 = \text{Si}(\pi)$. Hence $0 \leq \text{Si}(n\pi) \leq \text{Si}(\pi)$ for every $n \geq 0$.

Step 3 — the intermediate points. On $[n\pi, (n+1)\pi]$ the function $\sin u/u$ has constant sign, hence Si is monotone there and every value lies between $\text{Si}(n\pi)$ and $\text{Si}((n+1)\pi)$, both in $[0, \text{Si}(\pi)]$ by Step 2. Hence $0 \leq \text{Si}(x) \leq \text{Si}(\pi)$ for every $x \geq 0$.

Step 4 — the version with a parameter. The substitution $u = \lambda t$ gives $\int_{c_1}^{c_2} \frac{\sin(\lambda t)}{t} dt = \int_{\lambda c_1}^{\lambda c_2} \frac{\sin u}{u} du = \text{Si}(\lambda c_2) - \text{Si}(\lambda c_1)$, and the difference of two numbers in $[0, \text{Si}(\pi)]$ has modulus $\leq \text{Si}(\pi)$. The numerical value $\text{Si}(\pi) = 1.851937052$ is computed by two independent routes in Section 17.6. $\square$

Theorem 17.12: Dirichlet–Jordan criterion. Let $f \in L^1(\mathbb{T})$ and let $\theta_0 \in \mathbb{T}$ be such that f is of bounded variation on $[\theta_0 - \delta_0, \theta_0 + \delta_0]$ for some $\delta_0 \in (0, \pi)$. Then the one-sided limits $f(\theta_0^\pm)$ exist and are finite, and

$$S_N f(\theta_0) \rightarrow \frac{f(\theta_0^+) + f(\theta_0^-)}{2} \quad (N \rightarrow \infty).$$

At a point of continuity the limit is $f(\theta_0)$; at a jump point it is the arithmetic mean of the two one-sided values.

Proof. Step 1 — the one-sided limits exist. This is Lemma 17.6(iii) applied to f on the interval $[\theta_0 - \delta_0, \theta_0 + \delta_0]$ (separately for the real and imaginary parts).

Step 2 — reduction. Set $L = \frac{1}{2}(f(\theta_0^+) + f(\theta_0^-))$ and $\psi(t) = f(\theta_0 + t) + f(\theta_0 - t) - 2L$ as in Definition 17.6. By Lemma 17.5, with $M = N + \frac{1}{2}$,

$$S_N f(\theta_0) - L = \frac{1}{2\pi} \int_0^\pi \frac{\psi(t)}{\sin(t/2)} \sin(Mt) dt.$$

By Lemma 17.3 one splits $\frac{1}{\sin(t/2)} = \frac{2}{t} + g(t)$ with $0 \leq g \leq \pi^2/24$:

$$S_N f(\theta_0) - L = \underbrace{\frac{1}{\pi} \int_0^\pi \frac{\psi(t)}{t} \sin(Mt) dt}_{A_N} + \underbrace{\frac{1}{2\pi} \int_0^\pi \psi(t) g(t) \sin(Mt) dt}_{B_N}.$$

Step 3 — the term B_N tends to zero. The function ψg lies in $L^1(0, \pi)$, because $\psi \in L^1(0, \pi)$ (Lemma 17.5) and g is bounded. Expanding $\sin(Mt) = \sin(Nt) \cos \frac{t}{2} + \cos(Nt) \sin \frac{t}{2}$ as in Step 3 of the proof of Theorem 17.11, Lemma 17.2 gives $B_N \rightarrow 0$.

Step 4 — structure of ψ near 0. Fix $\delta \in (0, \delta_0]$ with $\delta \leq \pi$. The functions $t \mapsto f(\theta_0 + t)$ and $t \mapsto f(\theta_0 - t)$ are of bounded variation on $[0, \delta]$ (restrictions and reflections of f , which is BV there), hence so is ψ ; set $\psi(0) = 0$, which makes ψ right-continuous at 0 because $\psi(0^+) = f(\theta_0^+) + f(\theta_0^-) - 2L = 0$. By Lemma 17.6(ii), with $V(t) = V_0^t(\psi)$, $\psi = p - q$ on $[0, \delta]$ with $p = \frac{V+\psi}{2}$ and $q = \frac{V-\psi}{2}$ non-decreasing and $p(0) = q(0) = 0$; in particular $p, q \geq 0$. By Lemma 17.7, $V(0^+) = 0$, hence also $p(0^+) = q(0^+) = 0$.

Step 5 — uniform estimate near the origin. Let $\varepsilon > 0$. By Step 4 there is $\delta_1 \in (0, \delta]$ with $p(\delta_1) < \varepsilon$ and $q(\delta_1) < \varepsilon$. Consider

$$h(t) = \frac{\sin(Mt)}{t} \in L^1(0, \delta_1), \quad H(x) = \int_0^x h = \text{Si}(Mx),$$

where the last equality is the substitution $u = Mt$ and h is bounded by M near 0. The function $P(t) = p(\delta_1) - p(t)$ is non-negative and non-increasing on $[0, \delta_1]$, with $P(0) = p(\delta_1)$. By Lemma 17.8 there is $\xi \in [0, \delta_1]$ with $\int_0^{\delta_1} Ph = p(\delta_1) \text{Si}(M\xi)$, hence

$$\int_0^{\delta_1} p h = p(\delta_1) \int_0^{\delta_1} h - \int_0^{\delta_1} Ph = p(\delta_1) [\text{Si}(M\delta_1) - \text{Si}(M\xi)].$$

By Lemma 17.9 the bracket has modulus $\leq \text{Si}(\pi) < 1.852$, hence $|\int_0^{\delta_1} p h| < 1.852\varepsilon$, and the same bound holds for q . Subtracting,

$$\left| \int_0^{\delta_1} \psi(t) \frac{\sin(Mt)}{t} dt \right| < 2 \cdot 1.852\varepsilon = 3.704\varepsilon \quad \text{for every } N.$$

Note that the bound is *uniform in N* : this is the point where the bounded variation hypothesis does all the work.

Step 6 — the tail away from the origin. On $[\delta_1, \pi]$ the function $\psi(t)/t$ is summable, because $|\psi(t)/t| \leq |\psi(t)|/\delta_1$ and $\psi \in L^1(0, \pi)$. Expanding $\sin(Mt)$ again as in Step 3, Lemma 17.2 gives

$$\int_{\delta_1}^\pi \frac{\psi(t)}{t} \sin(Mt) dt \rightarrow 0 \quad (N \rightarrow \infty).$$

Step 7 — conclusion. Combining Steps 5 and 6,

$$\limsup_{N \rightarrow \infty} |A_N| \leq \frac{1}{\pi} \cdot 3.704\varepsilon < 1.18\varepsilon,$$

and since $\varepsilon > 0$ is arbitrary, $A_N \rightarrow 0$. With Step 3, $B_N \rightarrow 0$, hence $S_N f(\theta_0) - L \rightarrow 0$. $\square$

Corollary 17.6: Piecewise monotone functions. Let $f \in L^1(\mathbb{T})$ be bounded and piecewise monotone in a neighbourhood of θ_0 , i.e. such that $[\theta_0 - \delta_0, \theta_0 + \delta_0]$ splits into finitely many intervals on each of which f is monotone. Then $S_N f(\theta_0) \rightarrow \frac{1}{2}(f(\theta_0^+) + f(\theta_0^-))$.

Proof. On each subinterval f is monotone and bounded, hence of bounded variation by Lemma 17.6(i) (with $q = 0$ or $p = 0$); by additivity of the variation (Step 2 of the proof of Lemma 17.6) the variation on the whole $[\theta_0 - \delta_0, \theta_0 + \delta_0]$ is the sum of finitely many finite quantities, hence finite. Theorem 17.12 applies. $\square$

Example 17.1: The square wave and the sawtooth wave. The square wave of Example (Volume II, Chapter 4) is piecewise constant, hence piecewise monotone: by Corollary 17.6 its series converges at $\theta = 0$ to $\frac{1}{2}(1 + (-1)) = 0$, as already observed in Observation 17.4. The sawtooth function $f(\theta) = \theta$ for $\theta \in (-\pi, \pi)$, extended periodically, is increasing on $(-\pi, \pi)$ and has a jump from π to $-\pi$ at $\theta = \pi$: it is of bounded variation on every interval, with $V_{-\pi}^{\pi} = 2\pi$, and Theorem 17.12 gives

$$S_N f(\pi) \rightarrow \frac{\pi + (-\pi)}{2} = 0.$$

The direct check is immediate: the coefficients are $\hat{f}(n) = \frac{i(-1)^n}{n}$ for $n \neq 0$, so that $f(\theta) \sim \frac{1}{2} \sum_{n \geq 1} \frac{(-1)^{n+1}}{n} \sin(n\theta)$, and at $\theta = \pi$ every term $\sin(n\pi)$ vanishes: $S_N f(\pi) = 0$ for every N . $\checkmark$

Remark 17.12: What is not proved here about the Dirichlet–Jordan criterion. Theorem 17.12 is pointwise. Its uniform version — if f is of bounded variation on $\mathbb{T}$ and continuous on a closed interval $[\alpha, \beta]$, then $S_N f \rightarrow f$ uniformly on $[\alpha, \beta]$ — requires making uniform in θ_0 all the estimates of Steps 5 and 6, and in particular Lemma 17.7. It is not proved in this chapter: it is an imported result, found in Zygmund, *Trigonometric Series, Chapter II*. Nothing that follows relies on it.

17.5. Uniqueness of the coefficients

Corollary 17.2 established the uniqueness of the coefficients for square-summable functions, deriving it from Parseval’s identity. For merely summable functions Parseval’s identity is not available, and another argument is needed: Fejér’s theorem.

Theorem 17.13: Uniqueness of Fourier coefficients in L^1 . Let $f \in L^1(\mathbb{T})$ with $\hat{f}(n) = 0$ for every $n \in \mathbb{Z}$. Then $f = 0$ almost everywhere. Consequently, if $f, g \in L^1(\mathbb{T})$ have the same Fourier coefficients then $f = g$ almost everywhere; if moreover both are continuous, they coincide everywhere.

Proof. Step 1 — the continuous case. Let f be continuous with all coefficients zero. Then $S_n f = \sum_{|k| \leq n} \hat{f}(k) e_k = 0$ for every n , hence also $\sigma_N f = \frac{1}{N+1} \sum_{n=0}^N S_n f = 0$ for every N (Definition 17.3). By Theorem 17.7, $\sigma_N f \rightarrow f$ uniformly, hence f is the uniform limit of the identically zero sequence: $f \equiv 0$.

Step 2 — the antiderivative. Now let $f \in L^1(\mathbb{T})$ with all coefficients zero and set

$$F(\theta) = \int_0^\theta f(t) dt, \quad \theta \in [0, 2\pi].$$

Since $\hat{f}(0) = \frac{1}{2\pi} \int_0^{2\pi} f = 0$, $F(2\pi) = 0 = F(0)$: hence F extends to a continuous, 2π -periodic function on $\mathbb{T}$ (it is continuous by Step 1 of the proof of Lemma 17.8, applied to $h = f$).

Step 3 — the coefficients of the antiderivative. Let $n \neq 0$. The function $\theta \mapsto e^{-in\theta}/(-in)$ is an antiderivative of $e^{-in\theta}$; since F is absolutely continuous with $F' = f$ almost everywhere (Lebesgue’s differentiation theorem, a prerequisite declared in Observation 17.15), integration

by parts for absolutely continuous functions gives

$$\int_0^{2\pi} F(\theta) e^{-in\theta} d\theta = \left[F(\theta) \frac{e^{-in\theta}}{-in} \right]_0^{2\pi} - \int_0^{2\pi} f(\theta) \frac{e^{-in\theta}}{-in} d\theta = 0 + \frac{1}{in} \int_0^{2\pi} f(\theta) e^{-in\theta} d\theta = 0,$$

where the boundary term vanishes because $F(2\pi) = F(0) = 0$ and $e^{-2\pi in} = 1$, and the last integral is $2\pi \hat{f}(n) = 0$. Hence $\hat{F}(n) = 0$ for every $n \neq 0$.

Step 4 — conclusion. Let $c = \hat{F}(0)$ and $G = F - c$. Then G is continuous, 2π -periodic, and $\hat{G}(n) = \hat{F}(n) - c \hat{1}(n) = 0$ for every n (by Proposition 17.1, $\hat{1}(n) = \delta_{n0}$). By Step 1, $G \equiv 0$, i.e. F is constant. A constant function has zero derivative, hence $f = F' = 0$ almost everywhere.

Step 5 — the general form. If f and g have the same coefficients, by linearity $\widehat{f - g}(n) = 0$ for every n and Steps 1–4 give $f = g$ almost everywhere. If both are continuous and differ at a point θ_1 , by continuity they would differ on a neighbourhood of θ_1 , which has positive measure: contradiction. $\square$

***Remark 17.13: Two uniqueness results, two independent proofs.** Corollary 17.2 and Theorem 17.13 say the same thing in two different settings, and neither relies on the other: the first goes through Parseval (hence through completeness, hence through Fejér), the second through Fejér directly plus the antiderivative step. The second is stronger, because $L^2(\mathbb{T}) \subset L^1(\mathbb{T})$ (Lemma 17.1) and the inclusion is strict: the function $f(\theta) = |\theta|^{-1/2}$ on $(-\pi, \pi)$ lies in L^1 and not in L^2 , since $\int_0^\pi t^{-1} dt$ diverges while $\int_0^\pi t^{-1/2} dt = 2\sqrt{\pi}$ converges.*

17.6. The sine-integral: two independent computations

Theorem 17.9 reduces the Wilbraham–Gibbs constant to the number $\frac{2}{\pi} \text{Si}(\pi)$, and Lemma 17.9 uses the same number as a uniform bound. It is therefore worth computing it carefully, and twice.

***Proposition 17.3: Series expansion of the sine integral.** For every $x \in \mathbb{R}$,*

$$\text{Si}(x) = \int_0^x \frac{\sin u}{u} du = \sum_{k=0}^{\infty} \frac{(-1)^k x^{2k+1}}{(2k+1)(2k+1)!},$$

and the series converges for every x . For $x > 0$ it is alternating with terms eventually decreasing in modulus, so that the truncation error after the term of index k does not exceed the modulus of the term of index $k+1$.

Proof. Step 1 — the series of the integrand. From the exponential series one gets $\sin u = \sum_{k \geq 0} \frac{(-1)^k u^{2k+1}}{(2k+1)!}$, convergent for every $u \in \mathbb{C}$; dividing by $u \neq 0$,

$$\frac{\sin u}{u} = \sum_{k=0}^{\infty} \frac{(-1)^k u^{2k}}{(2k+1)!},$$

an identity that also holds at $u = 0$ with the value 1 of the continuous extension.

Step 2 — term-by-term integration. On every interval $[0, R]$ the series converges totally, because $\left| \frac{u^{2k}}{(2k+1)!} \right| \leq \frac{R^{2k}}{(2k+1)!}$ and $\sum_k \frac{R^{2k}}{(2k+1)!} < \infty$ (ratio test). By the Weierstrass criterion the convergence is uniform on $[0, R]$, and a uniformly convergent series of continuous functions may be integrated term by term:

$$\int_0^x \frac{\sin u}{u} du = \sum_{k=0}^{\infty} \frac{(-1)^k}{(2k+1)!} \int_0^x u^{2k} du = \sum_{k=0}^{\infty} \frac{(-1)^k x^{2k+1}}{(2k+1)(2k+1)!}.$$

Step 3 — error control. Setting $c_k = \frac{x^{2k+1}}{(2k+1)(2k+1)!}$ for $x > 0$, the ratio

$$\frac{c_{k+1}}{c_k} = \frac{x^2(2k+1)}{(2k+3)(2k+2)(2k+3)}$$

is < 1 as soon as $(2k+3)^2(2k+2) > x^2(2k+1)$, which happens for every k such that $2k+3 > x$. From that index on the series is alternating with terms decreasing in modulus and tending to zero, so by the Leibniz criterion the truncation error is bounded by the first neglected term. $\square$

Remark 17.14: The value of $\text{Si}(\pi)$, computed twice. *First route: the series of Proposition 17.3 with $x = \pi$. The terms $c_k = \pi^{2k+1}/((2k+1)(2k+1)!)$ and the partial sums are*

k	term $(-1)^k c_k$	partial sum
0	+3.141592653590	3.141592653590
1	-1.722570926683	1.419021726906
2	+0.510032807975	1.929054534882
3	-0.085609218474	1.843445316408
4	+0.009127320735	1.852572637142
5	-0.000670039177	1.851902597965
6	+0.000035869447	1.851938467412
7	-0.000001461024	1.851937006388
8	+0.000000046777	1.851937053165

Since $2k+3 > \pi$ already for $k = 1$, from the second term on the Leibniz criterion holds and the error after $k = 8$ does not exceed $c_9 = \pi^{19}/(19 \cdot 19!) = 1.21 \cdot 10^{-9}$. Continuing the sum until double precision is exhausted gives

$$\text{Si}(\pi) = 1.851937051982\dots$$

Second route: numerical quadrature, independent of the series. The following script, actually run, integrates $\sin u/u$ on $[0, \pi]$ with the composite Simpson rule, which uses the series expansion in no way whatsoever:

```
import math
def simpson(f, a, b, n):          # n even
    h = (b - a) / n
    s = f(a) + f(b)
    for k in range(1, n):
        s += (4 if k % 2 else 2) * f(a + k*h)
    return s * h / 3
sinc = lambda t: 1.0 if t == 0.0 else math.sin(t)/t
for n in (100, 1000, 10000, 100000):
    print(n, "%.12f" % simpson(sinc, 0.0, math.pi, n))
```

Output: $n = 100$ gives 1.851937052658; $n = 1000$ gives 1.851937051983; $n = 10000$ and $n = 100000$ both give 1.851937051982. The gap between the two routes is $8.4 \cdot 10^{-15}$, i.e. the order of the double-precision rounding error. $\checkmark$

Consequence: the Gibbs constant. Theorem 17.9 gives

$$\frac{2}{\pi} \text{Si}(\pi) = \frac{2 \cdot 1.851937051982}{3.141592653590} = 1.178979744472,$$

hence an overshoot of 0.178979744, i.e. 17.8980% of the half-amplitude and 8.9490% of the total amplitude of the jump: these are the values stated in Theorem 17.9. $\checkmark$

Third check, directly on the partial sums. Evaluating $S_{2m-1}f(\theta_m)$ with $\theta_m = \pi/(2m)$ on the square wave, i.e. summing $\frac{4}{\pi} \sum_{j=1}^m \frac{\sin((2j-1)\theta_m)}{2j-1}$, one gets

m	θ_m	$S_{2m-1}f(\theta_m)$
1	1.57079633	1.273239545
5	0.31415927	1.182328209
20	0.07853982	1.179188137
100	0.01570796	1.178988078
1 000	0.00157080	1.178979828
20 000	0.00007854	1.178979745

The sequence converges to the value 1.178979744 predicted by Theorem 17.9, and the convergence is of order $1/m^2$ (from $m = 1\,000$ to $m = 20\,000$ the error goes from $8.4 \cdot 10^{-8}$ to $2 \cdot 10^{-10}$). ✓

17.7. Uniform convergence for regular functions: the remainder estimate

Theorem 17.5 establishes that the series of a C^1 function converges uniformly. Here it is also stated how fast, with an explicit remainder estimate depending only on the quadratic norm of the derivative.

Theorem 17.14: Remainder estimate for functions of class C^k . Let $k \geq 1$ and $f \in C^k(\mathbb{T})$. Then

$$\sum_{|n|>N} |\hat{f}(n)| \leq \sqrt{\frac{2}{(2k-1)N^{2k-1}}} \|f^{(k)}\|_2,$$

and consequently, for every $N \geq 1$,

$$\|f - S_N f\|_\infty \leq \sqrt{\frac{2}{(2k-1)N^{2k-1}}} \|f^{(k)}\|_2.$$

In particular, for $k = 1$, $\|f - S_N f\|_\infty \leq \sqrt{2/N} \|f'\|_2$, and for $k = 2$, $\|f - S_N f\|_\infty \leq \sqrt{2/(3N^3)} \|f''\|_2$.

Proof. Step 1 — the coefficients of the derivative. Step (ii) of the proof of Theorem 17.5 shows, integrating by parts over a period and using periodicity to cancel the boundary term, that $\widehat{f'}(n) = in\hat{f}(n)$. Iterating k times (legitimate because $f, f', \dots, f^{(k-1)}$ are continuous and periodic) gives

$$\widehat{f^{(k)}}(n) = (in)^k \hat{f}(n), \quad \text{hence} \quad |\hat{f}(n)| = \frac{|\widehat{f^{(k)}}(n)|}{|n|^k} \quad (n \neq 0).$$

Step 2 — Cauchy–Schwarz on the tail. For every $N \geq 1$,

$$\sum_{|n|>N} |\hat{f}(n)| = \sum_{|n|>N} \frac{1}{|n|^k} |\widehat{f^{(k)}}(n)| \leq \left(\sum_{|n|>N} \frac{1}{n^{2k}} \right)^{1/2} \left(\sum_{|n|>N} |\widehat{f^{(k)}}(n)|^2 \right)^{1/2}.$$

Step 3 — the two factors. The second factor is bounded by $\|f^{(k)}\|_2$ by Bessel's inequality (Proposition 17.2(iv)), applicable because $f^{(k)}$ is continuous and hence lies in $L^2(\mathbb{T})$ (Lemma 17.1). For the first, comparing the sum with the integral of the decreasing function

x^{-2k} ,

$$\sum_{n>N} \frac{1}{n^{2k}} \leq \int_N^\infty \frac{dx}{x^{2k}} = \frac{1}{(2k-1)N^{2k-1}}, \quad \text{hence} \quad \sum_{|n|>N} \frac{1}{n^{2k}} \leq \frac{2}{(2k-1)N^{2k-1}},$$

the factor 2 coming from the symmetry between n and $-n$. Substituting gives the first inequality in the statement.

Step 4 — from the tail to the uniform remainder. Since $\sum_n |\hat{f}(n)| < \infty$ (this is the estimate of Step 3 with $N = 1$, plus the finitely many terms with $|n| \leq 1$), Theorem 17.5(i) guarantees that the Fourier series converges uniformly and its sum is f , which is continuous. Hence for every θ

$$|f(\theta) - S_N f(\theta)| = \left| \sum_{|n|>N} \hat{f}(n) e^{in\theta} \right| \leq \sum_{|n|>N} |\hat{f}(n)|,$$

and taking the supremum over θ concludes the proof.

Step 5 — the two numerical cases. For $k = 1$: $2/((2-1)N) = 2/N$. For $k = 2$: $2/(3N^3)$. $\square$

Example 17.2: Checking the estimate on a Poisson kernel. Take $r = \frac{1}{2}$ in Theorem 17.8:

$$f(\theta) = P_{1/2}(\theta) = \frac{1 - \frac{1}{4}}{1 - \cos \theta + \frac{1}{4}} = \frac{3}{5 - 4 \cos \theta}, \quad \hat{f}(n) = 2^{-|n|}.$$

The function is of class C^∞ because the denominator never vanishes ($5 - 4 \cos \theta \geq 1$).

Exact remainder. Since the coefficients are positive, the maximum of the remainder occurs at $\theta = 0$:

$$\|f - S_N f\|_\infty = \sum_{|n|>N} 2^{-|n|} = 2 \sum_{n>N} 2^{-n} = 2 \cdot 2^{-N} = 2^{1-N}.$$

The estimate of Theorem 17.14 with $k = 1$. By Step 1 of that proof, $\hat{f}'(n) = in 2^{-|n|}$, hence by Parseval (Theorem 17.1)

$$\|f'\|_2^2 = \sum_{n \in \mathbb{Z}} n^2 4^{-|n|} = 2 \sum_{n \geq 1} n^2 \left(\frac{1}{4}\right)^n = 2 \cdot \frac{x(1+x)}{(1-x)^3} \Big|_{x=1/4},$$

$$\|f'\|_2^2 = 2 \cdot \frac{\frac{1}{4} \cdot \frac{5}{4}}{\left(\frac{3}{4}\right)^3} = 2 \cdot \frac{20}{27} = \frac{40}{27} = 1.481481\dots,$$

having used the identity $\sum_{n \geq 1} n^2 x^n = \frac{x(1+x)}{(1-x)^3}$ for $|x| < 1$ (obtained by differentiating the geometric series twice). Hence $\|f'\|_2 = \sqrt{40/27} = 1.217161$, and the estimate is

$$\|f - S_N f\|_\infty \leq \sqrt{\frac{2}{N}} \cdot 1.217161.$$

Independent check. The square of the norm was recomputed by Simpson quadrature of $\frac{1}{2\pi} \int_0^{2\pi} |f'|^2$ with $f'(\theta) = -\frac{12 \sin \theta}{(5-4 \cos \theta)^2}$ and $2 \cdot 10^5$ subintervals: one gets 1.481481481482 against $40/27 = 1.481481481481$. $\checkmark$

Comparison. For $N = 5, 10, 20$:

N	exact remainder 2^{1-N}	estimate $\sqrt{2/N} \ f'\ _2$
5	0.0625000000	0.769800
10	0.0019531250	0.544331
20	0.0000019073	0.384900

The estimate always holds but is loose, and for a reason of principle: it uses only *one* derivative, and with one derivative one cannot do better than $N^{-1/2}$, while this f is analytic and its coefficients decay geometrically. Applying Theorem 17.14 with $k = 4$ and $\|f^{(4)}\|_2$ finite would give $O(N^{-7/2})$: the more regularity is used, the tighter the estimate. This is the same moral as in Observation 17.5.

17.8. Panorama: what this chapter does not prove

Remark 17.15: What remains imported. The chapter proves all of its statements in full, but rests on a few results imported from other branches of analysis, listed here once and for all with a precise indication of where they are used and what would be missing without them.

- **Density of step functions in L^1 of a bounded interval.** Used in Step 3 of the proof of Lemma 17.2. It is the only non-elementary ingredient of the Riemann–Lebesgue lemma: without it only the cases of step functions (Steps 1–2) and, by another route, of square-summable functions (Corollary 17.1) would remain proved.
- **Density of $C(\mathbb{T})$ in $L^2(\mathbb{T})$.** Used in Step 2 of the proof of Theorem 17.1. Without it, the completeness of the trigonometric system would remain proved only on continuous functions.
- **Dominated convergence theorem.** Used in Steps 4 and 5 of the proof of Theorem 17.9, in Step 4 of Lemma 17.4, and in Steps 1 and 4 of Lemma 17.8.
- **Lebesgue’s differentiation theorem and integration by parts for absolutely continuous functions.** Used in Steps 3 and 4 of the proof of Theorem 17.13. Without them, uniqueness would remain proved for continuous functions (Step 1) and for square-summable ones (Corollary 17.2), but not for all $f \in L^1(\mathbb{T})$.
- **Uniform boundedness principle (Banach–Steinhaus).** Used once, in Corollary 17.4. Without it the divergence of the Lebesgue constants (Theorem 17.10) and the identity $\|\Lambda_N\| = L_N$ (Lemma 17.4) would remain proved, but not the existence of the continuous function with a divergent series, which is non-constructive precisely because it follows from that principle.
- **The sharp asymptotic of the Lebesgue constants, $L_N = \frac{4}{\pi^2} \ln N + O(1)$, and the uniform version of the Dirichlet–Jordan criterion:** both merely cited (Observation 17.10 and Observation 17.12), with the source, and never used.

INFO

Panorama — the two extremes of the theory (stated, not proved). Observation 17.9 has already introduced them; here their precise form and bibliographic placement are given. Neither is provable with the tools of this chapter, and for that reason neither appears in a *theorem* environment.

Kolmogorov (1926). There exists $f \in L^1(\mathbb{T})$ whose Fourier series diverges at every point of $\mathbb{T}$. The construction, and the later variant with divergence at every point and unbounded partial sums, are given in Zygmund, *Trigonometric Series*, Chapter VIII, “Divergence of Fourier Series” (pp. 298–315). Corollary 17.4 is the smaller, non-constructive sibling of this result: it says that continuity is not enough for convergence at *one* point; Kolmogorov says that summability is not enough at *any* point.

Carleson (1966) and Hunt (1968). For every $f \in L^2(\mathbb{T})$ the Fourier series converges to f almost everywhere; R. A. Hunt extended the result to $L^p(\mathbb{T})$ for every $p > 1$. This is the statement that positively settles the question left open by du Bois-Reymond: divergence

can occur, but only on a set of measure zero. The original proof is in L. Carleson, *On convergence and growth of partial sums of Fourier series*, Acta Mathematica **116** (1966), 135–157.

Between the two extremes lies everything this chapter proves: convergence in quadratic mean for every $f \in L^2$ (Theorem 17.1), pointwise convergence under Dini (Theorem 17.11) or under bounded variation (Theorem 17.12), uniform convergence under C^1 regularity (Theorem 17.14), and — with no hypothesis beyond continuity — that of the Fejér means (Theorem 17.7).

17.9. Exercises inherited from Volume II

The exercises that follow come from Volume II, Chapter 4, and concern the topics of this chapter. They are reproduced in full, with their solutions, which follow in the same order as the exercises.

Exercises

Exercise 17.1. Compute directly from Definition 17.2 the value $D_N(0)$ (caution: the closed form of Theorem 17.2 has an apparent $0/0$ singularity at $\theta = 0$) and check that it agrees with the limit of the closed form as $\theta \rightarrow 0$.

Exercise 17.2: S4 — The Lebesgue constant diverges. Prove that the Lebesgue constant

$$L_N = \frac{1}{2\pi} \int_{-\pi}^{\pi} |D_N(\theta)| d\theta$$

satisfies $L_N \geq c \ln N$ for some constant $c > 0$ and for N large enough, and explain why this makes it impossible to deduce the uniform convergence of the partial sums from the mere continuity of f .

Exercise 17.3: S5 — The Fejér means as a triangular filter. Prove that $\widehat{\sigma_N f}(n) = (1 - \frac{|n|}{N+1})\hat{f}(n)$ for $|n| \leq N$ and 0 otherwise, and deduce that σ_N is a low-pass filter with a triangular frequency response. Compare with S_N , which is the ideal low-pass filter, and explain in light of Observation 17.7 why the first does not produce Gibbs and the second does.

Exercise 17.4: S6 — Positivity and absence of overshoot. Prove that if $K_N \geq 0$ and $\frac{1}{2\pi} \int K_N = 1$, then for every bounded f

$$\inf f \leq (f * K_N)(\theta) \leq \sup f \quad \text{for every } \theta.$$

Deduce that the Fejér means and the Abel–Poisson means can never “exceed” the extreme values of f , while the partial sums can (Gibbs phenomenon).

Solutions

Solution. From Definition 17.2, $D_N(0) = \sum_{n=-N}^N e^{in \cdot 0} = \sum_{n=-N}^N 1 = 2N + 1$ (the sum of $2N + 1$ terms all equal to 1). By the closed form of Theorem 17.2, $D_N(\theta) = \sin((N + \frac{1}{2})\theta) / \sin(\theta/2)$: as $\theta \rightarrow 0$ both numerator and denominator tend to 0 (form $0/0$), but applying

the well-known limit $\sin x \approx x$ as $x \rightarrow 0$,

$$\lim_{\theta \rightarrow 0} \frac{\sin((N + \frac{1}{2})\theta)}{\sin(\theta/2)} \approx \lim_{\theta \rightarrow 0} \frac{(N + \frac{1}{2})\theta}{\theta/2} = 2 \left(N + \frac{1}{2} \right) = 2N + 1,$$

in perfect agreement with the direct computation: the singularity at $\theta = 0$ is removable, as one expects from a kernel that is in fact a trigonometric polynomial (hence C^∞) everywhere, apparent singularity included.

Solution. S4. *Step 1 — reduction to a real integral.* By Theorem 17.2 and the evenness of D_N ,

$$L_N = \frac{1}{2\pi} \int_{-\pi}^{\pi} \left| \frac{\sin((N + \frac{1}{2})\theta)}{\sin(\theta/2)} \right| d\theta = \frac{1}{\pi} \int_0^{\pi} \frac{|\sin((N + \frac{1}{2})\theta)|}{\sin(\theta/2)} d\theta.$$

Step 2 — bounding the denominator. For $\theta \in [0, \pi]$, $\sin(\theta/2) \leq \theta/2$ (the inequality $\sin x \leq x$ for $x \geq 0$), hence

$$L_N \geq \frac{2}{\pi} \int_0^{\pi} \frac{|\sin((N + \frac{1}{2})\theta)|}{\theta} d\theta.$$

Step 3 — change of variable. With $u = (N + \frac{1}{2})\theta$:

$$L_N \geq \frac{2}{\pi} \int_0^{(N+1/2)\pi} \frac{|\sin u|}{u} du \geq \frac{2}{\pi} \int_0^{N\pi} \frac{|\sin u|}{u} du.$$

Step 4 — estimate of the harmonic tail. Split into intervals of length π and bound $1/u$ by its minimum on each:

$$\int_0^{N\pi} \frac{|\sin u|}{u} du \geq \sum_{k=1}^{N-1} \int_{k\pi}^{(k+1)\pi} \frac{|\sin u|}{u} du \geq \sum_{k=1}^{N-1} \frac{1}{(k+1)\pi} \int_{k\pi}^{(k+1)\pi} |\sin u| du.$$

The last integral equals 2 on every interval of length π , hence

$$\int_0^{N\pi} \frac{|\sin u|}{u} du \geq \frac{2}{\pi} \sum_{k=2}^N \frac{1}{k} \geq \frac{2}{\pi} (\ln N - 1),$$

using $\sum_{k=2}^N 1/k \geq \int_2^{N+1} \frac{dx}{x} \geq \ln N - 1$.

Step 5 — conclusion.

$$L_N \geq \frac{2}{\pi} \cdot \frac{2}{\pi} (\ln N - 1) = \frac{4}{\pi^2} (\ln N - 1) \rightarrow \infty.$$

(One can prove, with more work, the sharp asymptotic $L_N \sim \frac{4}{\pi^2} \ln N$.)

Step 6 — why this prevents uniform convergence. For every N , the functional $\Lambda_N : C(\mathbb{T}) \rightarrow \mathbb{C}$, $\Lambda_N(f) = S_N f(0)$, is linear and continuous, and its operator norm is exactly L_N (the supremum of $|\Lambda_N(f)|$ over $\|f\|_\infty \leq 1$ is obtained by approximating the function $\operatorname{sgn} D_N$ with continuous functions). Since $\sup_N \|\Lambda_N\| = \sup_N L_N = \infty$, the *uniform boundedness principle* (Banach–Steinhaus) guarantees the existence of $f \in C(\mathbb{T})$ with $\sup_N |S_N f(0)| = \infty$: the Fourier series of that continuous f diverges at $\theta = 0$. This is du Bois-Reymond's theorem, cited in Observation 17.6, and it shows that continuity alone cannot suffice for uniform convergence.

Solution. S5. *Step 1 — coefficients of the partial sums.* By definition, $S_k f = \sum_{|n| \leq k} \hat{f}(n) e_n$, hence

$$\widehat{S_k f}(n) = \begin{cases} \hat{f}(n) & |n| \leq k, \\ 0 & |n| > k. \end{cases}$$

Step 2 — averaging. By linearity of the coefficients,

$$\widehat{\sigma_N f}(n) = \frac{1}{N+1} \sum_{k=0}^N \widehat{S_k f}(n) = \frac{\hat{f}(n)}{N+1} \cdot \#\{k \in \{0, \dots, N\} : k \geq |n|\}.$$

If $|n| > N$ the set is empty and the coefficient vanishes; if $|n| \leq N$ it contains the integers from $|n|$ to N , i.e. $N+1-|n|$ elements. Hence

$$\widehat{\sigma_N f}(n) = \frac{N+1-|n|}{N+1} \hat{f}(n) = \left(1 - \frac{|n|}{N+1}\right) \hat{f}(n), \quad |n| \leq N,$$

in agreement with Theorem 17.6 and with the convolution theorem (Theorem (Volume II, Chapter 4)), since $\sigma_N f = f * F_N$ and $\widehat{F_N}(n) = 1 - |n|/(N+1)$.

Step 3 — reading it as a filter. The sequence $n \mapsto \widehat{\sigma_N}$ is the *frequency response* of the filter: it equals 1 at zero frequency, decreases *linearly* down to zero at $|n| = N+1$. It is a triangular (Bartlett) window. By comparison, S_N has a rectangular response: 1 for $|n| \leq N$, 0 beyond.

Step 4 — why the triangle produces no Gibbs. The rectangular response corresponds, in the time domain, to the Dirichlet kernel, which *oscillates and changes sign*; the triangular response corresponds to the Fejér kernel, which is the square of a function and hence *non-negative*. By Exercise S6, a non-negative kernel of unit integral cannot produce values outside the interval $[\inf f, \sup f]$: no overshoot is possible. A sharp cutoff in frequency, instead, inevitably produces oscillations in time — the other face of the same uncertainty principle.

Solution. S6. *Step 1 — the estimate.* Let $m = \inf f$ and $M = \sup f$. Since $K_N \geq 0$, multiplying by $K_N(t)$ preserves the inequalities:

$$m K_N(t) \leq f(\theta - t) K_N(t) \leq M K_N(t) \quad \text{for every } t.$$

Integrating over a period and dividing by 2π (a monotone operation):

$$m \cdot \frac{1}{2\pi} \int K_N \leq (f * K_N)(\theta) \leq M \cdot \frac{1}{2\pi} \int K_N.$$

Step 2 — normalisation. By hypothesis $\frac{1}{2\pi} \int K_N = 1$, hence

$$\inf f \leq (f * K_N)(\theta) \leq \sup f.$$

Step 3 — application to the two positive kernels. The Fejér kernel satisfies (a) and (b) of Theorem 17.6, and the Poisson kernel the analogous properties of Theorem 17.8. Hence for every bounded f

$$\inf f \leq \sigma_N f(\theta) \leq \sup f, \quad \inf f \leq (f * P_r)(\theta) \leq \sup f.$$

For the square wave, with $\inf f = -1$ and $\sup f = 1$, the Fejér means always stay in $[-1, 1]$: no overshoot.

Step 4 — why the argument fails for S_N . Step 1 uses $K_N \geq 0$ in an essential way: if the kernel changes sign, multiplying by it *reverses* the inequalities where it is negative, and the chain breaks. The Dirichlet kernel oscillates, and indeed Theorem 17.9 shows that $S_N f$ reaches 1.17898: outside the interval $[-1, 1]$ of the values of f .

Inherited quiz

The items that follow come from the quiz of Volume II, Chapter 4, and are renumbered here.

1. The Gibbs phenomenon shows itself as
 - A) slower convergence
 - B) persistent overshoot ($\approx 9\%$) near a discontinuity
 - C) divergence of the series
 - D) absence of pointwise convergence
2. At a jump point, the Fourier series of a piecewise C^1 function converges
 - A) to the left limit
 - B) to the right limit
 - C) to the average of the two one-sided limits
 - D) it does not converge
3. The Fejér kernel, unlike the Dirichlet kernel,
 - A) is non-negative
 - B) has integral different from 1
 - C) is not periodic
 - D) is not a trigonometric polynomial
4. Fejér's theorem guarantees that, for f continuous on $\mathbb{T}$,
 - A) $S_N f \rightarrow f$ uniformly
 - B) $\sigma_N f \rightarrow f$ uniformly
 - C) $S_N f \rightarrow f$ everywhere
 - D) nothing more than L^2 convergence
5. The Gibbs overshoot, as a fraction of the *total amplitude* of the jump, is about
 - A) 17.90%
 - B) 8.95%
 - C) 1.18%
 - D) it tends to 0
6. The Lebesgue constant $L_N = \frac{1}{2\pi} \int |D_N|$
 - A) equals 1 for every N
 - B) tends to 0
 - C) diverges like $\ln N$
 - D) is bounded but not constant
7. If $f \in C^k(\mathbb{T})$, its coefficients satisfy
 - A) $\hat{f}(n) = o(|n|^{-k})$
 - B) $\hat{f}(n) = o(|n|^k)$
 - C) $\hat{f}(n)$ constant
 - D) nothing can be said
8. Carleson's theorem (1966) states that for $f \in L^2(\mathbb{T})$ the Fourier series converges
 - A) everywhere
 - B) almost everywhere
 - C) at no point
 - D) only uniformly

BEST PRACTICE

Answer key.

1-B: Theorem 17.9: the overshoot has a positive limit. **2-C:** Theorem 17.4; see Observation 17.4. **3-A:** Theorem 17.6(a): it is a square, and this is the reason for all of Fejér's good properties. **4-B:** Theorem 17.7; A is false (du Bois-Reymond, Observation 17.6).
5-B: Theorem 17.9: 17.90% is the fraction of the *half*-amplitude, 8.95% that of the total amplitude. **6-C:** Exercise S4: $L_N \geq \frac{4}{\pi^2}(\ln N - 1)$. **7-A:** Observation 17.5: more regularity, faster decay. **8-B:** Observation 17.9; "everywhere" is already false for continuous functions.

Inherited formulary

The lines that follow come from the formulary of Volume II, Chapter 4.

The three kernels

$$D_N(\theta) = \frac{\sin((N + \frac{1}{2})\theta)}{\sin(\theta/2)}, \quad F_N(\theta) = \frac{1}{N+1} \left(\frac{\sin \frac{(N+1)\theta}{2}}{\sin \frac{\theta}{2}} \right)^2,$$

$$P_r(\theta) = \frac{1-r^2}{1-2r\cos\theta+r^2}, \quad \widehat{D}_N(n) = [|n| \leq N], \quad \widehat{F}_N(n) = \left(1 - \frac{|n|}{N+1}\right)_+, \quad \widehat{P}_r(n) = r^{|n|}$$

Convergence

$$L^2: \text{always} \quad \Bigg| \quad \text{pointwise: } f \text{ piecewise } C^1 \Rightarrow S_N f(\theta_0) \rightarrow \frac{1}{2}(f(\theta_0^+) + f(\theta_0^-))$$

$$\text{uniform: } \sum_n |\hat{f}(n)| < \infty \quad \Bigg| \quad \text{Fejér: } f \text{ continuous} \Rightarrow \sigma_N f \rightarrow f \text{ uniformly}$$

$$\text{Gibbs: } \lim S_N f(\theta_N) = \frac{2}{\pi} \text{Si}(\pi) = 1.178979744 \dots \quad (+8.95\% \text{ of the jump})$$

17.10. Assigned exercises

These are *new* exercises, distinct both from the inherited ones (Section 17.9) and from the worked ones in Section 17.11. The answers are in the Teacher's key (Section 17.13).

Exercise 17.5: Dini and bounded variation: neither contains the other. *Goal:* to handle the two pointwise convergence conditions and understand that they are independent. *Estimated time:* 45 minutes. *Type:* proof-based with numerical check.

- Let $f(\theta) = |\theta|^{1/2}$ on $(-\pi, \pi)$, extended periodically. Verify the Dini condition at $\theta_0 = 0$ with $L = 0$ and deduce $S_N f(0) \rightarrow 0$ from Theorem 17.11. Why does Corollary 17.5 already suffice on its own?
- Let $g(\theta) = 1/\ln(1/|\theta|)$ for $0 < |\theta| \leq \frac{1}{2}$, $g(0) = 0$ and $g(\theta) = 1/\ln 2$ for $\frac{1}{2} \leq |\theta| \leq \pi$, extended periodically. Prove that g is continuous at 0 but that the Dini condition *fails* there (compute $\int_0^{1/2} \frac{dt}{t \ln(1/t)}$ with the substitution $s = \ln(1/t)$), and that nevertheless $S_N g(0) \rightarrow 0$ by Corollary 17.6.
- Let $h(\theta) = |\theta|^{1/2} \sin(1/|\theta|)$ for $\theta \neq 0$, $h(0) = 0$. Prove that h satisfies the Dini condition at 0 with $L = 0$ and that it is *not* of bounded variation on any neighbourhood of 0 (evaluate h at the points $\theta_k = \frac{2}{(2k+1)\pi}$, where $\sin(1/\theta_k) = (-1)^k$).
- Numerically compute $S_N f(0)$ for the f of (a) with $N = 10, 50, 200$ and estimate the observed order of infinitesimal. Compare it with the order predicted by the decay $\hat{f}(n) = O(|n|^{-3/2})$.

Exercise 17.6: Lebesgue constants: from below, from above, exactly. *Goal:* to make Theorem 17.10 quantitative and measure its looseness. *Estimated time:* 40 minutes. *Type:* symbolic and numerical computation.

- Prove that $D_2(\theta) = 1 + 2\cos\theta + 2\cos 2\theta$ and find its zeros in $(0, \pi)$ using the closed form of Theorem 17.2; then compute L_2 by exact piecewise integration and compare it with the value 1.642188 in the table of Observation 17.10.
- Redo Step 3 of the proof of Theorem 17.10 using the finer bound $g(t) \leq \frac{\pi t}{24}$ of Lemma 17.3 instead of the mere $g \leq \frac{\pi^2}{24}$: by how much does the additive constant improve?
- Prove that the lower bound $\frac{4}{\pi^2}(\ln N - 1)$ is negative for $N \leq 2$ and find the smallest N for which it becomes positive. What does this say about the quality of the estimate

for small N ?

- (d) Explain in three lines why $L_N \rightarrow \infty$ prevents $\|S_N f - f\|_\infty \rightarrow 0$ for every continuous f , invoking Lemma 17.4 and Corollary 17.4.

Exercise 17.7: The remainder estimate put to the test. *Goal:* to use Theorem 17.14 on a family for which the exact remainder can be computed, and to measure its slack. *Estimated time:* 40 minutes. *Type:* symbolic and numerical computation. Let $f_r = P_r$, the Poisson kernel (Theorem 17.8), with $\hat{f}_r(n) = r^{|n|}$.

- (a) Prove that $\|f_r - S_N f_r\|_\infty = \frac{2r^{N+1}}{1-r}$ and that $\|f'_r\|_2^2 = \frac{2r^2(1+r^2)}{(1-r^2)^3}$, using $\sum_{n \geq 1} n^2 x^n = \frac{x(1+x)}{(1-x)^3}$.
- (b) For $r = \frac{3}{4}$ compute the two sides of the estimate of Theorem 17.14 with $k = 1$ for $N = 10$ and $N = 20$, and state by what factor the estimate is loose.
- (c) For $r = \frac{1}{2}$ find the smallest N for which the estimate with $k = 1$ guarantees $\|f - S_N f\|_\infty < 10^{-2}$, and the smallest N for which the inequality is *true*. Comment on the ratio between the two numbers.
- (d) Repeat (c) with $k = 2$, knowing that $\|f''_{1/2}\|_2^2 = \frac{760}{81}$, and observe by how much the prediction improves.

17.11. Worked exercises

Exercise 17.8: The Fourier series of $|\theta|$ and the sum $\sum (2k+1)^{-2}$. *Type:* computation of coefficients, pointwise convergence, sum of a numerical series. Compute the Fourier series of $f(\theta) = |\theta|$ on $[-\pi, \pi]$, extended periodically, justify the convergence at $\theta = 0$, and deduce the value of $\sum_{k \geq 0} (2k+1)^{-2}$.

Solution. Strategy. The function is even, hence the series consists only of cosines and the coefficients are computed on $[0, \pi]$ with a single integration by parts. Convergence at $\theta = 0$ is not to be taken for granted: it is obtained from Corollary 17.5, because $|\theta|$ is Lipschitz. Evaluating the series at $\theta = 0$ turns an identity of functions into a numerical identity.

Step 1 — the constant term. By Definition 17.1,

$$\hat{f}(0) = \frac{1}{2\pi} \int_{-\pi}^{\pi} |\theta| d\theta = \frac{1}{\pi} \int_0^{\pi} \theta d\theta = \frac{1}{\pi} \cdot \frac{\pi^2}{2} = \frac{\pi}{2}.$$

Step 2 — the nonzero-index coefficients. Since f is even, the imaginary part of the integrand $(-|\theta| \sin(n\theta))$ is odd and contributes nothing:

$$\hat{f}(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} |\theta| e^{-in\theta} d\theta = \frac{1}{\pi} \int_0^{\pi} \theta \cos(n\theta) d\theta.$$

Integrating by parts with $u = \theta$ and $dv = \cos(n\theta) d\theta$,

$$\int_0^{\pi} \theta \cos(n\theta) d\theta = \left[\frac{\theta \sin(n\theta)}{n} \right]_0^{\pi} - \frac{1}{n} \int_0^{\pi} \sin(n\theta) d\theta = 0 + \left[\frac{\cos(n\theta)}{n^2} \right]_0^{\pi} = \frac{(-1)^n - 1}{n^2},$$

since $\sin(n\pi) = 0$. Hence

$$\hat{f}(n) = \frac{(-1)^n - 1}{\pi n^2} = \begin{cases} -\frac{2}{\pi n^2} & n \text{ odd,} \\ 0 & n \text{ even, } n \neq 0. \end{cases}$$

Step 3 — the series. Collecting the terms $\pm n$ with n odd, and using $e^{in\theta} + e^{-in\theta} = 2\cos(n\theta)$,

$$|\theta| \sim \frac{\pi}{2} - \frac{4}{\pi} \sum_{k=0}^{\infty} \frac{\cos((2k+1)\theta)}{(2k+1)^2}.$$

Step 4 — convergence at $\theta = 0$. The function $|\theta|$ satisfies $||\theta| - |0|| = |\theta|$, hence the hypothesis of Corollary 17.5 with $\alpha = 1$, $C = 1$: the series converges at $\theta = 0$ to the value $f(0) = 0$. (Alternatively: $\sum_n |\hat{f}(n)| = \frac{4}{\pi} \sum_k (2k+1)^{-2} < \infty$, hence Theorem 17.5(i) gives uniform convergence.)

Step 5 — the sum of the numerical series. Setting $\theta = 0$ in Step 3 and using Step 4,

$$0 = \frac{\pi}{2} - \frac{4}{\pi} \sum_{k \geq 0} \frac{1}{(2k+1)^2} \quad \Rightarrow \quad \boxed{\sum_{k=0}^{\infty} \frac{1}{(2k+1)^2} = \frac{\pi^2}{8} = 1.2337005501 \dots}$$

Independent check 1: from the Basel series. Splitting the even indices from the odd ones in $\sum_{n \geq 1} n^{-2} = \pi^2/6$ (Example, Volume II, Chapter 4) and observing that the even indices give $\sum_{m \geq 1} (2m)^{-2} = \frac{1}{4} \sum_m m^{-2}$,

$$\sum_{k \geq 0} \frac{1}{(2k+1)^2} = \left(1 - \frac{1}{4}\right) \sum_{n \geq 1} \frac{1}{n^2} = \frac{3}{4} \cdot \frac{\pi^2}{6} = \frac{\pi^2}{8}. \quad \checkmark$$

Independent check 2: numerical summation. Summing the first $2 \cdot 10^6$ terms gives 1.2337004251, against $\pi^2/8 = 1.2337005501$: the gap $1.25 \cdot 10^{-7}$ matches the estimated tail $\sum_{k > K} (2k+1)^{-2} \approx \frac{1}{4K} = 1.25 \cdot 10^{-7}$. $\checkmark$

Typical mistakes. (i) Forgetting the constant term $\pi/2$ and concluding that the cosine series equals $|\theta|$: one would get $\sum (2k+1)^{-2} = 0$. (ii) Using L^2 convergence (Theorem 17.1) to justify the substitution $\theta = 0$: convergence in norm says *nothing* about the value at a single point, which has measure zero; a pointwise criterion is needed. (iii) Writing $\hat{f}(n) = -2/(\pi n^2)$ for every $n \neq 0$, forgetting that the even-index coefficients vanish.

Extension. Applying Parseval's identity (Theorem 17.1) to the same function: $\|f\|_2^2 = \frac{1}{2\pi} \int_{-\pi}^{\pi} \theta^2 d\theta = \frac{\pi^2}{3}$, while $\sum_n |\hat{f}(n)|^2 = \frac{\pi^2}{4} + 2 \sum_{k \geq 0} \frac{4}{\pi^2 (2k+1)^4}$. Equating,

$$\sum_{k=0}^{\infty} \frac{1}{(2k+1)^4} = \frac{\pi^4}{96} = 1.0146780316 \dots,$$

a value confirmed by the numerical sum of the first $2 \cdot 10^5$ terms, which gives 1.0146780316. $\checkmark$

Exercise 17.9: The sawtooth wave: jump, Gibbs and Fejér means. *Type:* pointwise convergence at a jump, numerical check of the Gibbs phenomenon, comparison with Cesàro means. Let $f(\theta) = \theta$ for $\theta \in (-\pi, \pi)$, extended periodically. Determine the limit of $S_N f(\pi)$, the maximum of $S_N f$ immediately to the left of the jump and its limit, and check that the Fejér means show no overshoot.

Solution. Strategy. The function is odd and monotone on $(-\pi, \pi)$: Corollary 17.6 gives at once the value at the jump. For the maximum one differentiates the partial sum, which is a telescoping sum of cosines, exactly as in Step 2 of the proof of Theorem 17.9.

Step 1 — the coefficients. By oddness, $\hat{f}(0) = 0$ and for $n \neq 0$

$$\hat{f}(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \theta e^{-in\theta} d\theta = \frac{-i}{\pi} \int_0^{\pi} \theta \sin(n\theta) d\theta = \frac{-i}{\pi} \cdot \frac{-\pi(-1)^n}{n} = \frac{i(-1)^n}{n},$$

having used $\int_0^{\pi} \theta \sin(n\theta) d\theta = \left[-\frac{\theta \cos(n\theta)}{n} \right]_0^{\pi} + \frac{1}{n} \int_0^{\pi} \cos(n\theta) d\theta = -\frac{\pi(-1)^n}{n}$. Hence

$$S_N f(\theta) = 2 \sum_{n=1}^N \frac{(-1)^{n+1}}{n} \sin(n\theta).$$

Step 2 — the value at the jump. f is increasing on $(-\pi, \pi)$, hence of bounded variation on every closed interval contained in a period; at $\theta_0 = \pi$ the one-sided limits are $f(\pi^-) = \pi$ and $f(\pi^+) = -\pi$. By Theorem 17.12, $S_N f(\pi) \rightarrow \frac{\pi+(-\pi)}{2} = 0$. The check is immediate: $\sin(n\pi) = 0$ for every n , hence $S_N f(\pi) = 0$ for every N . ✓

Step 3 — reflection about the jump. Set $\varphi = \pi - \theta$. Since $\sin(n\theta) = \sin(n\pi - n\varphi) = (-1)^{n+1} \sin(n\varphi)$, the two signs cancel and

$$S_N f(\pi - \varphi) = 2 \sum_{n=1}^N \frac{\sin(n\varphi)}{n} =: g_N(\varphi).$$

Step 4 — the first maximum. Differentiating and using the product-to-sum formula $\sin A - \sin B = 2 \cos \frac{A+B}{2} \sin \frac{A-B}{2}$ with $A = (N + \frac{1}{2})\varphi$ and $B = \frac{\varphi}{2}$,

$$g'_N(\varphi) = 2 \sum_{n=1}^N \cos(n\varphi) = D_N(\varphi) - 1 = \frac{\sin((N + \frac{1}{2})\varphi) - \sin \frac{\varphi}{2}}{\sin(\varphi/2)} = \frac{2 \cos \frac{(N+1)\varphi}{2} \sin \frac{N\varphi}{2}}{\sin(\varphi/2)}.$$

On $(0, \pi)$ the denominator is positive; the first zero of the numerator is $\varphi_1 = \frac{\pi}{N+1}$ (it kills the cosine), which precedes $\frac{2\pi}{N}$ (the first zero of the sine). On $(0, \varphi_1)$ both factors are positive, hence g_N increases and φ_1 is its first maximum. In terms of θ , the first maximum of $S_N f$ to the left of the jump is

$$\theta_N^* = \pi - \frac{\pi}{N+1} = \frac{N\pi}{N+1}.$$

Evaluating numerically:

N	$\theta_N^* = \frac{N\pi}{N+1}$	$S_N f(\theta_N^*)$	$S_N f(\theta_N^*)/\pi$
10	2.855993	3.413945	1.086693
50	3.079993	3.642073	1.159308
200	3.125963	3.688231	1.174000
1 000	3.138454	3.700735	1.177981

Step 5 — the limit, by an exact route. Setting $h = \frac{\pi}{N+1}$,

$$S_N f(\theta_N^*) = g_N(h) = 2 \sum_{n=1}^N \frac{\sin(nh)}{n} = 2 \sum_{n=1}^N \frac{\sin(nh)}{nh} h,$$

which is the Riemann sum of the continuous function $u \mapsto \frac{\sin u}{u}$ at the points $u_n = nh$ of the uniform partition of $[0, \pi]$ of step h (the last point is $Nh = \pi - h \rightarrow \pi$). Since $\frac{\sin u}{u}$ is continuous on $[0, \pi]$ (with value 1 at 0), the Riemann sums converge to the integral:

$$\lim_{N \rightarrow \infty} S_N f(\theta_N^*) = 2 \int_0^{\pi} \frac{\sin u}{u} du = 2 \operatorname{Si}(\pi) = 3.703874,$$

in agreement with the values in the table. The ratio to the limiting value π tends to

$$\frac{2 \operatorname{Si}(\pi)}{\pi} = 1.178980,$$

exactly the constant of Theorem 17.9: the overshoot is 17.898% of the half-amplitude of the jump (here π), i.e. 8.949% of the total amplitude 2π . ✓

Independent check. The constant does not depend on the function, only on the jump: the same 1.178980 appears for the square wave (Observation 17.14, third table), where the jump equals 2 instead of 2π . Two different functions, the same constant: a sign that the phenomenon depends only on the Dirichlet kernel. ✓

Step 6 — the Fejér means. By Theorem 17.6(a)–(b) the Fejér kernel is non-negative and of integral 1; by Exercise 17.4, $\inf f \leq \sigma_N f \leq \sup f$, i.e. $-\pi \leq \sigma_N f \leq \pi$. Sampling $\sigma_{50}f$ at 2001 points of $[0, \pi]$ gives a maximum of $2.760923 < \pi$: no overshoot. ✓

Typical mistakes. (i) Concluding $S_N f(\pi) \rightarrow \pi$ “because $f(\pi^-) = \pi$ ”: Theorem 17.12 gives the *average*, and here even $S_N f(\pi) = 0$ for every N . (ii) Deducing from Step 5 that the series does not converge: it converges at every point (Step 2), it is uniform convergence that is missing. (iii) Looking for the zeros of g'_N without applying the product-to-sum formula, and not noticing that the first of them comes from the factor $\cos \frac{(N+1)\varphi}{2}$ and not from the factor $\sin \frac{N\varphi}{2}$.

Extension. Repeat the computation for the function $f(\theta) = \pi - \theta$ on $(0, 2\pi)$: it is the same function shifted, the jump has amplitude 2π and the Gibbs constant is the same. Check that the ratio overshoot/jump is invariant under translations and vertical dilations, as must be the case for a phenomenon depending only on the kernel.

Exercise 17.10: The first Lebesgue constant in closed form. *Type:* exact computation of an integral with an absolute value, and comparison with a general estimate. Compute $L_1 = \frac{1}{2\pi} \int_{-\pi}^{\pi} |D_1(\theta)| d\theta$ in closed form and compare the result with the two sides of Theorem 17.10.

Solution. Strategy. An integral with an absolute value is computed by splitting the domain at the points where the integrand changes sign. Here D_1 is a trigonometric polynomial of degree 1 and its zeros can be found explicitly.

Step 1 — elementary form of D_1 . From Definition 17.2, $D_1(\theta) = e^{-i\theta} + 1 + e^{i\theta} = 1 + 2\cos\theta$. The closed form of Theorem 17.2 gives the same result: with $x = \theta/2$,

$$\frac{\sin(3x)}{\sin x} = \frac{3\sin x - 4\sin^3 x}{\sin x} = 3 - 4\sin^2 x = 3 - 2(1 - \cos 2x) = 1 + 2\cos\theta. \quad \checkmark$$

Step 2 — the sign change. $1 + 2\cos\theta = 0$ for $\cos\theta = -\frac{1}{2}$, i.e. $\theta = \frac{2\pi}{3}$ in the interval $[0, \pi]$. For $\theta < \frac{2\pi}{3}$, $\cos\theta > -\frac{1}{2}$ and $D_1 > 0$; for $\theta > \frac{2\pi}{3}$, $D_1 < 0$.

Step 3 — the integral. D_1 is even, hence $L_1 = \frac{1}{\pi} \int_0^{\pi} |1 + 2\cos\theta| d\theta$ and

$$\int_0^{\pi} |1 + 2\cos\theta| d\theta = \int_0^{2\pi/3} (1 + 2\cos\theta) d\theta - \int_{2\pi/3}^{\pi} (1 + 2\cos\theta) d\theta.$$

With the antiderivative $\theta + 2\sin\theta$ and $\sin \frac{2\pi}{3} = \frac{\sqrt{3}}{2}$, $\sin \pi = 0$:

$$\int_0^{2\pi/3} = \frac{2\pi}{3} + \sqrt{3}, \quad \int_{2\pi/3}^{\pi} = (\pi + 0) - \left(\frac{2\pi}{3} + \sqrt{3}\right) = \frac{\pi}{3} - \sqrt{3},$$

hence

$$\int_0^{\pi} |1 + 2\cos\theta| d\theta = \left(\frac{2\pi}{3} + \sqrt{3}\right) - \left(\frac{\pi}{3} - \sqrt{3}\right) = \frac{\pi}{3} + 2\sqrt{3},$$

and finally

$$L_1 = \frac{1}{3} + \frac{2\sqrt{3}}{\pi} = 1.435991124\dots$$

Independent check 1: quadrature of $|1 + 2\cos\theta|$. Simpson with $4 \cdot 10^5$ subintervals on $[0, \pi]$ gives 1.435991124. ✓

Independent check 2: quadrature of the closed form. Integrating instead $|\sin(\frac{3}{2}\theta)/\sin(\frac{\theta}{2})|$, a formally different function, one still gets 1.435991124: the two expressions of D_1 really do coincide. ✓

Step 4 — comparison with Theorem 17.10. For $N = 1$ the lower bound is $\frac{4}{\pi^2}(\ln 1 - 1) = -0.4053$ and the upper bound $\frac{2}{\pi}(1 + \ln \frac{3\pi}{2}) + \frac{\pi^2}{24} = 2.034738$. The inequality $-0.4053 \leq 1.435991 \leq 2.034738$ holds, but the lower bound is trivial: for small N the lower estimate says nothing, and this is the price of the step $\sin(\theta/2) \leq \theta/2$, which loses a factor of $\pi/2$.

Typical mistakes. (i) Forgetting the absolute value and computing $\frac{1}{2\pi} \int D_1 = 1$: one would get a constant Lebesgue constant, and with it Corollary 17.4 would disappear. (ii) Getting the sign wrong in the second integral. (iii) Taking $\theta = \frac{\pi}{3}$ as a zero, confusing $\cos\theta = -\frac{1}{2}$ with $\cos\theta = \frac{1}{2}$.

Extension. Repeat the computation for L_2 : the zeros of $D_2 = 1 + 2\cos\theta + 2\cos 2\theta$ in $(0, \pi)$ must be found numerically and the integral splits into three pieces; the result is 1.642188, in agreement with the table of Observation 17.10. Note that $L_2 - L_1 = 0.206$ while $\frac{4}{\pi^2} \ln 2 = 0.281$: the growth is already close to the asymptotic one.

17.12. Self-assessment quiz

- (Definition) The Lebesgue constant L_N is
 - $\frac{1}{2\pi} \int_{-\pi}^{\pi} D_N(\theta) d\theta$
 - $\frac{1}{2\pi} \int_{-\pi}^{\pi} |D_N(\theta)| d\theta$
 - $\max_{[-\pi, \pi]} |D_N|$
 - $D_N(0) = 2N + 1$
- (Hypothesis) In Theorem 17.11 the condition required on $\psi(t) = f(\theta_0 + t) + f(\theta_0 - t) - 2L$ is the finiteness of
 - $\int_0^{\pi} |\psi(t)| dt$
 - $\int_0^{\pi} \frac{|\psi(t)|}{t} dt$
 - $\int_0^{\pi} \frac{|\psi(t)|}{t^2} dt$
 - $\int_0^{\pi} \psi(t) D_N(t) dt$
- (Symbolic computation) The closed form $D_1(\theta) = \sin(\frac{3}{2}\theta)/\sin(\frac{\theta}{2})$ coincides with
 - $1 + 2\cos\theta$
 - $2\cos\theta$
 - $1 + \cos\theta + \cos 2\theta$
 - $3\cos\theta$
- (Numerical computation) The Wilbraham–Gibbs constant $\frac{2}{\pi} \text{Si}(\pi)$ equals, to six decimals,
 - 1.178980
 - 1.851937
 - 0.089490
 - 1.570796
- (Proof step) In the proof of Theorem 17.12 the estimate *uniform in N* on the piece $(0, \delta_1)$ is obtained
 - from the Riemann–Lebesgue lemma
 - from the second mean value theorem applied to $p(\delta_1) - p$, combined with the boundedness of Si
 - from the positivity of the Fejér kernel
 - from Bessel’s inequality
- (Error diagnosis) A student observes that $\frac{1}{2\pi} \int_{-\pi}^{\pi} D_N = 1$ for every N and concludes that for every continuous f , $\|S_N f - f\|_{\infty} \rightarrow 0$. The mistake is
 - the integral of D_N is not 1
 - the bound requires $\frac{1}{2\pi} \int |D_N| = L_N$, which diverges like $\ln N$
 - D_N is not periodic
 - $S_N f$ is not a trigonometric polynomial
- (Transfer) For $f(\theta) = \frac{3}{5-4\cos\theta}$, which has $\hat{f}(n) = 2^{-|n|}$, the remainder $\|f - S_{10}f\|_{\infty}$ equals exactly

- A) $2^{-9} = 0.001953125$ B) 0.544331 C) 2^{-10} D) 0
8. (Source and metacognition) Carleson's theorem, which this chapter states it does not prove, is published in
- A) Acta Mathematica **116** (1966), 135–157
- B) Zygmund, *Trigonometric Series*, Ch. VIII
- C) Stein–Shakarchi, *Fourier Analysis*, Ch. 2
- D) Dym–McKean, *Fourier Series and Integrals*, 1972

17.13. Teacher's key

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 1–4).

- 1) **B.** *Rationale:* this is Definition 17.5: the absolute value is the whole point, because without it the integral equals 1 for every N (Step 1 of the proof of Theorem 17.4). *Distractors:* A is exactly the normalisation, which does not depend on N ; C is the maximum, which equals $2N + 1$ and grows *linearly*, not logarithmically; D is the value at 0. *Diagnosed error:* confusing the normalisation with the L^1 norm. *Source:* Zygmund, Ch. II; here Definition 17.5 and Theorem 17.10. *Prerequisite:* Dirichlet kernel (Definition 17.2). *Remediation:* compute L_1 as in Worked exercise 17.10 and compare it with $\frac{1}{2\pi} \int D_1 = 1$.
- 2) **B.** *Rationale:* division by t is what makes $\psi/\sin(t/2)$ summable (Step 2 of the proof of Theorem 17.11), because $\frac{1}{\sin(t/2)} = \frac{2}{t} + g(t)$ with g bounded (Lemma 17.3). *Distractors:* A always holds for $f \in L^1$ (Lemma 17.5) and is therefore not a hypothesis; C is stronger than necessary and would already exclude Lipschitz f ; D depends on N and is not a hypothesis on f . *Diagnosed error:* failing to identify which singularity needs to be compensated. *Source:* Zygmund, Ch. II; Stein–Shakarchi, Ch. 3. *Prerequisite:* Lemma 17.5. *Remediation:* verify the condition for $f = |\theta|^{1/2}$ and see it fail for $1/\ln(1/|\theta|)$ (Exercise 17.5).
- 3) **A.** *Rationale:* $D_1 = e^{-i\theta} + 1 + e^{i\theta} = 1 + 2\cos\theta$; the same expression is obtained from the closed form with $\sin 3x = 3\sin x - 4\sin^3 x$ (Step 1 of Worked exercise 17.10). *Distractors:* B forgets the term $n = 0$; C is $\frac{1}{2}(1 + D_2)$ written wrongly; D is not even of mean 1. *Diagnosed error:* forgetting the constant mode in the sum $\sum_{|n| \leq N}$. *Source:* Definition 17.2 and Theorem 17.2. *Prerequisite:* de Moivre's formula. *Remediation:* write D_2 in the two forms and check their equality at $\theta = \pi/2$.
- 4) **A.** *Rationale:* $\frac{2}{\pi} \text{Si}(\pi) = \frac{2 \cdot 1.851937052}{3.141592654} = 1.178980$ (Observation 17.14). *Distractors:* B is $\text{Si}(\pi)$ without the factor $2/\pi$; C is the overshoot as a fraction of the *total* amplitude (8.949%); D is $\pi/2$, the value of $\text{Si}(+\infty)$. *Diagnosed error:* confusing the value of the integral with the overshoot constant. *Source:* Theorem 17.9 and Observation 17.14. *Prerequisite:* Proposition 17.3. *Remediation:* redo the square-wave table for $m = 100$ and $m = 1000$.

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 5–8).

- 5) **B.** *Rationale:* this is Step 5 of the proof of Theorem 17.12: Lemma 17.8 reduces the integral to $p(\delta_1)[\text{Si}(M\delta_1) - \text{Si}(M\xi)]$ and Lemma 17.9 bounds the bracket by $\text{Si}(\pi)$ *independently* of N . *Distractors:* A only gives a limit as $N \rightarrow \infty$ at fixed δ_1 , and is used in Step 6, not in Step 5; C concerns Fejér, not Dirichlet; D holds in L^2 and says nothing about pointwise values. *Diagnosed error:* not distinguishing a uniform estimate from a passage to the limit. *Source:* Zygmund, Ch. II; here Lemmas 17.8 and 17.9. *Prerequisite:* Jordan decomposition (Lemma 17.6). *Remediation:* redo Step 5 with ψ monotone, where $q \equiv 0$.

6) **B. Rationale:** the bound $|S_N f(\theta)| \leq \|f\|_\infty \frac{1}{2\pi} \int |D_N|$ of Step 2 of Lemma 17.4 involves the modulus, and $\frac{1}{2\pi} \int |D_N| = L_N \rightarrow \infty$ by Theorem 17.10. *Distractors:* A is false (the integral really does equal 1); C is false (D_N is a trigonometric polynomial); D is false by Definition 17.1. *Diagnosed error:* bringing the modulus inside the integral without noticing that the constant gets worse. *Source:* Corollary 17.4. *Prerequisite:* Theorem 17.3. *Remediation:* compute $S_1 f(0)$ for the continuous f that approximates $\operatorname{sgn} D_1$ and see that it is close to $L_1 = 1.436 > 1$.

7) **A. Rationale:** the coefficients are positive, hence the maximum of the remainder is at $\theta = 0$ and equals $\sum_{|n|>10} 2^{-|n|} = 2 \cdot 2^{-10} = 2^{-9}$ (Example 17.2). *Distractors:* B is the estimate of Theorem 17.14, not the true remainder, and is loose by a factor of 279; C forgets the factor 2 from the two signs of n ; D confuses convergence with exactness at finite N . *Diagnosed error:* mistaking a bound for the value. *Source:* Example 17.2. *Prerequisite:* geometric series. *Remediation:* redo the computation with $r = \frac{3}{4}$ (Exercise 17.7).

8) **A. Rationale:** this is the exact bibliographic reference, given in the infobox of Section 17.8 and in the sources environment. *Distractors:* B is where Kolmogorov's example is found, not Carleson's theorem; C is the elementary chapter on Fejér and good kernels; D is a 1972 textbook, hence later than 1966 but not the original place of publication. *Diagnosed error:* confusing a secondary source with the primary one. *Source:* L. Carleson, Acta Mathematica **116** (1966), 135–157. *Prerequisite:* none. *Remediation:* identify in the sources environment which entry is primary and which is a textbook.

BEST PRACTICE

Assigned exercises — summary answers.

17.5. (a) $\psi(t) = 2t^{1/2}$, hence $\int_0^\pi \frac{|\psi|}{t} dt = 2 \int_0^\pi t^{-1/2} dt = 4\sqrt{\pi} < \infty$: Dini holds and $S_N f(0) \rightarrow 0$. Corollary 17.5 suffices because f is $\frac{1}{2}$ -Hölder at 0 with $C = 1$. (b) With $s = \ln(1/t)$, $\frac{dt}{t} = -ds$ and $\int_0^{1/2} \frac{dt}{t \ln(1/t)} = \int_{\ln 2}^{+\infty} \frac{ds}{s} = +\infty$, hence Dini fails (here $\psi(t) = 2g(t)$); but g is even, increasing on $(0, \frac{1}{2})$ and constant on $[\frac{1}{2}, \pi]$, hence piecewise monotone, and Corollary 17.6 gives convergence to $g(0) = 0$. (c) $|\psi(t)| = 2|h(t)| \leq 2t^{1/2}$ gives Dini as in (a). At the points $\theta_k = \frac{2}{(2k+1)\pi}$, $h(\theta_k) = (-1)^k \theta_k^{1/2}$, hence $|h(\theta_k) - h(\theta_{k+1})| = \theta_k^{1/2} + \theta_{k+1}^{1/2} \geq \theta_{k+1}^{1/2}$; summing over k and noting that $\sum_k \theta_{k+1}^{1/2} = \sum_k \sqrt{2/((2k+3)\pi)}$ diverges, the variation of h on $[0, \theta_0]$ is infinite: $h \notin BV$ on any neighbourhood of 0. (d) $S_{10}f(0) = 0.24697$, $S_{50}f(0) = 0.11231$, $S_{200}f(0) = 0.05635$: the ratios $0.24697/0.11231 = 2.199$ and $0.11231/0.05635 = 1.993$ are close to $\sqrt{5} = 2.236$ and to $\sqrt{4} = 2$, i.e. the order is $N^{-1/2}$, consistent with $\sum_{|n|>N} |n|^{-3/2} = O(N^{-1/2})$.

17.6. (a) $D_2 = 1 + 2\cos\theta + 2\cos 2\theta$ has, in $(0, \pi)$, the two zeros of $\sin(\frac{5}{2}\theta)$, i.e. $\theta = \frac{2\pi}{5}$ and $\theta = \frac{4\pi}{5}$; splitting the integral into three pieces and using the antiderivative $\theta + 2\sin\theta + \sin 2\theta$ gives $L_2 = 1.642188$, in agreement with the table. (b) $\frac{1}{\pi} \int_0^\pi |\sin(M\theta)| \frac{\pi\theta}{24} d\theta \leq \frac{1}{24} \cdot \frac{\pi^2}{2} = \frac{\pi^2}{48} = 0.2056$: the additive constant halves, from 0.4112 to 0.2056. (c) $\ln N - 1 > 0$ for $N \geq 3$ ($\ln 3 = 1.0986$): for $N \leq 2$ the lower bound is negative and hence empty of content; this is the sign that the estimate is asymptotic and should not be used for small N . (d) If $\|S_N f - f\|_\infty \rightarrow 0$ held for every $f \in C(\mathbb{T})$, then $\Lambda_N(f) = S_N f(0) \rightarrow f(0)$ for every f , i.e. the family $\{\Lambda_N\}$ would be pointwise bounded; by Banach–Steinhaus it would then be bounded in norm too, against $\|\Lambda_N\| = L_N \rightarrow \infty$ (Lemma 17.4, Corollary 17.4).

17.7. (a) $\|f_r - S_N f_r\|_\infty = \sum_{|n|>N} r^{|n|} = 2 \sum_{n>N} r^n = \frac{2r^{N+1}}{1-r}$ (maximum at $\theta = 0$ because the coefficients are positive); $\|f'_r\|_2^2 = \sum_n n^2 r^{2|n|} = 2 \sum_{n \geq 1} n^2 (r^2)^n = \frac{2r^2(1+r^2)}{(1-r^2)^3}$. (b) For $r = \frac{3}{4}$: $\|f'_r\|_2^2 = \frac{7200}{343} = 20.991254$ and $\|f'\|_2 = 4.581621$; exact remainder 0.33788 against estimate 2.04896 for $N = 10$ (factor 6.1), and 0.019027 against 1.448836 for $N = 20$ (factor 76). (c) For $r = \frac{1}{2}$ the estimate $\sqrt{2/N} \cdot 1.217161 < 10^{-2}$ requires $N \geq 29\,630$, while $2^{1-N} < 10^{-2}$

already holds from $N = 8$: the estimate with a single derivative is off by more than three orders of magnitude, because it does not “see” the geometric decay of the coefficients. (d) With $k = 2$ and $\|f''\|_2 = \sqrt{760/81} = 3.063122$, the estimate $\sqrt{2/(3N^3)}\|f''\|_2 < 10^{-2}$ is satisfied from $N \geq 40$: three orders of magnitude gained by using one more derivative.

17.14. Formulary of the chapter

Coefficients, projection, Bessel, Parseval.

$$\hat{f}(n) = \frac{1}{2\pi} \int_0^{2\pi} f(\theta) e^{-in\theta} d\theta, \quad S_N f = \sum_{|n| \leq N} \hat{f}(n) e_n, \quad |\hat{f}(n)| \leq \|f\|_1 \leq \|f\|_2 \leq \|f\|_\infty.$$

$$\|f - S_N f\|_2^2 = \|f\|_2^2 - \sum_{|n| \leq N} |\hat{f}(n)|^2; \quad \sum_{n \in \mathbb{Z}} |\hat{f}(n)|^2 \leq \|f\|_2^2 \quad (\text{Bessel}),$$

with equality for every $f \in L^2(\mathbb{T})$ (Parseval), because the system is complete.

Riemann–Lebesgue and the pointwise criteria.

$$g \in L^1(a, b) \implies \int_a^b g(t) e^{i\lambda t} dt \rightarrow 0 \quad (|\lambda| \rightarrow \infty).$$

$$S_N f(\theta_0) - L = \frac{1}{2\pi} \int_0^\pi \psi(t) \frac{\sin((N + \frac{1}{2})t)}{\sin(t/2)} dt, \quad \psi(t) = f(\theta_0 + t) + f(\theta_0 - t) - 2L.$$

$$\text{Dini: } \int_0^\pi \frac{|\psi(t)|}{t} dt < \infty \quad \Bigg| \quad \text{Dirichlet–Jordan: } f \in BV \text{ near } \theta_0,$$

in both cases $S_N f(\theta_0) \rightarrow L = \frac{1}{2}(f(\theta_0^+) + f(\theta_0^-))$. Useful: $\frac{1}{\sin(t/2)} = \frac{2}{t} + g(t)$ with $0 \leq g(t) \leq \frac{\pi t}{24} \leq \frac{\pi^2}{24}$ on $(0, \pi]$.

Lebesgue constants, sine integral, Gibbs.

$$L_N = \frac{1}{2\pi} \int_{-\pi}^\pi |D_N|, \quad \frac{4}{\pi^2} (\ln N - 1) \leq L_N \leq \frac{2}{\pi} \left(1 + \ln((N + \frac{1}{2})\pi)\right) + \frac{\pi^2}{24},$$

$$L_1 = \frac{1}{3} + \frac{2\sqrt{3}}{\pi} = 1.435991, \quad \|\Lambda_N\| = L_N \implies \exists f \in C(\mathbb{T}) : \sup_N |S_N f(0)| = \infty.$$

$$\text{Si}(x) = \sum_{k \geq 0} \frac{(-1)^k x^{2k+1}}{(2k+1)(2k+1)!}, \quad 0 \leq \text{Si}(x) \leq \text{Si}(\pi) = 1.851937052,$$

$$\frac{2}{\pi} \text{Si}(\pi) = 1.178979744 \quad (+17.898\% \text{ of the half-amplitude, } +8.949\% \text{ of the jump}).$$

Regularity and remainder.

$$\widehat{f^{(k)}}(n) = (in)^k \hat{f}(n); \quad f \in C^k(\mathbb{T}) \implies \|f - S_N f\|_\infty \leq \sqrt{\frac{2}{(2k-1)N^{2k-1}}} \|f^{(k)}\|_2.$$

Notable cases: $k = 1$ gives $\sqrt{2/N}\|f'\|_2$; $k = 2$ gives $\sqrt{2/(3N^3)}\|f''\|_2$. Check example: $f = \frac{3}{5-4\cos\theta}$, $\hat{f}(n) = 2^{-|n|}$, $\|f - S_N f\|_\infty = 2^{1-N}$, $\|f'\|_2 = \sqrt{40/27} = 1.217161$.

Sources and bibliography

- [1] A. Zygmund, *Trigonometric Series*, 3rd edition (volumes I and II combined, with a foreword by R. A. Fefferman), Cambridge Mathematical Library, Cambridge University Press, Cambridge, 2002 (digital edition 2015, DOI 10.1017/CB09781316036587; ISBN 978-0-521-89053-3). Chapter II “Fourier Coefficients. Elementary Theorems on Convergence” (pp. 35–73): this is the source of the Riemann–Lebesgue lemma (Lemma 17.2), of Dini’s criterion (Theorem 17.11), of the Dirichlet–Jordan criterion (Theorem 17.12), of the Lebesgue constants (Theorem 17.10) and of the Gibbs phenomenon (Theorem 17.9); it also contains the sharp asymptotic $L_N = \frac{4}{\pi^2} \ln N + O(1)$ and the uniform version of Dirichlet–Jordan, both declared *imported* in Observation 17.15. Chapter III “Summability of Fourier Series” (pp. 74–126) for the Fejér kernel and the Cesàro means (Theorems 17.6 and 17.7). Chapter VIII “Divergence of Fourier Series” (pp. 298–315) for Kolmogorov’s example, reported as panorama in Section 17.8. Title, edition, publisher, year and table of contents with chapter pagination verified on the volume’s record in the Cambridge Core catalogue — verified on 6 September 2026.

CHAPTER 18

Partial differential equations on the circle and in the disc

Three equations govern almost all of the classical physics of continuous media: Laplace's equation $\Delta u = 0$, the heat equation $u_t = \kappa \Delta u$ and the wave equation $u_{tt} = c^2 \Delta u$. On an arbitrary domain these are three hard problems. On the circle and on the disc they become three *solvable* problems, for one reason only: rotational symmetry. It makes the Laplace operator commute with rotations, and hence the characters $e^{in\theta}$ — the very ones that in Chapter 17 form the Fourier basis — are automatically its eigenfunctions in the angular variable. What is left is a single ordinary equation in the radial variable: Euler's equation for Laplace, Bessel's equation for heat and waves. The whole chapter is the working-out of this sentence.

The route is the following. We start from the Laplacian in polar coordinates (Theorem 18.1), *derived* from the change of variables and not postulated, with the divergence-form corollary (Corollary 18.1). We then apply separation of variables to Laplace's equation in the disc: Lemma 18.2 splits the problem into two ordinary equations, Lemma 18.3 shows that periodicity of the angle alone *quantises* the separation constant to n^2 with n an integer, Lemma 18.4 solves the radial equation, and Theorem 18.2 discards the singular solutions at the origin. A single mode survives for each integer, $r^{|n|}e^{in\theta}$, and summing the modes recovers — with Corollary 18.2 — the Poisson formula of Chapter 16, which is not reproved here but recalled in the form established by Theorem 17.8. The maximum principle (Theorem 18.4) closes the Dirichlet problem with uniqueness and stability.

The second part is dynamic. The heat equation on $\mathbb{T}$ (Theorem 18.5) shows the phenomenon typical of parabolic problems: every mode decays like $e^{-\kappa n^2 t}$, the solution becomes C^∞ instantaneously, and converges to the mean of the datum. The wave equation on $\mathbb{T}$, instead, is solved in closed form (Theorem 18.7, d'Alembert's formula made periodic), conserves energy (Proposition 18.7) and is periodic in time (Proposition 18.8): no regularisation, no forgetting. Finally the circular membrane: separation leads to Bessel's equation (Lemma 18.7), the Bessel function of the first kind is defined by its series (Definition 18.7), the series is shown to converge everywhere (Theorem 18.8), to solve the equation (Theorem 18.9), the other independent solution is shown to be unbounded at the origin (Proposition 18.12), and J_n is shown to have infinitely many positive, simple zeros (Theorem 18.10). The zeros give the frequencies of the drum's modes, and are taken from the tabulated values quoted by the NIST Digital Library of Mathematical Functions, recomputed here twice by independent routes.

The material that the executive plan moved here from Volume II (Chapter 4, Sec.8) — the remark on the ring that diffuses heat, the two exercises and their solutions — is kept in full and is found in Observation 18.4 and in Section 18.11. What Volume II took as known (the Laplacian in polar coordinates, separation of variables, Bessel functions) is proved here.

INFO

Level and prerequisites. Level **C** (undergraduate), with three passages at level **D**: the proof that the second solution of Bessel's equation is unbounded at the origin (Proposition 18.12), Sturm's comparison (Lemma 18.9), and the computation of the norm of the

radial eigenfunctions (Theorem 18.11).

Internal prerequisites. Fourier series on the circle: coefficients, convergence in L^2 and Parseval's identity, uniform convergence, the Poisson kernel and Abel summation (Chapter 17, Definition 17.1, Theorem 17.1, Theorem 17.5, Definition 17.4, Theorem 17.8); harmonic functions in the disc, the mean-value property and the Dirichlet problem (Chapter 16); real and imaginary part of z^n , polar form (Chapter 6); the circle as a quotient space and 2π -periodic functions (Chapter 12); curvature and arc length for plane curves (Chapter 2).

External prerequisites, assumed and not reproved:

- differential calculus in two variables: the chain rule for compositions of C^2 functions, Schwarz's theorem on the interchange of the order of differentiation, the second-derivative test for an interior maximum point;
- the divergence theorem (Gauss–Green formula) on a regular plane domain, used once, in Proposition 18.9;
- elementary theory of linear ordinary differential equations: existence and uniqueness of the solution of the Cauchy problem for a second-order linear equation with continuous coefficients and nonvanishing leading coefficient, and the dimension-2 vector-space structure of the solution set;
- power series: radius of convergence, uniform convergence on compact sets, term-by-term differentiation;
- Weierstrass's criterion for total convergence and the interchange of series and integral under uniform convergence.

Everything else is proved here.

What is learned. How to transport a differential operator through a change of coordinates without missing a term; recognising when separation of variables is legitimate and exactly what it produces; understanding that periodicity is a *boundary condition* that quantises; distinguishing parabolic from hyperbolic behaviour by how the modes decay; building the Bessel function from scratch and proving its properties; reading a table of zeros and deriving from it the frequencies of a drum, knowing why they are not harmonic.

Warning. Conventions of the chapter.

- $D_a = \{(x, y) \in \mathbb{R}^2 : x^2 + y^2 < a^2\}$ is the open disc centred at the origin with radius $a > 0$, $\overline{D_a}$ its closure, ∂D_a the circle of radius a ; $D = D_1$ is the unit disc and $\mathbb{T} = \partial D$ the unit circle, identified with $\mathbb{R}/2\pi\mathbb{Z}$.
- A function on $\mathbb{T}$ is a function on $\mathbb{R}$ of period 2π ; $\hat{f}(n)$ denotes the Fourier coefficient $\frac{1}{2\pi} \int_{-\pi}^{\pi} f(\theta) e^{-in\theta} d\theta$ of Definition 17.1.
- We write $u(x, y)$ for a function in Cartesian coordinates and $U(r, \theta) = u(r \cos \theta, r \sin \theta)$ for the same function read in polar coordinates; when there is no ambiguity we use the same letter for both, as is customary.
- $\Delta = \partial_x^2 + \partial_y^2$ is the Laplace operator; $u_t, u_{tt}, u_\theta, u_{\theta\theta}, u_r, u_{rr}$ are the indicated partial derivatives.
- $\kappa > 0$ is the thermal diffusivity, $c > 0$ the propagation speed: both carry the physical dimensions that make the equations homogeneous, and in the numerical computations we use SI units.
- Numerical values are rounded to the seventh decimal digit and recomputed twice by independent routes; the symbol $\checkmark$ marks a successful check.
- J_n is the Bessel function of the first kind of integer order $n \geq 0$ and $j_{n,k}$ its k -th positive zero, in the notation of the NIST Digital Library of Mathematical Functions, Sec.10.21(i).

18.1. The Laplacian in polar coordinates

None of what follows works unless the Laplace operator is first rewritten in the coordinates suited to the domain. The rewriting is a pure exercise in the chain rule, but it must be carried out in full: it is where sign errors and forgotten terms hide, and it is also where the term $\frac{1}{r} u_r$ that makes the origin singular appears, apparently out of nowhere.

Definition 18.1: Laplace operator and harmonic functions. Let $\Omega \subseteq \mathbb{R}^2$ be open and $u \in C^2(\Omega)$. The **Laplace operator** (or *Laplacian*) of u is

$$\Delta u = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}.$$

The function u is called **harmonic** in Ω if $\Delta u = 0$ at every point of Ω .

Lemma 18.1: Derivatives of the polar transformation. Let $\Phi : (0, +\infty) \times \mathbb{R} \rightarrow \mathbb{R}^2 \setminus \{(0, 0)\}$, $\Phi(r, \theta) = (r \cos \theta, r \sin \theta)$. Then Φ is of class C^∞ , its Jacobian determinant equals $r > 0$, and for every $u \in C^2$ defined on an open set $\Omega \subseteq \mathbb{R}^2 \setminus \{(0, 0)\}$, setting $U = u \circ \Phi$, the identities

$$U_r = u_x \cos \theta + u_y \sin \theta, \quad U_\theta = -r u_x \sin \theta + r u_y \cos \theta,$$

hold on $\Phi^{-1}(\Omega)$, where u_x, u_y are evaluated at $\Phi(r, \theta)$.

Proof. The two components of Φ are $x(r, \theta) = r \cos \theta$ and $y(r, \theta) = r \sin \theta$, products and compositions of C^∞ functions: hence $\Phi \in C^\infty$. Its Jacobian matrix is

$$D\Phi(r, \theta) = \begin{pmatrix} x_r & x_\theta \\ y_r & y_\theta \end{pmatrix} = \begin{pmatrix} \cos \theta & -r \sin \theta \\ \sin \theta & r \cos \theta \end{pmatrix}, \quad \det D\Phi = r \cos^2 \theta + r \sin^2 \theta = r,$$

positive because $r > 0$. The chain rule for the composition $U = u \circ \Phi$ gives

$$U_r = u_x x_r + u_y y_r = u_x \cos \theta + u_y \sin \theta, \quad U_\theta = u_x x_\theta + u_y y_\theta = -r u_x \sin \theta + r u_y \cos \theta,$$

which are the two identities sought. $\square$

Theorem 18.1: The Laplacian in polar coordinates. Let $\Omega \subseteq \mathbb{R}^2 \setminus \{(0, 0)\}$ be open, $u \in C^2(\Omega)$ and $U(r, \theta) = u(r \cos \theta, r \sin \theta)$. Then, for every (r, θ) with $\Phi(r, \theta) \in \Omega$,

$$(\Delta u)(\Phi(r, \theta)) = U_{rr} + \frac{1}{r} U_r + \frac{1}{r^2} U_{\theta\theta}$$

Proof. Write $c = \cos \theta$ and $s = \sin \theta$; all derivatives of u are understood to be evaluated at $\Phi(r, \theta)$. Since $u \in C^2$, by Schwarz's theorem $u_{xy} = u_{yx}$.

Step 1 — the second radial derivative. Differentiate with respect to r the first identity of Lemma 18.1, recalling that c and s do not depend on r and that, again by the chain rule, $\partial_r(u_x \circ \Phi) = u_{xx}c + u_{xy}s$ and $\partial_r(u_y \circ \Phi) = u_{yx}c + u_{yy}s$:

$$U_{rr} = (u_{xx}c + u_{xy}s)c + (u_{yx}c + u_{yy}s)s = u_{xx}c^2 + 2u_{xy}cs + u_{yy}s^2. \quad (1)$$

Step 2 — the second angular derivative. Differentiate with respect to θ the second identity of Lemma 18.1. Here r is fixed, while c and s depend on θ and so do $u_x \circ \Phi$, $u_y \circ \Phi$;

the chain rule gives $\partial_\theta(u_x \circ \Phi) = -r u_{xx}s + r u_{xy}c$ and $\partial_\theta(u_y \circ \Phi) = -r u_{yx}s + r u_{yy}c$. Hence

$$U_{\theta\theta} = \underbrace{-r u_x c}_{\partial_\theta(-rs)u_x} - rs(-r u_{xx}s + r u_{xy}c) + \underbrace{-r u_y s}_{\partial_\theta(rc)u_y} + rc(-r u_{yx}s + r u_{yy}c).$$

Collecting terms,

$$U_{\theta\theta} = -r(u_x c + u_y s) + r^2(u_{xx}s^2 - 2u_{xy}cs + u_{yy}c^2) = -r U_r + r^2(u_{xx}s^2 - 2u_{xy}cs + u_{yy}c^2), \quad (2)$$

where the last equality again uses Lemma 18.1.

Step 3 — the sum. From (2) one gets

$$\frac{1}{r^2}U_{\theta\theta} = -\frac{1}{r}U_r + u_{xx}s^2 - 2u_{xy}cs + u_{yy}c^2,$$

and adding this to (1) term by term:

$$U_{rr} + \frac{1}{r^2}U_{\theta\theta} = u_{xx}(c^2 + s^2) + 2u_{xy}cs - 2u_{xy}cs + u_{yy}(s^2 + c^2) - \frac{1}{r}U_r = u_{xx} + u_{yy} - \frac{1}{r}U_r,$$

because $c^2 + s^2 = 1$ (Pythagorean identity, Volume I). Moving $\frac{1}{r}U_r$ to the left gives $U_{rr} + \frac{1}{r}U_r + \frac{1}{r^2}U_{\theta\theta} = u_{xx} + u_{yy} = \Delta u$, which is the claim. $\square$

Corollary 18.1: Divergence form. Under the hypotheses of Theorem 18.1,

$$\Delta u = \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial U}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 U}{\partial \theta^2}.$$

Proof. By Leibniz's rule $\partial_r(rU_r) = U_r + rU_{rr}$, hence $\frac{1}{r}\partial_r(rU_r) = \frac{1}{r}U_r + U_{rr}$. Substituting into the formula of Theorem 18.1 gives the statement. $\square$

Example 18.1: The elementary harmonic modes. Let $n \geq 0$ be an integer and $U(r, \theta) = r^n \cos n\theta$. Then

$$U_{rr} = n(n-1)r^{n-2} \cos n\theta, \quad \frac{1}{r}U_r = n r^{n-2} \cos n\theta, \quad \frac{1}{r^2}U_{\theta\theta} = -n^2 r^{n-2} \cos n\theta,$$

and the sum is $(n^2 - n + n - n^2)r^{n-2} \cos n\theta = 0$: the function is harmonic on $\mathbb{R}^2 \setminus \{(0, 0)\}$. The same computation, with $\sin n\theta$ in place of $\cos n\theta$, gives the same result.

Independent check. In Cartesian coordinates $r^n \cos n\theta = \operatorname{Re}(z^n)$ with $z = x + iy$ (polar form, Chapter 6); since z^n is holomorphic on all of $\mathbb{C}$, its real part is harmonic by the Cauchy–Riemann equations (Chapter 15). For $n = 2$ one has $\operatorname{Re}(z^2) = x^2 - y^2$ and $\Delta(x^2 - y^2) = 2 - 2 = 0$; a numerical check with centred finite differences of step $h = 10^{-4}$ at the point $(0.7, 0.4)$ returns the value 0 for the Laplacian, exact in double precision. $\checkmark$

Likewise $r^{-n} \cos n\theta$ is harmonic on $\mathbb{R}^2 \setminus \{(0, 0)\}$: the computation is identical with $-n$ in place of n , and $(-n)^2 - (-n) + (-n) - (-n)^2 = 0$.

Proposition 18.1: Radial harmonic functions. Let $0 \leq \rho_1 < \rho_2 \leq +\infty$ and let $U = U(r)$ be of class C^2 on (ρ_1, ρ_2) , independent of θ . Then U is harmonic if and only if there exist $A, B \in \mathbb{R}$ with

$$U(r) = A + B \ln r, \quad \rho_1 < r < \rho_2.$$

Proof. Since $U_{\theta\theta} = 0$, by Corollary 18.1 the condition $\Delta U = 0$ is equivalent to $\frac{1}{r}(rU')' = 0$, i.e., since $r > 0$, to $(rU')' = 0$ on (ρ_1, ρ_2) .

A function with zero derivative on an interval is constant: hence $rU'(r) = B$ for some constant $B \in \mathbb{R}$, i.e. $U'(r) = B/r$. Integrating on (ρ_1, ρ_2) , where $r \mapsto 1/r$ has primitive $\ln r$, gives $U(r) = A + B \ln r$ with $A \in \mathbb{R}$.

Conversely, if $U = A + B \ln r$ then $rU' = B$ is constant, hence $(rU')' = 0$ and $\Delta U = 0$. $\square$

Remark 18.1: Why the origin is a special point. Theorem 18.1 is stated on open sets that do not contain the origin, and not out of pedantry: the transformation Φ is neither injective nor regular at $r = 0$ (its Jacobian equals r , which vanishes there), and the coefficients $1/r$ and $1/r^2$ of the formula blow up. The price is paid in two opposite ways. On one hand spurious solutions appear, such as $\ln r$ and $r^{-n} \cos n\theta$, which solve the equation away from the origin but do not extend regularly to the centre: it is Proposition 18.1 that exhibits them. On the other hand, whenever one wants a solution defined on the whole disc one must explicitly impose a regularity condition at $r = 0$: this is exactly what Theorem 18.2 will do, and it is the mechanism that, in Section 18.7, will eliminate the second solution of Bessel's equation.

Figure 18.1: Polar coordinates: the circles $r = \text{const}$ and the rays $\theta = \text{const}$ meet orthogonally. The plotted point has $r = 2.2$ and $\theta = 38^\circ$, i.e. $x = 2.2 \cos 38^\circ = 1.7336238$ and $y = 2.2 \sin 38^\circ = 1.3544553$ (values checked by independent computation). The shaded area element has sides dr and $r d\theta$: this is the factor r of the Jacobian determinant of Lemma 18.1, and the same asymmetry between the two directions produces the term $\frac{1}{r} u_r$ of Theorem 18.1.

18.2. Laplace's equation in the disc: separation of variables

The method of separation of variables consists in seeking, among all solutions, those of the very particular form “function of r times function of θ ”. It is a drastic restriction, and it is by no means obvious that it leads anywhere: it does, because the equation, rewritten in polar coordinates, has coefficients that do not mix the two variables. Lemma 18.2 makes the step precise; the two following lemmas show that the boundary conditions — periodicity in θ , regularity at $r = 0$ — select exactly a countable family of modes.

Definition 18.2: The Dirichlet problem in the disc. Let $a > 0$ and let $f : \partial D_a \rightarrow \mathbb{R}$ be continuous. The **Dirichlet problem** in the disc D_a with boundary datum f consists in finding $u \in C^2(D_a) \cap C(\overline{D_a})$ with

$$\Delta u = 0 \quad \text{in } D_a, \quad u|_{\partial D_a} = f.$$

Identifying ∂D_a with $\mathbb{T}$ via $\theta \mapsto (a \cos \theta, a \sin \theta)$, the datum is written as a 2π -periodic function $f(\theta)$.

Lemma 18.2: Separation of variables for Laplace's equation. Let $R \in C^2((0, a))$ and $\Theta \in C^2(\mathbb{R})$, neither identically zero, and suppose that $U(r, \theta) = R(r)\Theta(\theta)$ satisfies

$$U_{rr} + \frac{1}{r}U_r + \frac{1}{r^2}U_{\theta\theta} = 0 \quad \text{for every } (r, \theta) \in (0, a) \times \mathbb{R}.$$

Then there exists $\lambda \in \mathbb{R}$ such that

$$\Theta'' + \lambda\Theta = 0 \quad \text{on } \mathbb{R}, \quad r^2R'' + rR' - \lambda R = 0 \quad \text{on } (0, a).$$

Proof. Substituting $U = R\Theta$ and multiplying by r^2 (legitimate since $r > 0$) the equation becomes

$$(r^2R''(r) + rR'(r))\Theta(\theta) + R(r)\Theta''(\theta) = 0 \quad \text{for every } (r, \theta) \in (0, a) \times \mathbb{R}. \quad (*)$$

Step 1 — the radial equation. Since $\Theta \not\equiv 0$, there exists $\theta_0 \in \mathbb{R}$ with $\Theta(\theta_0) \neq 0$. Set

$$\lambda := -\frac{\Theta''(\theta_0)}{\Theta(\theta_0)} \in \mathbb{R}.$$

Evaluating $(*)$ at $\theta = \theta_0$ and dividing by $\Theta(\theta_0) \neq 0$ gives

$$r^2R''(r) + rR'(r) + \frac{\Theta''(\theta_0)}{\Theta(\theta_0)}R(r) = 0, \quad \text{i.e.} \quad r^2R'' + rR' - \lambda R = 0,$$

and this for every $r \in (0, a)$, because θ_0 is fixed while r is arbitrary.

Step 2 — the angular equation. Substitute the result of Step 1 into $(*)$: for every (r, θ) ,

$$\lambda R(r)\Theta(\theta) + R(r)\Theta''(\theta) = 0, \quad \text{i.e.} \quad R(r)(\Theta''(\theta) + \lambda\Theta(\theta)) = 0.$$

Since $R \not\equiv 0$, there exists $r_0 \in (0, a)$ with $R(r_0) \neq 0$; evaluating at $r = r_0$ and dividing by $R(r_0)$ gives $\Theta''(\theta) + \lambda\Theta(\theta) = 0$ for every $\theta \in \mathbb{R}$.

The number λ is real because Θ and Θ'' are real-valued functions. $\square$

Lemma 18.3: Periodicity quantises the separation constant. Let $\lambda \in \mathbb{R}$ and let $\Theta \in C^2(\mathbb{R})$ be a solution, not identically zero, of $\Theta'' + \lambda\Theta = 0$ that is 2π -periodic. Then $\lambda = n^2$ for some integer $n \geq 0$, and

- if $n = 0$, Θ is constant;
- if $n \geq 1$, $\Theta(\theta) = A \cos n\theta + B \sin n\theta$ with $(A, B) \neq (0, 0)$.

Conversely, for every integer $n \geq 0$ the functions indicated are 2π -periodic solutions.

Proof. The equation $\Theta'' + \lambda\Theta = 0$ is linear, second order, with constant coefficients; its solution space has dimension 2. We distinguish three cases according to the sign of λ .

Case $\lambda < 0$. Setting $\mu = \sqrt{-\lambda} > 0$, the solutions are $\Theta(\theta) = Ae^{\mu\theta} + Be^{-\mu\theta}$. Such a function is 2π -periodic only if it is bounded on $\mathbb{R}$ (a continuous periodic function is bounded, because its supremum is attained on a period, which is compact). But if $A \neq 0$ then $\Theta(\theta) \rightarrow \pm\infty$ as $\theta \rightarrow +\infty$, and if $B \neq 0$ then $\Theta(\theta) \rightarrow \pm\infty$ as $\theta \rightarrow -\infty$: in either case Θ is unbounded. Hence $A = B = 0$ and $\Theta \equiv 0$, excluded by hypothesis. The case $\lambda < 0$ does not occur.

Case $\lambda = 0$. The solutions are $\Theta(\theta) = A + B\theta$. Periodicity $\Theta(\theta + 2\pi) = \Theta(\theta)$ gives $2\pi B = 0$, i.e. $B = 0$: Θ is constant, and nonzero by hypothesis. This is the case $n = 0$, with $\lambda = 0 = 0^2$.

Case $\lambda > 0$. Setting $\mu = \sqrt{\lambda} > 0$, the solutions are $\Theta(\theta) = A \cos \mu\theta + B \sin \mu\theta$ with $(A, B) \neq (0, 0)$. Imposing $\Theta(2\pi) = \Theta(0)$ and $\Theta'(2\pi) = \Theta'(0)$: since two solutions of the same second-order linear equation with the same Cauchy data coincide, these two equalities are *equivalent* to 2π -periodicity of Θ (apply uniqueness for the Cauchy problem to the function $\theta \mapsto \Theta(\theta + 2\pi)$, which solves the same equation). They read

$$\begin{cases} A \cos 2\pi\mu + B \sin 2\pi\mu = A, \\ \mu(-A \sin 2\pi\mu + B \cos 2\pi\mu) = \mu B, \end{cases} \quad \text{i.e., since } \mu \neq 0, \quad \mathcal{R}_{2\pi\mu} \begin{pmatrix} A \\ B \end{pmatrix} = \begin{pmatrix} A \\ B \end{pmatrix},$$

where $\mathcal{R}_\varphi = \begin{pmatrix} \cos \varphi & \sin \varphi \\ -\sin \varphi & \cos \varphi \end{pmatrix}$ is the rotation matrix through angle $-\varphi$. A rotation of the plane that fixes a nonzero vector is the identity (Chapter 5); hence $\mathcal{R}_{2\pi\mu} = I$, i.e. $\cos 2\pi\mu = 1$ and $\sin 2\pi\mu = 0$, which is equivalent to $2\pi\mu \in 2\pi\mathbb{Z}$, i.e. $\mu \in \mathbb{Z}$. Since $\mu > 0$, $\mu = n$ is an integer ≥ 1 and $\lambda = n^2$.

Converse. For $n = 0$ a constant solves $\Theta'' = 0$ and is periodic; for $n \geq 1$, $(A \cos n\theta + B \sin n\theta)'' = -n^2(A \cos n\theta + B \sin n\theta)$ and the function has period $2\pi/n$, hence also 2π . $\square$

Lemma 18.4: *The radial equation is of Euler type. Let $n \geq 0$ be an integer. The C^2 solutions of the equation*

$$r^2 R'' + r R' - n^2 R = 0 \quad \text{on } (0, +\infty)$$

are all and only

$$R(r) = A r^n + B r^{-n} \quad (n \geq 1), \quad R(r) = A + B \ln r \quad (n = 0), \quad A, B \in \mathbb{R}.$$

Proof. Step 1 — the change of variable $r = e^s$. The map $s \mapsto e^s$ is a C^∞ diffeomorphism of $\mathbb{R}$ onto $(0, +\infty)$. Setting $S(s) := R(e^s)$, the chain rule gives

$$S'(s) = e^s R'(e^s) = r R'(r), \quad S''(s) = e^s R'(e^s) + e^{2s} R''(e^s) = r R'(r) + r^2 R''(r),$$

with $r = e^s$. Hence $r^2 R'' + r R' = S''$, and the equation becomes

$$S''(s) - n^2 S(s) = 0, \quad s \in \mathbb{R}.$$

Step 2 — solving the constant-coefficient equation. For $n \geq 1$ the solutions are $S(s) = A e^{ns} + B e^{-ns}$; returning to $r = e^s$, i.e. $s = \ln r$, one gets $R(r) = A r^n + B r^{-n}$. For $n = 0$ the equation is $S'' = 0$, with solutions $S(s) = A + Bs$, i.e. $R(r) = A + B \ln r$.

Step 3 — there are no others. The correspondence $R \mapsto S$ is a bijection between the C^2 solutions of the two equations (the inverse is $R(r) = S(\ln r)$, and the computation of Step 1 reads both ways); since the solution space of $S'' - n^2 S = 0$ has dimension 2 and is described exactly by the formulas of Step 2, the same holds for R . Note that for $n = 0$ one recovers Proposition 18.1, as it must. $\square$

Theorem 18.2: Regularity at the origin discards the singular solutions. *Let $n \geq 0$ be an integer and let R be a solution of $r^2 R'' + r R' - n^2 R = 0$ on $(0, a)$, not identically zero, such that R is bounded on a right neighbourhood of 0. Then, in the notation of Lemma 18.4, $B = 0$: that is, $R(r) = A r^n$ with $A \neq 0$ for $n \geq 1$, and R is a nonzero constant for $n = 0$. In particular the function*

$$U(r, \theta) = R(r)\Theta(\theta)$$

is, up to multiplicative constants, one of the modes

$$1, \quad r^n \cos n\theta, \quad r^n \sin n\theta \quad (n \geq 1),$$

all of which extend continuously to $r = 0$.

Proof. **Case $n \geq 1$.** By Lemma 18.4, $R(r) = Ar^n + Br^{-n}$. If $B \neq 0$, then, since $r^n \rightarrow 0$ and $r^{-n} \rightarrow +\infty$ as $r \rightarrow 0^+$,

$$|R(r)| \geq |B|r^{-n} - |A|r^n \rightarrow +\infty,$$

contradicting the boundedness hypothesis. Hence $B = 0$ and $R(r) = Ar^n$; if also $A = 0$ then $R \equiv 0$, which is excluded. The function $r \mapsto Ar^n$ extends continuously at $r = 0$ with value 0.

Case $n = 0$. By Lemma 18.4, $R(r) = A + B \ln r$. If $B \neq 0$, then $|R(r)| \geq |B| |\ln r| - |A| \rightarrow +\infty$ as $r \rightarrow 0^+$, contradicting the hypothesis. Hence $B = 0$ and $R \equiv A \neq 0$.

The modes. Combining with Lemma 18.3, which forces $\lambda = n^2$ and gives $\Theta = A' \cos n\theta + B' \sin n\theta$ (constant for $n = 0$), one gets that $U = R\Theta$ is a linear combination of $r^n \cos n\theta$ and $r^n \sin n\theta$, i.e., for $n = 0$, a constant. Each of these modes is harmonic on $\mathbb{R}^2 \setminus \{(0, 0)\}$ by Example 18.1, and since $r^n \cos n\theta = \operatorname{Re}(z^n)$ and $r^n \sin n\theta = \operatorname{Im}(z^n)$ are polynomials in x, y , they extend to C^∞ harmonic functions on all of $\mathbb{R}^2$. $\square$

Remark 18.2: What periodicity did, exactly. It is worth isolating the mechanism, because it will return identical for the membrane. Lemma 18.2 produces a free parameter λ that, taken the two problems separately, could be any real number. It is the requirement that Θ be a well-defined function on the circle — that is, 2π -periodic: in the language of Chapter 12, that it pass to the quotient $\mathbb{R}/2\pi\mathbb{Z}$ — that reduces the set of admissible λ to the discrete set $\{0, 1, 4, 9, \dots\}$. There is no boundary condition imposed by hand: the topology of the circle is the boundary condition. The second filter, boundedness at $r = 0$, is instead not topological but analytic, and arises from the degeneration of polar coordinates discussed in Observation 18.1.

Theorem 18.3: Series solution of the Dirichlet problem in the disc. Let $f : \mathbb{T} \rightarrow \mathbb{R}$ be continuous, with Fourier coefficients $\hat{f}(n)$, and let $a > 0$. Set, for $0 \leq r < a$ and $\theta \in \mathbb{R}$,

$$u(r, \theta) := \sum_{n \in \mathbb{Z}} \hat{f}(n) \left(\frac{r}{a}\right)^{|n|} e^{in\theta}.$$

Then:

- (i) the series converges absolutely and uniformly on every closed disc $\{r \leq \rho\}$ with $\rho < a$, and so do all the series obtained by differentiating it term by term any number of times in r and in θ ; consequently $u \in C^\infty(D_a)$;
- (ii) $\Delta u = 0$ in D_a ;
- (iii) $u(r, \cdot) \rightarrow f$ uniformly on $\mathbb{T}$ as $r \rightarrow a^-$; setting $u|_{\partial D_a} = f$ gives $u \in C(\overline{D_a})$, and u solves the Dirichlet problem of Definition 18.2.

Proof. Set $t = r/a \in [0, 1)$, so that $u(r, \theta) = \sum_n \hat{f}(n) t^{|n|} e^{in\theta}$.

Step 1 — estimating the coefficients. Directly from Definition 17.1,

$$|\hat{f}(n)| = \left| \frac{1}{2\pi} \int_{-\pi}^{\pi} f(\varphi) e^{-in\varphi} d\varphi \right| \leq \frac{1}{2\pi} \int_{-\pi}^{\pi} |f| =: M,$$

finite because f is continuous on the compact set $\mathbb{T}$.

Step 2 — total convergence of the differentiated series. Fix $\rho < a$ and $\sigma := \rho/a < 1$. The general term of the series is $g_n(r, \theta) = \hat{f}(n) a^{-|n|} r^{|n|} e^{in\theta}$; differentiating it p times in r and

q times in θ gives, for $r \leq \rho$ and $|n| \geq p$,

$$\left| \partial_r^p \partial_\theta^q g_n \right| = |\hat{f}(n)| \cdot |n|^q \cdot \frac{|n|(|n|-1) \cdots (|n|-p+1)}{a^{|n|}} r^{|n|-p} \leq \frac{M}{\rho^p} |n|^{q+p} \sigma^{|n|},$$

while for $|n| < p$ the p -th derivative in r vanishes. The numerical series $\sum_{n \in \mathbb{Z}} |n|^{q+p} \sigma^{|n|}$ converges (ratio test: the ratio of consecutive terms tends to $\sigma < 1$). By the Weierstrass criterion all the differentiated series converge totally, hence uniformly, on $\{r \leq \rho\} \times \mathbb{R}$. The theorem on term-by-term differentiation of series (applied successively in each variable) then gives $u \in C^\infty$ on $\{r < \rho\}$ for every $\rho < a$, i.e. on D_a , with derivatives obtained term by term.

Step 3 — harmonicity. Every term $t^{|n|} e^{in\theta} = (r/a)^{|n|} (\cos n\theta + i \sin n\theta)$ is harmonic on $\mathbb{R}^2 \setminus \{(0,0)\}$ by Example 18.1 and, by Theorem 18.2, extends to a harmonic function on all of $\mathbb{R}^2$. Since by Step 2 the Laplacian can be computed term by term,

$$\Delta u = \sum_{n \in \mathbb{Z}} \hat{f}(n) a^{-|n|} \Delta(r^{|n|} e^{in\theta}) = 0 \quad \text{in } D_a.$$

Step 4 — the boundary value. By the definition of the Poisson kernel (Definition 17.4) and by Theorem 17.8, for every $t \in [0, 1)$

$$\sum_{n \in \mathbb{Z}} t^{|n|} \hat{f}(n) e^{in\theta} = (f * P_t)(\theta) \longrightarrow f(\theta) \quad \text{uniformly in } \theta, \text{ as } t \rightarrow 1^-.$$

With $t = r/a$, this is exactly $u(r, \cdot) \rightarrow f$ uniformly as $r \rightarrow a^-$. Uniform convergence guarantees that the function extended by setting $u = f$ on ∂D_a is continuous on $\overline{D_a}$: indeed if $(r_k, \theta_k) \rightarrow (a, \theta_*)$ then

$$|u(r_k, \theta_k) - f(\theta_*)| \leq \underbrace{\|u(r_k, \cdot) - f\|_\infty}_{\rightarrow 0} + \underbrace{|f(\theta_k) - f(\theta_*)|}_{\rightarrow 0 \text{ by continuity of } f}.$$

Hence $u \in C^2(D_a) \cap C(\overline{D_a})$, $\Delta u = 0$ and $u|_{\partial D_a} = f$: the Dirichlet problem is solved. $\square$

Corollary 18.2: The Poisson formula recovered. Under the hypotheses of Theorem 18.3, for every $0 \leq r < a$ and $\theta \in \mathbb{R}$

$$u(r, \theta) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{a^2 - r^2}{a^2 - 2ar \cos(\theta - \varphi) + r^2} f(\varphi) d\varphi.$$

Proof. Set $t = r/a < 1$; by Step 2 of the proof of Theorem 18.3 the series $\sum_n \hat{f}(n) t^{|n|} e^{in\theta}$ converges uniformly in θ ; substituting the definition of $\hat{f}(n)$ and interchanging series and integral (legitimate by uniform convergence of the kernel, see Step 4 cited above) gives

$$u(r, \theta) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \left(\sum_{n \in \mathbb{Z}} t^{|n|} e^{in(\theta - \varphi)} \right) f(\varphi) d\varphi = \frac{1}{2\pi} \int_{-\pi}^{\pi} P_t(\theta - \varphi) f(\varphi) d\varphi,$$

with P_t the Poisson kernel of Definition 17.4. The closed form $P_t(\psi) = \frac{1 - t^2}{1 - 2t \cos \psi + t^2}$ is Theorem 17.8, which is *not* reproved here. Substituting $t = r/a$ and multiplying numerator and denominator by a^2 ,

$$P_{r/a}(\psi) = \frac{1 - r^2/a^2}{1 - 2(r/a) \cos \psi + r^2/a^2} = \frac{a^2 - r^2}{a^2 - 2ar \cos \psi + r^2},$$

which is the announced formula. $\square$

Remark 18.3: Two routes to the same kernel. The Poisson formula was obtained in Chapter 16 directly, as the integral kernel that solves the Dirichlet problem, and in Chapter 17 as the Abel summation kernel of the Fourier series (Theorem 17.8). Corollary 18.2 shows that it is also the unavoidable result of separation of variables: once it is established that the only regular harmonic modes are $r^{|n|}e^{in\theta}$, and once it is imposed that the sum equal f at the boundary, the coefficient of the n -th mode can only be $\hat{f}(n)$, and the sum of the two-sided geometric series can only be the Poisson kernel. None of the three derivations is more fundamental than the others; the third is the one that generalises, because it uses nothing specific to the disc except rotational symmetry, and indeed it will reappear unchanged in Section 18.6 with Bessel's equation in place of Euler's.

Example 18.2: A Dirichlet problem solved and checked. We solve the Dirichlet problem in the unit disc with boundary datum $f(\theta) = \cos^2 \theta$.

Step 1 — expanding the datum. From the double-angle formula $\cos^2 \theta = \frac{1}{2} + \frac{1}{2} \cos 2\theta$ (Volume I), hence $\hat{f}(0) = \frac{1}{2}$, $\hat{f}(\pm 2) = \frac{1}{4}$ and $\hat{f}(n) = 0$ otherwise.

Step 2 — the solution. By Theorem 18.3 with $a = 1$ the series reduces to three terms:

$$u(r, \theta) = \frac{1}{2} + \frac{1}{4}r^2e^{2i\theta} + \frac{1}{4}r^2e^{-2i\theta} = \frac{1}{2} + \frac{r^2}{2} \cos 2\theta.$$

Check 1: direct verification of harmonicity. With $U = \frac{1}{2} + \frac{r^2}{2} \cos 2\theta$ one has $U_{rr} = \cos 2\theta$, $\frac{1}{r}U_r = \cos 2\theta$, $\frac{1}{r^2}U_{\theta\theta} = -2 \cos 2\theta$; the sum is 0. ✓ In Cartesian coordinates $u = \frac{1}{2} + \frac{x^2 - y^2}{2}$, whose Laplacian is $\frac{1}{2}(2 - 2) = 0$. ✓

Check 2: the Poisson integral, computed numerically. For $r = \frac{1}{2}$ and $\theta = \frac{\pi}{3}$ the closed form gives

$$u\left(\frac{1}{2}, \frac{\pi}{3}\right) = \frac{1}{2} + \frac{1}{8} \cos \frac{2\pi}{3} = \frac{1}{2} - \frac{1}{16} = 0.4375.$$

The Poisson integral of Corollary 18.2, evaluated by the trapezoidal rule on 400 000 subintervals of $[-\pi, \pi]$ (Python script run), gives 0.4375000000: the two routes agree to ten decimal places. ✓ The same comparison at $(r, \theta) = (0.5, 0)$ gives 0.6250000000 versus 0.6250000000 and at $(0.8, 1)$ gives 0.3668330123 versus 0.3668330123. ✓

18.3. Maximum principle, uniqueness, stability

Theorem 18.3 constructs a solution. That it is the only one, and that it depends continuously on the datum, is not a formality: without these two properties the problem would not be well posed and no numerical computation would make sense. Both follow from a single principle, valid for arbitrary bounded domains, that uses neither symmetry nor the series.

Theorem 18.4: Weak maximum principle. Let $\Omega \subset \mathbb{R}^2$ be open, bounded and nonempty, and let $u \in C^2(\Omega) \cap C(\bar{\Omega})$ with $\Delta u = 0$ in Ω . Then

$$\max_{\bar{\Omega}} u = \max_{\partial\Omega} u, \quad \min_{\bar{\Omega}} u = \min_{\partial\Omega} u.$$

Proof. The two extrema exist because $\bar{\Omega}$ and $\partial\Omega$ are nonempty compact sets (Ω is bounded, hence $\bar{\Omega}$ is closed and bounded; $\partial\Omega \neq \emptyset$ because otherwise Ω would be both closed and open and hence, being bounded and nonempty, equal to $\mathbb{R}^2$, a contradiction).

Step 1 — a strictly subharmonic perturbation. Let $\varepsilon > 0$ and

$$v_\varepsilon(x, y) := u(x, y) + \varepsilon(x^2 + y^2).$$

Then $v_\varepsilon \in C^2(\Omega) \cap C(\overline{\Omega})$ and

$$\Delta v_\varepsilon = \Delta u + \varepsilon \Delta(x^2 + y^2) = 0 + \varepsilon \cdot 4 = 4\varepsilon > 0 \quad \text{in } \Omega.$$

Step 2 — v_ε has no interior maxima. Suppose, for contradiction, that v_ε has a maximum point $p \in \Omega$ (interior). Then, for every coordinate direction, the one-variable function $t \mapsto v_\varepsilon(p + te_1)$ has an interior maximum at $t = 0$ and is of class C^2 in a neighbourhood of 0; the second-derivative test gives $\partial_x^2 v_\varepsilon(p) \leq 0$. Likewise $\partial_y^2 v_\varepsilon(p) \leq 0$. Adding, $\Delta v_\varepsilon(p) \leq 0$, contradicting Step 1.

Step 3 — the maximum lies on the boundary. The function v_ε is continuous on the compact set $\overline{\Omega}$, hence attains a maximum at some $q \in \overline{\Omega}$; by Step 2, $q \notin \Omega$, i.e. $q \in \partial\Omega$. Therefore $\max_{\overline{\Omega}} v_\varepsilon = \max_{\partial\Omega} v_\varepsilon$.

Step 4 — letting ε tend to zero. Let $M := \max_{\overline{\Omega}}(x^2 + y^2) < \infty$ (Ω is bounded). For every $(x, y) \in \overline{\Omega}$,

$$u(x, y) \leq v_\varepsilon(x, y) \leq \max_{\partial\Omega} v_\varepsilon \leq \max_{\partial\Omega} u + \varepsilon M.$$

The left-hand side does not depend on ε ; letting $\varepsilon \rightarrow 0^+$ gives $u(x, y) \leq \max_{\partial\Omega} u$ for every $(x, y) \in \overline{\Omega}$, i.e. $\max_{\overline{\Omega}} u \leq \max_{\partial\Omega} u$. The opposite inequality is obvious because $\partial\Omega \subseteq \overline{\Omega}$.

Step 5 — the minimum. Apply what has been proved to $-u$, which is still harmonic, and use $\min w = -\max(-w)$. $\square$

Corollary 18.3: Uniqueness and stability for the Dirichlet problem. Let $\Omega \subset \mathbb{R}^2$ be open, bounded, nonempty.

(i) If $u_1, u_2 \in C^2(\Omega) \cap C(\overline{\Omega})$ are harmonic in Ω and agree on $\partial\Omega$, then $u_1 = u_2$ on $\overline{\Omega}$.

(ii) If moreover $u_i|_{\partial\Omega} = f_i$, then $\max_{\overline{\Omega}} |u_1 - u_2| = \max_{\partial\Omega} |f_1 - f_2|$.

In particular the solution constructed in Theorem 18.3 is the unique solution of the Dirichlet problem in the disc.

Proof. (ii) Let $w := u_1 - u_2$. By linearity of the Laplace operator w is harmonic in Ω , continuous on $\overline{\Omega}$, and $w|_{\partial\Omega} = f_1 - f_2$. By Theorem 18.4,

$$\max_{\overline{\Omega}} w = \max_{\partial\Omega} (f_1 - f_2) \quad \text{and} \quad \min_{\overline{\Omega}} w = \min_{\partial\Omega} (f_1 - f_2).$$

Since for a real function $\max |w| = \max\{\max w, -\min w\}$, one obtains $\max_{\overline{\Omega}} |w| = \max_{\partial\Omega} |f_1 - f_2|$.

(i) This is the case $f_1 = f_2$ of (ii): $\max_{\overline{\Omega}} |w| = 0$, i.e. $w \equiv 0$.

Finally, the function constructed in Theorem 18.3 belongs to $C^2(D_a) \cap C(\overline{D_a})$ and is harmonic with datum f : by (i) it is the only one. $\square$

Proposition 18.2: Mean-value property on concentric circles. Let u be the solution of Theorem 18.3. Then, for every $0 \leq r < a$,

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} u(r, \theta) d\theta = \hat{f}(0) = u(0),$$

that is, the mean of u over every circle concentric with the boundary equals the value at the centre, which in turn is the mean of the boundary datum.

Proof. By Step 2 of the proof of Theorem 18.3 the series converges uniformly in θ for fixed $r < a$, so it may be integrated term by term:

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} u(r, \theta) d\theta = \sum_{n \in \mathbb{Z}} \hat{f}(n) \left(\frac{r}{a}\right)^{|n|} \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{in\theta} d\theta.$$

By orthonormality of the trigonometric system (Proposition 17.1) the integral equals 1 for $n = 0$ and 0 otherwise: only the term $\hat{f}(0)(r/a)^0 = \hat{f}(0)$ remains. Setting $r = 0$ in the series also gives $u(0) = \hat{f}(0)$, because $(0/a)^{|n|} = 0$ for $n \neq 0$ and $= 1$ for $n = 0$. $\square$

18.4. Application: the heat equation on the circle

We move from stationary solutions to evolving ones. The thin, insulated ring is the simplest compact domain without boundary: there are no endpoints at which to impose conditions, and the only condition is again periodicity. The paragraph that follows is the one inherited from Volume II and is kept verbatim; the subsequent results complete it with existence, uniqueness, the maximum principle and a quantitative decay estimate.

Remark 18.4: Heat diffusion on a ring. The heat equation $\partial_t u = \partial_\theta^2 u$ on $\mathbb{T}$ (a thin insulated ring) is solved by seeking solutions of the form $u(\theta, t) = \sum_n c_n(t) e^{in\theta}$: substituting, $c'_n(t) = -n^2 c_n(t)$, hence $c_n(t) = c_n(0) e^{-n^2 t}$. The solution is

$$u(\theta, t) = \sum_{n \in \mathbb{Z}} \hat{u}_0(n) e^{-n^2 t} e^{in\theta},$$

where $\hat{u}_0(n)$ are the Fourier coefficients of the initial datum. High-frequency components ($|n|$ large) decay much faster ($e^{-n^2 t}$): heat “flattens” fine details first, exactly as expected physically. This is the prototype, in the simplest case (1 spatial dimension, compact domain $\mathbb{T}$), of the problems that in Volume III we will treat on the two-dimensional disc with Bessel functions.

Definition 18.3: Cauchy problem for heat on $\mathbb{T}$ and the heat kernel. Let $\kappa > 0$ and $f : \mathbb{T} \rightarrow \mathbb{R}$. The **Cauchy problem** for the heat equation on $\mathbb{T}$ consists in finding u continuous on $\mathbb{T} \times [0, +\infty)$, of class C^2 in θ and C^1 in t for $t > 0$, with

$$u_t = \kappa u_{\theta\theta} \quad \text{for } t > 0, \quad u(\theta, 0) = f(\theta).$$

For $t > 0$ the function

$$H_t(\theta) := \frac{1}{2\pi} \sum_{n \in \mathbb{Z}} e^{-\kappa n^2 t} e^{in\theta}$$

is called the **heat kernel** on $\mathbb{T}$.

Proposition 18.3: The heat kernel is well defined and smooth. For every $t > 0$ the series defining H_t converges totally on $\mathbb{R}$ together with all its derivatives in θ ; $H_t \in C^\infty(\mathbb{T})$, is real and even, and

$$\int_{-\pi}^{\pi} H_t(\theta) d\theta = 1, \quad \partial_t H_t = \kappa \partial_\theta^2 H_t \quad (t > 0).$$

Proof. Step 1 — convergence. For $t \geq t_0 > 0$ and every $q \geq 0$, $|\partial_\theta^q (e^{-\kappa n^2 t} e^{in\theta})| = |n|^q e^{-\kappa n^2 t} \leq |n|^q e^{-\kappa n^2 t_0}$, and the numerical series $\sum_n |n|^q e^{-\kappa n^2 t_0}$ converges (the ratio of consec-

utive terms tends to 0). By the Weierstrass criterion the convergence is total, hence uniform, and by the theorem on term-by-term differentiation of series $H_t \in C^\infty$ with derivatives computable term by term. The same argument with $\partial_t(e^{-\kappa n^2 t}) = -\kappa n^2 e^{-\kappa n^2 t}$ shows that one may also differentiate term by term in t , uniformly for $t \geq t_0$.

Step 2 — reality and parity. Pairing the terms n and $-n$,

$$H_t(\theta) = \frac{1}{2\pi} \left(1 + 2 \sum_{n \geq 1} e^{-\kappa n^2 t} \cos n\theta \right),$$

which is real and even in θ .

Step 3 — normalisation. Integrating term by term (legitimate by Step 1) and using $\int_{-\pi}^{\pi} e^{in\theta} d\theta = 2\pi \delta_{n0}$ (Proposition 17.1), only the term $n = 0$ survives: $\int_{-\pi}^{\pi} H_t = \frac{1}{2\pi} \cdot 2\pi = 1$.

Step 4 — the equation. Differentiating term by term, $\partial_t H_t = \frac{1}{2\pi} \sum_n (-\kappa n^2) e^{-\kappa n^2 t} e^{in\theta}$ and $\partial_\theta^2 H_t = \frac{1}{2\pi} \sum_n (in)^2 e^{-\kappa n^2 t} e^{in\theta} = \frac{1}{2\pi} \sum_n (-n^2) e^{-\kappa n^2 t} e^{in\theta}$; multiplying the second by κ gives the first. $\square$

Theorem 18.5: Existence, instantaneous smoothing and the initial datum. Let $f \in L^1(\mathbb{T})$ (in particular f continuous) and set, for $t > 0$,

$$u(\theta, t) := \sum_{n \in \mathbb{Z}} \hat{f}(n) e^{-\kappa n^2 t} e^{in\theta} = (f * H_t)(\theta).$$

Then:

- (i) the series and all its term-by-term derivatives converge totally on $\mathbb{T} \times [t_0, +\infty)$ for every $t_0 > 0$; hence $u \in C^\infty(\mathbb{T} \times (0, +\infty))$, regardless of the regularity of f ;
- (ii) $u_t = \kappa u_{\theta\theta}$ for $t > 0$;
- (iii) if $\sum_n |\hat{f}(n)| < \infty$ (for instance if $f \in C^1(\mathbb{T})$), then $u(\cdot, t) \rightarrow f$ uniformly on $\mathbb{T}$ as $t \rightarrow 0^+$, and setting $u(\cdot, 0) = f$ the function u solves the Cauchy problem of Definition 18.3;
- (iv) if $f \in L^2(\mathbb{T})$, then $\|u(\cdot, t) - f\|_2 \rightarrow 0$ as $t \rightarrow 0^+$.

Proof. **Step 1 — (i).** As in Step 1 of Proposition 18.3, $|\hat{f}(n)| \leq \frac{1}{2\pi} \int |f| =: M$ and for $t \geq t_0$

$$\left| \partial_t^p \partial_\theta^q (\hat{f}(n) e^{-\kappa n^2 t} e^{in\theta}) \right| \leq M (\kappa n^2)^p |n|^q e^{-\kappa n^2 t_0},$$

and $\sum_{n \in \mathbb{Z}} n^{2p+q} e^{-\kappa n^2 t_0} < \infty$ because the Gaussian exponential beats every power. The Weierstrass criterion and the theorem on term-by-term differentiation of series give the claim. The equality $u = f * H_t$ is obtained by substituting the definition of $\hat{f}(n)$ and interchanging series and integral, legitimate by uniform convergence.

Step 2 — (ii). Differentiating term by term (Step 1),

$$u_t = \sum_n (-\kappa n^2) \hat{f}(n) e^{-\kappa n^2 t} e^{in\theta}, \quad \kappa u_{\theta\theta} = \kappa \sum_n (-n^2) \hat{f}(n) e^{-\kappa n^2 t} e^{in\theta},$$

and the two series coincide term by term.

Step 3 — (iii). If $\sum_n |\hat{f}(n)| < \infty$, then by Theorem 17.5 the Fourier series of f converges uniformly to f . For every θ and every $t > 0$,

$$|u(\theta, t) - f(\theta)| = \left| \sum_{n \in \mathbb{Z}} \hat{f}(n) (e^{-\kappa n^2 t} - 1) e^{in\theta} \right| \leq \sum_{n \in \mathbb{Z}} |\hat{f}(n)| (1 - e^{-\kappa n^2 t}).$$

The series on the right does not depend on θ ; each of its terms tends to 0 as $t \rightarrow 0^+$ and is dominated by $|\hat{f}(n)|$, which is summable. Given $\varepsilon > 0$, choose N with $\sum_{|n| > N} |\hat{f}(n)| < \varepsilon/2$

and then t small enough that $\sum_{|n| \leq N} |\hat{f}(n)|(1 - e^{-\kappa n^2 t}) < \varepsilon/2$ (a finite sum of infinitesimals). Then the estimate is $< \varepsilon$ uniformly in θ . Hence $u(\cdot, t) \rightarrow f$ uniformly; continuity of u on $\mathbb{T} \times [0, +\infty)$ follows as in Step 4 of the proof of Theorem 18.3.

Step 4 — (iv). By Parseval's identity (Theorem 17.1),

$$\|u(\cdot, t) - f\|_2^2 = \sum_{n \in \mathbb{Z}} |\hat{f}(n)|^2 (1 - e^{-\kappa n^2 t})^2.$$

Each term is $\leq |\hat{f}(n)|^2$, summable and independent of t , and tends to 0 as $t \rightarrow 0^+$; with the same two-piece argument of Step 3 (small tail plus finite sum of infinitesimals) the sum tends to 0. $\square$

Theorem 18.6: Uniqueness for the heat equation on $\mathbb{T}$. Let $T > 0$ and let u be continuous on $\mathbb{T} \times [0, T]$, with $u_t, u_\theta, u_{\theta\theta}$ continuous on $\mathbb{T} \times (0, T]$, such that $u_t = \kappa u_{\theta\theta}$ for $0 < t \leq T$ and $u(\cdot, 0) = 0$. Then $u \equiv 0$.

Proof. **Step 1 — the energy.** For $0 < t \leq T$ set

$$E(t) := \int_{-\pi}^{\pi} u(\theta, t)^2 d\theta \geq 0.$$

Since u and u_t are continuous on $\mathbb{T} \times [\delta, T]$ for every $\delta > 0$, one may differentiate under the integral sign (Leibniz's theorem, compact domain):

$$E'(t) = 2 \int_{-\pi}^{\pi} u u_t d\theta = 2\kappa \int_{-\pi}^{\pi} u u_{\theta\theta} d\theta.$$

Step 2 — integration by parts. The function $\theta \mapsto u(\theta, t)$ is 2π -periodic and C^2 ; integrating by parts on $[-\pi, \pi]$ the boundary term $[u u_\theta]_{-\pi}^{\pi}$ vanishes by periodicity, leaving

$$E'(t) = -2\kappa \int_{-\pi}^{\pi} (u_\theta)^2 d\theta \leq 0.$$

Step 3 — conclusion. Hence E is nonincreasing on $(0, T]$ and, since u is continuous up to $t = 0$ with $u(\cdot, 0) = 0$, one has $E(t) \rightarrow 0$ as $t \rightarrow 0^+$ (uniform convergence on an interval of finite length). From E nonincreasing and $\lim_{t \rightarrow 0^+} E(t) = 0$ it follows that $E(t) \leq 0$ for every $t \in (0, T]$; together with $E \geq 0$ this gives $E \equiv 0$. Since $u(\cdot, t)$ is continuous and $\int u^2 = 0$, one concludes $u(\cdot, t) \equiv 0$ for every $t \in (0, T]$, and by continuity also at $t = 0$. $\square$

Proposition 18.4: Maximum principle for heat on $\mathbb{T}$. Let $T > 0$ and let u be continuous on $\mathbb{T} \times [0, T]$, with $u_t, u_{\theta\theta}$ continuous on $\mathbb{T} \times (0, T]$ and $u_t = \kappa u_{\theta\theta}$ for $0 < t \leq T$. Then

$$\min_{\mathbb{T}} u(\cdot, 0) \leq u(\theta, t) \leq \max_{\mathbb{T}} u(\cdot, 0) \quad \text{for every } (\theta, t) \in \mathbb{T} \times [0, T].$$

Proof. **Step 1 — the perturbed function.** Let $\varepsilon > 0$ and $w(\theta, t) := u(\theta, t) - \varepsilon t$. Then w is continuous on $\mathbb{T} \times [0, T]$ and for $0 < t \leq T$

$$w_t - \kappa w_{\theta\theta} = u_t - \varepsilon - \kappa u_{\theta\theta} = -\varepsilon < 0.$$

Step 2 — the maximum of w is at $t = 0$. The set $\mathbb{T} \times [0, T]$ is compact ($\mathbb{T}$ is compact, Chapter 12), hence w attains a maximum there at some point (θ_1, t_1) . Suppose, for contradiction, $t_1 > 0$. Then:

- the function $\theta \mapsto w(\theta, t_1)$ has a maximum (interior, because $\mathbb{T}$ has no boundary) at θ_1 , hence $w_{\theta\theta}(\theta_1, t_1) \leq 0$ by the second-derivative test;

- the function $t \mapsto w(\theta_1, t)$ has a maximum on $[0, T]$ at $t = t_1 > 0$: if $t_1 < T$ it is an interior maximum and $w_t(\theta_1, t_1) = 0$; if $t_1 = T$ it is a maximum at the right endpoint and $w_t(\theta_1, T) \geq 0$ (otherwise w would be strictly decreasing just to the left of T and would attain larger values). In either case $w_t(\theta_1, t_1) \geq 0$.

It follows that $w_t - \kappa w_{\theta\theta} \geq 0$ at (θ_1, t_1) , contradicting Step 1. Hence $t_1 = 0$ and $\max_{\mathbb{T} \times [0, T]} w = \max_{\mathbb{T}} w(\cdot, 0) = \max_{\mathbb{T}} u(\cdot, 0)$.

Step 3 — letting ε tend to zero. For every (θ, t) , $u(\theta, t) = w(\theta, t) + \varepsilon t \leq \max_{\mathbb{T}} u(\cdot, 0) + \varepsilon T$; letting $\varepsilon \rightarrow 0^+$ gives the upper bound. Applying the result to $-u$, which satisfies the same equation, gives the lower bound. $\square$

Proposition 18.5: Exponential decay to the mean. Let $f \in L^2(\mathbb{T})$ and let u be the solution of Theorem 18.5. Then, for every $t > 0$,

$$\|u(\cdot, t) - \hat{f}(0)\|_2 \leq e^{-\kappa t} \|f - \hat{f}(0)\|_2,$$

and if moreover $\sum_n |\hat{f}(n)| < \infty$,

$$\sup_{\theta \in \mathbb{T}} |u(\theta, t) - \hat{f}(0)| \leq e^{-\kappa t} \sum_{n \neq 0} |\hat{f}(n)|.$$

In particular $u(\cdot, t) \rightarrow \hat{f}(0)$, the initial mean temperature, at an exponential rate governed by the first nonconstant mode, $n = \pm 1$.

Proof. By Theorem 18.5 one has $u(\theta, t) - \hat{f}(0) = \sum_{n \neq 0} \hat{f}(n) e^{-\kappa n^2 t} e^{in\theta}$, because the term $n = 0$ equals $\hat{f}(0)e^0 = \hat{f}(0)$.

Estimate in L^2 . By Parseval's identity (Theorem 17.1),

$$\|u(\cdot, t) - \hat{f}(0)\|_2^2 = \sum_{n \neq 0} |\hat{f}(n)|^2 e^{-2\kappa n^2 t} \leq e^{-2\kappa t} \sum_{n \neq 0} |\hat{f}(n)|^2 = e^{-2\kappa t} \|f - \hat{f}(0)\|_2^2,$$

where $n^2 \geq 1$ for $n \neq 0$ was used, hence $e^{-2\kappa n^2 t} \leq e^{-2\kappa t}$. Taking square roots gives the first estimate.

Uniform estimate. With the same bound $e^{-\kappa n^2 t} \leq e^{-\kappa t}$,

$$|u(\theta, t) - \hat{f}(0)| \leq \sum_{n \neq 0} |\hat{f}(n)| e^{-\kappa n^2 t} \leq e^{-\kappa t} \sum_{n \neq 0} |\hat{f}(n)|,$$

independently of θ . $\square$

Example 18.3: A non-smooth initial datum: $f(\theta) = |\theta|$. Let $\kappa = 1$ and $f(\theta) = |\theta|$ for $\theta \in [-\pi, \pi]$, extended by periodicity.

Step 1 — the coefficients. The function is even, so the sine coefficients vanish. One has $a_0 = \frac{1}{\pi} \int_{-\pi}^{\pi} |\theta| d\theta = \frac{1}{\pi} \cdot \pi^2 = \pi$ and, for $j \geq 1$, integrating by parts,

$$a_j = \frac{2}{\pi} \int_0^{\pi} \theta \cos j\theta d\theta = \frac{2}{\pi} \left[\frac{\theta \sin j\theta}{j} + \frac{\cos j\theta}{j^2} \right]_0^{\pi} = \frac{2}{\pi} \cdot \frac{(-1)^j - 1}{j^2},$$

i.e. $a_j = 0$ for j even and $a_j = -\frac{4}{\pi j^2}$ for j odd. Hence

$$f(\theta) = \frac{\pi}{2} - \frac{4}{\pi} \sum_{j \text{ odd}} \frac{\cos j\theta}{j^2}, \quad u(\theta, t) = \frac{\pi}{2} - \frac{4}{\pi} \sum_{j \text{ odd}} e^{-j^2 t} \frac{\cos j\theta}{j^2}.$$

The series of coefficients converges absolutely ($\sum_j 4/(\pi j^2) < \infty$), so part (iii) of Theorem 18.5 applies.

Step 2 — values. Summing the series (Python script run, 2000 terms):

$$u(0, 0.1) = 0.3568248232, \quad u(0, 0.5) = 0.7969657144, \quad u(1, 0.1) = 1.0039425011.$$

Independent check. The same three values were recomputed by a completely different route, as the convolution $(f * H_t)(\theta)$ with the heat kernel of Definition 18.3 truncated to 60 modes, integrated by the trapezoidal rule on 200 000 subintervals: this gives 0.3568248231, 0.7969657144 and 1.0039425011, i.e. the same digits to ten decimal places (a discrepancy of 10^{-10} on the first value, attributable to the quadrature). ✓

Reading. The datum has a corner at $\theta = 0$ and one at $\theta = \pm\pi$; after an arbitrarily small time the solution is C^∞ (Theorem 18.5(i)) and the value at the corner point has risen from 0 to 0.3568 at $t = 0.1$. The mean is $\hat{f}(0) = \pi/2 = 1.5707963$; at $t = 0.5$ the solution at 0 is already 0.7970, and Proposition 18.5 guarantees that the gap from the mean decays at least like e^{-t} .

Remark 18.5: Why heat cannot be run backwards. The factor $e^{-\kappa n^2 t}$ is a fierce contraction on high frequencies; to run time backwards one would have to multiply by $e^{+\kappa n^2 t}$, which blows up. Precisely: given $t > 0$ and any sequence (c_n) with $\sum |c_n|^2 < \infty$, the function $\sum c_n e^{in\theta}$ is the value at time t of a solution only if $\sum |c_n|^2 e^{2\kappa n^2 t} < \infty$, a much stronger condition. The backward problem is therefore ill posed in Hadamard's sense: the solution, when it exists, does not depend continuously on the datum. This contrasts sharply with the wave equation of Section 18.5, which is reversible: d'Alembert's formula (Theorem 18.7) makes sense for every $t \in \mathbb{R}$, positive or negative.

18.5. The wave equation on the circle

A taut string closed into a ring — for instance the string of an idealised conical pendulum, or more simply a one-dimensional model of an annular membrane — obeys the wave equation with a periodicity condition. Unlike heat, here a closed-form formula exists, is written in two lines and is exact: it is d'Alembert's formula, made periodic by the fact that the domain is a circle.

Definition 18.4: Cauchy problem for waves on $\mathbb{T}$. Let $c > 0$. Given $F \in C^2(\mathbb{T})$ and $G \in C^1(\mathbb{T})$, the **Cauchy problem** for the wave equation on $\mathbb{T}$ consists in finding $u \in C^2(\mathbb{T} \times \mathbb{R})$ with

$$u_{tt} = c^2 u_{\theta\theta} \text{ on } \mathbb{T} \times \mathbb{R}, \quad u(\theta, 0) = F(\theta), \quad u_t(\theta, 0) = G(\theta).$$

Lemma 18.5: Factorisation of the wave operator. For every $w \in C^2$ of two variables (θ, t) ,

$$\partial_t^2 w - c^2 \partial_\theta^2 w = (\partial_t - c \partial_\theta)(\partial_t + c \partial_\theta)w = (\partial_t + c \partial_\theta)(\partial_t - c \partial_\theta)w.$$

Moreover, setting $\xi = \theta + ct$ and $\eta = \theta - ct$ and $W(\xi, \eta) = w(\theta, t)$, one has $\partial_t^2 w - c^2 \partial_\theta^2 w = -4c^2 W_{\xi\eta}$.

Proof. Step 1 — the factorisation. Expanding,

$$(\partial_t - c \partial_\theta)(\partial_t + c \partial_\theta)w = w_{tt} + c w_{\theta t} - c w_{t\theta} - c^2 w_{\theta\theta},$$

and $w_{\theta t} = w_{t\theta}$ by Schwarz's theorem ($w \in C^2$): what remains is $w_{tt} - c^2 w_{\theta\theta}$. The same computation in the opposite order gives the same result.

Step 2 — the characteristic variables. The linear transformation $(\theta, t) \mapsto (\xi, \eta) = (\theta + ct, \theta - ct)$ is invertible, with $\theta = \frac{\xi + \eta}{2}$ and $t = \frac{\xi - \eta}{2c}$. By the chain rule,

$$w_\theta = W_\xi + W_\eta, \quad w_t = c(W_\xi - W_\eta),$$

and differentiating again,

$$w_{\theta\theta} = W_{\xi\xi} + 2W_{\xi\eta} + W_{\eta\eta}, \quad w_{tt} = c^2(W_{\xi\xi} - 2W_{\xi\eta} + W_{\eta\eta}).$$

Subtracting, $w_{tt} - c^2 w_{\theta\theta} = c^2(-2W_{\xi\eta} - 2W_{\xi\eta}) = -4c^2 W_{\xi\eta}$. $\square$

Theorem 18.7: Periodic d'Alembert formula. Let $F \in C^2(\mathbb{T})$ and $G \in C^1(\mathbb{T})$ and set

$$u(\theta, t) := \frac{1}{2} \left(F(\theta + ct) + F(\theta - ct) \right) + \frac{1}{2c} \int_{\theta - ct}^{\theta + ct} G(s) ds.$$

Then $u \in C^2(\mathbb{R}^2)$, is 2π -periodic in θ for every t , and solves the Cauchy problem of Definition 18.4. Moreover u is the unique solution.

Proof. Let $\mathcal{G}(s) := \int_0^s G(\sigma) d\sigma$, a primitive of G of class C^2 (because $G \in C^1$). Then

$$u(\theta, t) = \frac{1}{2} \left(F(\theta + ct) + F(\theta - ct) \right) + \frac{1}{2c} \left(\mathcal{G}(\theta + ct) - \mathcal{G}(\theta - ct) \right). \quad (**)$$

Step 1 — regularity. F is C^2 and $\mathcal{G}$ is C^2 ; the compositions with the affine functions $(\theta, t) \mapsto \theta \pm ct$ are C^2 , and a linear combination of C^2 functions is C^2 . Hence $u \in C^2(\mathbb{R}^2)$.

Step 2 — the equation. Differentiating (**):

$$u_t = \frac{c}{2} (F'(\xi) - F'(\eta)) + \frac{1}{2} (G(\xi) + G(\eta)), \quad u_\theta = \frac{1}{2} (F'(\xi) + F'(\eta)) + \frac{1}{2c} (G(\xi) - G(\eta)),$$

with $\xi = \theta + ct$, $\eta = \theta - ct$ and $\mathcal{G}' = G$. Differentiating once more:

$$u_{tt} = \frac{c^2}{2} (F''(\xi) + F''(\eta)) + \frac{c}{2} (G'(\xi) - G'(\eta)),$$

$$u_{\theta\theta} = \frac{1}{2} (F''(\xi) + F''(\eta)) + \frac{1}{2c} (G'(\xi) - G'(\eta)).$$

Multiplying the second by c^2 gives exactly the first: $u_{tt} = c^2 u_{\theta\theta}$.

Step 3 — the initial data. Setting $t = 0$ in (**) gives $\xi = \eta = \theta$, hence $u(\theta, 0) = \frac{1}{2} (F(\theta) + F(\theta)) + 0 = F(\theta)$; and from the formula for u_t , $u_t(\theta, 0) = \frac{c}{2} (F'(\theta) - F'(\theta)) + \frac{1}{2} (G(\theta) + G(\theta)) = G(\theta)$.

Step 4 — periodicity in θ . F is 2π -periodic, so both terms in F are. For $\mathcal{G}$ one has, for every s ,

$$\mathcal{G}(s + 2\pi) - \mathcal{G}(s) = \int_s^{s+2\pi} G = \int_{-\pi}^{\pi} G = 2\pi \hat{G}(0),$$

a constant independent of s (the integral of a periodic function over a period does not depend on the starting point). Hence

$$\mathcal{G}(\theta + 2\pi + ct) - \mathcal{G}(\theta + 2\pi - ct) = \left(\mathcal{G}(\theta + ct) + \int_{-\pi}^{\pi} G \right) - \left(\mathcal{G}(\theta - ct) + \int_{-\pi}^{\pi} G \right) = \mathcal{G}(\theta + ct) - \mathcal{G}(\theta - ct),$$

and $u(\theta + 2\pi, t) = u(\theta, t)$: the additive constant cancels, and periodicity holds *always*, even when G does not have zero mean.

Step 5 — uniqueness. Let u_1, u_2 be two solutions and $w = u_1 - u_2$: then $w \in C^2$, $w_{tt} = c^2 w_{\theta\theta}$, $w(\cdot, 0) = 0$ and $w_t(\cdot, 0) = 0$. Set

$$E(t) := \frac{1}{2} \int_{-\pi}^{\pi} (w_t^2 + c^2 w_\theta^2) d\theta.$$

The integrands are C^1 on a compact domain, so one may differentiate under the integral sign:

$$E'(t) = \int_{-\pi}^{\pi} (w_t w_{tt} + c^2 w_\theta w_{\theta t}) d\theta = \int_{-\pi}^{\pi} (c^2 w_t w_{\theta\theta} + c^2 w_\theta w_{t\theta}) d\theta = c^2 \int_{-\pi}^{\pi} \partial_\theta (w_t w_\theta) d\theta = 0,$$

because $w_t w_\theta$ is 2π -periodic in θ and the integral of its derivative over a period is zero. Hence E is constant; but $E(0) = \frac{1}{2} \int (0 + c^2 \cdot 0) = 0$ because $w_t(\cdot, 0) = 0$ and $w_\theta(\cdot, 0) = \partial_\theta (w(\cdot, 0)) = 0$. Thus $E \equiv 0$, and since the integrand is continuous and nonnegative, $w_t \equiv 0$ and $w_\theta \equiv 0$ on $\mathbb{R}^2$: w is constant, and equals 0 because $w(\cdot, 0) = 0$. $\square$

Proposition 18.6: The same solution, written as a Fourier series. Let F, G be trigonometric polynomials, $F = \sum_{|n| \leq N} \hat{F}(n) e^{in\theta}$ and $G = \sum_{|n| \leq N} \hat{G}(n) e^{in\theta}$. Then the solution of Theorem 18.7 is

$$u(\theta, t) = \hat{F}(0) + \hat{G}(0)t + \sum_{0 < |n| \leq N} \left(\hat{F}(n) \cos(cnt) + \frac{\hat{G}(n)}{cn} \sin(cnt) \right) e^{in\theta}.$$

Proof. Both sides depend linearly on (F, G) : it therefore suffices to verify the equality when $F(\theta) = e^{in\theta}$, $G = 0$, and when $F = 0$, $G(\theta) = e^{in\theta}$.

Case $F = e^{in\theta}$, $G = 0$. D'Alembert's formula gives

$$\frac{1}{2} (e^{in(\theta+ct)} + e^{in(\theta-ct)}) = e^{in\theta} \frac{e^{icnt} + e^{-icnt}}{2} = e^{in\theta} \cos(cnt),$$

by Euler's formula (Chapter 6); for $n = 0$ this reads $\cos 0 = 1$, in agreement with the term $\hat{F}(0)$.

Case $F = 0$, $G = e^{in\theta}$, $n \neq 0$. One has

$$\frac{1}{2c} \int_{\theta-ct}^{\theta+ct} e^{ins} ds = \frac{1}{2c} \cdot \frac{e^{in(\theta+ct)} - e^{in(\theta-ct)}}{in} = \frac{e^{in\theta}}{2c in} \cdot 2i \sin(cnt) = \frac{\sin(cnt)}{cn} e^{in\theta}.$$

Case $F = 0$, $G = 1$ (i.e. $n = 0$). One has $\frac{1}{2c} \int_{\theta-ct}^{\theta+ct} 1 ds = \frac{1}{2c} \cdot 2ct = t$, which is the term $\hat{G}(0)t$.

Summing the contributions with the coefficients $\hat{F}(n)$, $\hat{G}(n)$ gives the formula in the statement. $\square$

Proposition 18.7: Conservation of energy. Let u be the solution of Theorem 18.7. Then the function

$$E(t) = \frac{1}{2} \int_{-\pi}^{\pi} (u_t(\theta, t)^2 + c^2 u_\theta(\theta, t)^2) d\theta$$

is constant in t , and equals $E(0) = \frac{1}{2} \int_{-\pi}^{\pi} (G^2 + c^2 (F')^2) d\theta$.

Proof. The computation is that of Step 5 of the proof of Theorem 18.7, applied to u instead of w : the only properties used are $u \in C^2$, $u_{tt} = c^2 u_{\theta\theta}$ and 2π -periodicity in θ , all of which hold. This gives $E' \equiv 0$, hence E constant. The value at $t = 0$ is read off from the initial data: $u_t(\cdot, 0) = G$ and $u_\theta(\cdot, 0) = F'$. $\square$

Proposition 18.8: Periodicity in time. If $\hat{G}(0) = \frac{1}{2\pi} \int_{-\pi}^{\pi} G = 0$ (in particular if $G \equiv 0$), the solution of Theorem 18.7 is periodic in t with period $2\pi/c$:

$$u\left(\theta, t + \frac{2\pi}{c}\right) = u(\theta, t) \quad \text{for every } (\theta, t).$$

Proof. In the expression (**) from the proof of Theorem 18.7, replacing t by $t + \frac{2\pi}{c}$ means replacing $\xi = \theta + ct$ by $\xi + 2\pi$ and $\eta = \theta - ct$ by $\eta - 2\pi$. Now F is 2π -periodic, so $F(\xi + 2\pi) = F(\xi)$ and $F(\eta - 2\pi) = F(\eta)$. As for $\mathcal{G}$, Step 4 of the same proof gives $\mathcal{G}(s + 2\pi) = \mathcal{G}(s) + \int_{-\pi}^{\pi} G = \mathcal{G}(s)$, because by hypothesis $\int_{-\pi}^{\pi} G = 2\pi\hat{G}(0) = 0$: hence $\mathcal{G}$ is itself 2π -periodic and $\mathcal{G}(\xi + 2\pi) - \mathcal{G}(\eta - 2\pi) = \mathcal{G}(\xi) - \mathcal{G}(\eta)$. The two terms of (**) are therefore unchanged. $\square$

Example 18.4: Two modes that recombine. Let $c = 2$, $F(\theta) = \cos \theta + \frac{1}{2} \cos 3\theta$ and $G \equiv 0$.

By d'Alembert. $u(\theta, t) = \frac{1}{2}(F(\theta + 2t) + F(\theta - 2t))$.

By series. By Proposition 18.6, $u(\theta, t) = \cos(2t) \cos \theta + \frac{1}{2} \cos(6t) \cos 3\theta$.

Independent check. The two expressions were evaluated (Python script run) at three points:

(θ, t)	(0.4, 0.7)	(1.3, 0.25)	(2, 1.1)
d'Alembert	0.0677252004	0.2090770974	0.7010954284
series	0.0677252004	0.2090770974	0.7010954284

The discrepancies are 0, 0 and $1.1 \cdot 10^{-16}$, i.e. double-precision rounding error. $\checkmark$

Energy. By Proposition 18.7, $E = \frac{1}{2} \int_{-\pi}^{\pi} c^2 (F')^2 d\theta$ with $F' = -\sin \theta - \frac{3}{2} \sin 3\theta$; by orthogonality of the sines,

$$E = \frac{c^2}{2} \left(\pi \cdot 1^2 + \pi \cdot \left(\frac{3}{2}\right)^2 \right) = \frac{4}{2} \pi \left(1 + \frac{9}{4} \right) = \frac{13\pi}{2} = 20.4203522.$$

Numerical quadrature of the energy at the three instants $t = 0$, $t = 0.37$ and $t = 1.25$ gives 20.42035225 in all three cases. $\checkmark$

Periodicity. Since $\hat{G}(0) = 0$, Proposition 18.8 gives period $2\pi/c = \pi$; here the solution actually already has period π from the term $\cos(2t)$, and the second term $\cos(6t)$ has period $\pi/3$, which divides π .

Remark 18.6: Heat and waves compared. The two equations differ by a single symbol — u_t versus u_{tt} — and by everything else. On the Fourier modes, heat acts with the factor $e^{-\kappa n^2 t}$, real and decreasing, waves with $\cos(cnt)$ and $\sin(cnt)$, of bounded modulus and never infinitesimal. It follows that:

- heat regularises instantaneously (Theorem 18.5(i)), waves do not: d'Alembert's formula transports the corners of the datum without attenuating them;
- heat dissipates and forgets (Proposition 18.5), waves conserve energy (Proposition 18.7) and, on the circle, return periodically to the initial datum (Proposition 18.8);
- heat is irreversible (Observation 18.5), waves are reversible: the formula of Theorem 18.7 is defined for every $t \in \mathbb{R}$ and is invariant under $t \mapsto -t$ when $G \equiv 0$.

The time-periodicity of waves on $\mathbb{T}$ is a very special fact, which depends on the eigenvalues $\{n^2\}$ of the Laplacian on $\mathbb{T}$ having square roots that are all integers, hence commensurable. On the disc, as we shall see in Section 18.8, the eigenvalues are the squares of the Bessel zeros, whose ratios are neither integers nor simple fractions: the drum is not periodic and its sound is not harmonic (Observation 18.14).

Figure 18.2: The characteristics $\theta \pm ct = \text{const}$ in the strip $\mathbb{T} \times [0, +\infty)$ for $c = 2$ and $\theta_0 = -1$. Coordinates computed by hand: the right-going characteristic $\theta = \theta_0 + ct$ reaches $\theta = \pi$ at time $t = (\pi - \theta_0)/c = (3.1415927 + 1)/2 = 2.0707963$ and re-enters from $\theta = -\pi$; the left-going one $\theta = \theta_0 - ct$ reaches $\theta = -\pi$ at time $t = (\theta_0 + \pi)/c = (3.1415927 - 1)/2 = 1.0707963$ and re-enters from $\theta = \pi$. At time $t = 2\pi/c = \pi$ both have returned to the starting point: this is Proposition 18.8.

18.6. The circular membrane: from separation to Bessel's equation

The drum is the first problem in which separation of variables does not close with elementary functions. The reason is purely structural: in Laplace's equation the parameter λ appeared only through n^2 , and the radial equation was Euler's, homogeneous under dilations; here a term λr^2 also appears, which breaks the homogeneity and produces an equation whose solution must be built from scratch. That construction is the Bessel function.

Definition 18.5: The circular membrane problem. Let $a > 0$ and $c > 0$. The **circular membrane problem** (or drum problem) consists in seeking $u \in C^2(\overline{D_a} \times \mathbb{R})$ with

$$u_{tt} = c^2 \Delta u \text{ in } D_a \times \mathbb{R}, \quad u(x, y, t) = 0 \text{ for } (x, y) \in \partial D_a \text{ and every } t.$$

A nontrivial solution of the form $u(x, y, t) = T(t)V(x, y)$ is called a **normal mode** of the membrane.

Lemma 18.6: Separation of time and space. Let $T \in C^2(\mathbb{R})$ and $V \in C^2(\overline{D_a})$, both nontrivial, be such that $u = TV$ solves $u_{tt} = c^2 \Delta u$ in $D_a \times \mathbb{R}$. Then there is $\lambda \in \mathbb{R}$ with

$$T'' + \lambda c^2 T = 0 \text{ on } \mathbb{R}, \quad \Delta V + \lambda V = 0 \text{ in } D_a \quad (\text{Helmholtz's equation}).$$

If moreover u vanishes on $\partial D_a \times \mathbb{R}$ and $T \not\equiv 0$, then $V|_{\partial D_a} = 0$.

Proof. Substituting $u = TV$ gives $T''(t)V(p) = c^2 T(t)\Delta V(p)$ for every $p \in D_a$ and every $t \in \mathbb{R}$. **Step 1.** Since $V \not\equiv 0$ and V is continuous, there is $p_0 \in D_a$ with $V(p_0) \neq 0$ (if V vanished throughout D_a it would also vanish, by continuity, on $\overline{D_a}$). Set $\lambda := -\frac{\Delta V(p_0)}{V(p_0)} \in \mathbb{R}$; evaluating at $p = p_0$ and dividing by $V(p_0)$,

$$T''(t) = c^2 \frac{\Delta V(p_0)}{V(p_0)} T(t) = -\lambda c^2 T(t) \quad \text{for every } t.$$

Step 2. Substituting $T'' = -\lambda c^2 T$ into the starting identity: $-\lambda c^2 T(t)V(p) = c^2 T(t)\Delta V(p)$, i.e. $c^2 T(t)(\Delta V(p) + \lambda V(p)) = 0$. Choosing t_0 with $T(t_0) \neq 0$ (which exists because $T \not\equiv 0$) and dividing by $c^2 T(t_0) \neq 0$ gives $\Delta V + \lambda V = 0$ in D_a .

Step 3. If $u = TV$ vanishes on $\partial D_a \times \mathbb{R}$, evaluating at $t = t_0$ with $T(t_0) \neq 0$ gives $V(p) = 0$ for every $p \in \partial D_a$. $\square$

Proposition 18.9: *The eigenvalues of the Dirichlet problem are positive.* Let $V \in C^2(\overline{D_a})$ be nontrivial with $\Delta V + \lambda V = 0$ in D_a and $V|_{\partial D_a} = 0$. Then $\lambda > 0$.

Proof. **Step 1 — Green's identity.** By Leibniz's rule,

$$\operatorname{div}(V\nabla V) = \nabla V \cdot \nabla V + V \Delta V = |\nabla V|^2 + V \Delta V.$$

The disc D_a is a regular domain of the plane (its boundary is a C^∞ curve, Chapter 2) and $V\nabla V$ is a C^1 vector field on $\overline{D_a}$: by the divergence theorem,

$$\int_{D_a} (|\nabla V|^2 + V \Delta V) dA = \oint_{\partial D_a} V \frac{\partial V}{\partial \nu} ds = 0,$$

because $V = 0$ on ∂D_a and hence the boundary integrand is identically zero (ν is the outward normal).

Step 2 — using the equation. Substituting $\Delta V = -\lambda V$:

$$\int_{D_a} |\nabla V|^2 dA = \lambda \int_{D_a} V^2 dA. \quad (\dagger)$$

Step 3 — both integrals are positive. The right-hand side contains $\int_{D_a} V^2 > 0$: indeed V is continuous and nontrivial on $\overline{D_a}$ — and cannot vanish throughout D_a , since by continuity it would then vanish everywhere — so V^2 is continuous, nonnegative, and strictly positive on a nonempty open set. The left-hand side is ≥ 0 . Hence $\lambda \geq 0$.

Step 4 — ruling out $\lambda = 0$. If $\lambda = 0$, then $(\dagger)$ gives $\int_{D_a} |\nabla V|^2 = 0$; since the integrand is continuous and nonnegative, $\nabla V \equiv 0$ on D_a , so V is constant on the connected set D_a and, by continuity, on $\overline{D_a}$. Since $V = 0$ on the boundary, the constant is 0 and $V \equiv 0$: excluded by hypothesis. Hence $\lambda > 0$. $\square$

Lemma 18.7: *Angular separation and the birth of Bessel's equation.* Let $\lambda > 0$ and let $V(r, \theta) = R(r)\Theta(\theta)$, with $R \in C^2((0, a))$ and $\Theta \in C^2(\mathbb{R})$ 2π -periodic, both nontrivial, be a solution of $\Delta V + \lambda V = 0$ in $D_a \setminus \{0\}$. Then there is an integer $n \geq 0$ with

$$\Theta'' + n^2 \Theta = 0 \quad \text{and} \quad r^2 R'' + r R' + (\lambda r^2 - n^2) R = 0 \quad \text{on } (0, a).$$

Setting $s = \sqrt{\lambda} r$ and $\rho(s) := R(s/\sqrt{\lambda})$, the second equation becomes

$$s^2 \rho''(s) + s \rho'(s) + (s^2 - n^2) \rho(s) = 0, \quad 0 < s < \sqrt{\lambda} a.$$

Proof. **Step 1 — the equation in polar coordinates.** By Theorem 18.1, the equation $\Delta V + \lambda V = 0$ reads

$$R''\Theta + \frac{1}{r}R'\Theta + \frac{1}{r^2}R\Theta'' + \lambda R\Theta = 0;$$

multiplying by r^2 (legitimate, as $r > 0$),

$$(r^2 R'' + r R' + \lambda r^2 R)\Theta(\theta) + R(r)\Theta''(\theta) = 0 \quad \text{for every } (r, \theta) \in (0, a) \times \mathbb{R}. \quad (\ddagger)$$

Step 2 — separation. The argument of Lemma 18.2 is repeated verbatim. Choosing θ_0 with $\Theta(\theta_0) \neq 0$ and setting $\mu := -\Theta''(\theta_0)/\Theta(\theta_0)$, evaluating $(\ddagger)$ at θ_0 gives, for every $r \in (0, a)$,

$$r^2 R'' + r R' + (\lambda r^2 - \mu) R = 0.$$

Substituting this identity into (‡) gives $R(r)(\Theta''(\theta) + \mu\Theta(\theta)) = 0$ for every (r, θ) ; choosing r_0 with $R(r_0) \neq 0$ gives $\Theta'' + \mu\Theta = 0$ on $\mathbb{R}$.

Step 3 — quantisation. Θ is by hypothesis 2π -periodic, of class C^2 and nontrivial: by Lemma 18.3, $\mu = n^2$ with $n \geq 0$ an integer, and Θ is constant ($n = 0$) or a combination of $\cos n\theta$ and $\sin n\theta$.

Step 4 — rescaling. Let $s = \sqrt{\lambda}r$, i.e. $r = s/\sqrt{\lambda}$, and $\rho(s) = R(s/\sqrt{\lambda})$. By the chain rule $R'(r) = \sqrt{\lambda}\rho'(s)$ and $R''(r) = \lambda\rho''(s)$. Substituting,

$$r^2 R'' + rR' + (\lambda r^2 - n^2)R = \underbrace{r^2 \lambda}_{=s^2} \rho'' + \underbrace{r \sqrt{\lambda}}_{=s} \rho' + (\underbrace{\lambda r^2}_{=s^2} - n^2) \rho,$$

and the vanishing of the left-hand side is equivalent to $s^2 \rho'' + s\rho' + (s^2 - n^2)\rho = 0$. $\square$

Definition 18.6: Bessel's equation. Let $n \geq 0$. The second-order ordinary differential equation

$$x^2 y''(x) + x y'(x) + (x^2 - n^2)y(x) = 0, \quad x > 0,$$

is called **Bessel's equation of order n** . It is equation 10.2.1 of the NIST Digital Library of Mathematical Functions.

***Remark 18.7: Why elementary functions are not enough.** In Lemma 18.4 the radial equation $r^2 R'' + rR' - n^2 R = 0$ was invariant under the dilation $r \mapsto \alpha r$: every term has the same "weight" in r , and this is what allowed the substitution $r = e^s$ that turned it into an equation with constant coefficients. The term $\lambda r^2 R$ of Helmholtz's equation breaks this invariance: no elementary substitution reduces it to constant coefficients, and indeed it can be shown — though not here — that its solutions cannot be expressed by elementary functions. The point $x = 0$ is, in the standard terminology, a regular singular point: the equation, divided by x^2 , has coefficients $1/x$ and $1 - n^2/x^2$ that blow up at 0, but slowly enough to allow solutions of the form $x^n \cdot$ (power series). This is exactly the form we shall postulate — and verify — in Definition 18.7.*

18.7. The Bessel function of the first kind

We now define, by a series, the solution of Bessel's equation that stays bounded at the origin, and we prove all the properties we shall need for it: convergence, verification of the equation, behaviour at 0, recurrence formulas, singularity of the other solution, existence of infinitely many zeros, orthogonality.

Definition 18.7: Bessel function of the first kind of integer order. Let $n \geq 0$ be an integer. The **Bessel function of the first kind of order n** is

$$J_n(x) := \sum_{k=0}^{\infty} \frac{(-1)^k}{k!(n+k)!} \left(\frac{x}{2}\right)^{n+2k}, \quad x \in \mathbb{R}.$$

It is the case $\nu = n$ integer of formula 10.2.2 of the NIST Digital Library of Mathematical Functions, where $\Gamma(\nu + k + 1)$ takes the place of $(n + k)!$.

***Theorem 18.8: The Bessel series converges everywhere.** For every integer $n \geq 0$ the series of Definition 18.7 converges absolutely for every $x \in \mathbb{R}$ and uniformly on every bounded interval. The function J_n is of class C^∞ on $\mathbb{R}$ and its derivatives may be computed term by term.*

Proof. **Step 1 — absolute convergence.** Fix $x \neq 0$ and set $t_k = \frac{|x/2|^{n+2k}}{k!(n+k)!} > 0$. Then

$$\frac{t_{k+1}}{t_k} = \frac{(x/2)^2}{(k+1)(n+k+1)} \rightarrow 0 \quad (k \rightarrow \infty).$$

By the ratio test the series $\sum_k t_k$ converges; hence the series for $J_n(x)$ converges absolutely. For $x = 0$ all terms with $n + 2k > 0$ vanish and the series reduces to a single term (or to 0 if $n \geq 1$).

Step 2 — uniform convergence on bounded sets. Let $|x| \leq L$. Then $t_k \leq \frac{(L/2)^{n+2k}}{k!(n+k)!} =: M_k$, and $\sum_k M_k < \infty$ by Step 1 applied to $x = L$. By the Weierstrass test the convergence is uniform on $[-L, L]$.

Step 3 — regularity. The series is a power series in x : indeed $J_n(x) = x^n \sum_k b_k x^{2k}$ with $b_k = \frac{(-1)^k}{2^{n+2k} k!(n+k)!}$, and Step 1 shows that the radius of convergence of the power series $\sum_k b_k y^k$ (in $y = x^2$) is $+\infty$. A power series is of class C^∞ inside its disc of convergence and may be differentiated term by term as many times as one wishes; multiplying by the monomial x^n preserves the property. $\square$

Theorem 18.9: J_n solves Bessel's equation. For every integer $n \geq 0$ and every $x \in \mathbb{R}$,

$$x^2 J_n''(x) + x J_n'(x) + (x^2 - n^2) J_n(x) = 0.$$

Proof. Write $J_n(x) = \sum_{k \geq 0} a_k x^{n+2k}$ with

$$a_k = \frac{(-1)^k}{2^{n+2k} k!(n+k)!}.$$

By Theorem 18.8 one may differentiate term by term:

$$x^2 J_n'' = \sum_{k \geq 0} a_k (n+2k)(n+2k-1) x^{n+2k}, \quad x J_n' = \sum_{k \geq 0} a_k (n+2k) x^{n+2k}.$$

Step 1 — the first three terms. Adding the two expressions and subtracting $n^2 J_n$,

$$x^2 J_n'' + x J_n' - n^2 J_n = \sum_{k \geq 0} a_k [(n+2k)(n+2k-1) + (n+2k) - n^2] x^{n+2k} = \sum_{k \geq 0} a_k [(n+2k)^2 - n^2] x^{n+2k},$$

because $(n+2k)(n+2k-1) + (n+2k) = (n+2k)^2$. Now $(n+2k)^2 - n^2 = 4k^2 + 4nk = 4k(n+k)$, hence

$$x^2 J_n'' + x J_n' - n^2 J_n = \sum_{k \geq 1} 4k(n+k) a_k x^{n+2k},$$

where the sum starts at $k = 1$ because the factor $4k(n+k)$ vanishes at $k = 0$.

Step 2 — the fourth term. We have

$$x^2 J_n = \sum_{k \geq 0} a_k x^{n+2k+2} = \sum_{k \geq 1} a_{k-1} x^{n+2k}$$

(reindexing $k \mapsto k-1$).

Step 3 — the coefficients cancel. For $k \geq 1$,

$$4k(n+k) a_k = 4k(n+k) \cdot \frac{(-1)^k}{2^{n+2k} k!(n+k)!} = \frac{4(-1)^k}{2^{n+2k} (k-1)!(n+k-1)!} = \frac{(-1)^k}{2^{n+2k-2} (k-1)!(n+k-1)!},$$

having simplified k against $k!$ and $(n+k)$ against $(n+k)!$ and used $4 = 2^2$. On the other hand

$$a_{k-1} = \frac{(-1)^{k-1}}{2^{n+2k-2}(k-1)!(n+k-1)!},$$

which is the negative of the previous expression. Hence $4k(n+k)a_k + a_{k-1} = 0$ for every $k \geq 1$, and adding the results of Steps 1 and 2

$$x^2 J_n'' + x J_n' + (x^2 - n^2) J_n = \sum_{k \geq 1} [4k(n+k)a_k + a_{k-1}] x^{n+2k} = 0.$$

□

Proposition 18.10: Behaviour at the origin. Let $n \geq 0$ be an integer. Then

$$J_0(0) = 1, \quad J_n(0) = 0 \quad (n \geq 1), \quad \lim_{x \rightarrow 0^+} \frac{J_n(x)}{(x/2)^n} = \frac{1}{n!},$$

More precisely there exist $\delta_n > 0$ and constants $0 < c_1 \leq c_2$ such that

$$c_1 x^n \leq J_n(x) \leq c_2 x^n \quad \text{for } 0 < x \leq \delta_n;$$

in particular $J_n(x) > 0$ for $0 < x \leq \delta_n$.

Proof. Step 1 — the values at 0. In the series, the term $k = 0$ equals $\frac{1}{n!}(x/2)^n$ and every other term contains x with exponent $n+2k > n \geq 0$. At $x = 0$: if $n = 0$ the term $k = 0$ equals 1 and the others 0, so $J_0(0) = 1$; if $n \geq 1$ all terms vanish, so $J_n(0) = 0$.

Step 2 — the limit. Factoring out $(x/2)^n$,

$$\frac{J_n(x)}{(x/2)^n} = \sum_{k \geq 0} \frac{(-1)^k}{k!(n+k)!} \left(\frac{x}{2}\right)^{2k} = \frac{1}{n!} + \sum_{k \geq 1} \frac{(-1)^k}{k!(n+k)!} \left(\frac{x}{2}\right)^{2k},$$

and the series on the right is a power series in x with no constant term, hence continuous and zero at $x = 0$ (Theorem 18.8). The limit is $1/n!$.

Step 3 — the two-sided estimate. Let $g(x) := J_n(x)/(x/2)^n$ for $x > 0$ and $g(0) := 1/n!$: by Step 2, g is continuous on $[0, +\infty)$ and $g(0) = 1/n! > 0$. By persistence of sign there is $\delta_n > 0$ with $\frac{1}{2n!} \leq g(x) \leq \frac{2}{n!}$ for $0 \leq x \leq \delta_n$. Multiplying by $(x/2)^n = 2^{-n}x^n > 0$ gives

$$\underbrace{\frac{1}{2^{n+1}n!}}_{=:c_1} x^n \leq J_n(x) \leq \underbrace{\frac{2}{2^n n!}}_{=:c_2} x^n, \quad 0 < x \leq \delta_n,$$

and in particular $J_n(x) > 0$ on $(0, \delta_n]$. □

Proposition 18.11: Recurrence and derivative formulas. For every integer $n \geq 0$ and every $x > 0$:

- (i) $\frac{d}{dx}(x^{-n} J_n(x)) = -x^{-n} J_{n+1}(x)$;
- (ii) $\frac{d}{dx}(x^n J_n(x)) = x^n J_{n-1}(x)$ (for $n \geq 1$);
- (iii) $J_n'(x) = -J_{n+1}(x) + \frac{n}{x} J_n(x)$; in particular $J_0' = -J_1$;
- (iv) $J_{n-1}(x) + J_{n+1}(x) = \frac{2n}{x} J_n(x)$ (for $n \geq 1$).

Proof. All term-by-term differentiations are legitimate by Theorem 18.8.

(i) We have $x^{-n}J_n(x) = \sum_{k \geq 0} \frac{(-1)^k}{2^{n+2k}k!(n+k)!} x^{2k}$; differentiating, the term $k = 0$ is constant and disappears:

$$\frac{d}{dx}(x^{-n}J_n) = \sum_{k \geq 1} \frac{(-1)^k 2k}{2^{n+2k}k!(n+k)!} x^{2k-1} = \sum_{k \geq 1} \frac{(-1)^k}{2^{n+2k-1}(k-1)!(n+k)!} x^{2k-1}.$$

Setting $m = k - 1$,

$$= \sum_{m \geq 0} \frac{(-1)^{m+1}}{2^{n+2m+1}m!(n+m+1)!} x^{2m+1} = -x^{-n} \sum_{m \geq 0} \frac{(-1)^m}{m!(n+1+m)!} \left(\frac{x}{2}\right)^{(n+1)+2m} = -x^{-n}J_{n+1}(x),$$

where we used $\frac{x^{2m+1}}{2^{n+2m+1}} = x^{-n} \frac{x^{n+2m+1}}{2^{n+2m+1}} = x^{-n} \left(\frac{x}{2}\right)^{n+1+2m}$.

(ii) Similarly $x^n J_n(x) = \sum_{k \geq 0} \frac{(-1)^k}{2^{n+2k}k!(n+k)!} x^{2n+2k}$, and differentiating

$$\frac{d}{dx}(x^n J_n) = \sum_{k \geq 0} \frac{(-1)^k (2n+2k)}{2^{n+2k}k!(n+k)!} x^{2n+2k-1} = \sum_{k \geq 0} \frac{(-1)^k}{2^{n+2k-1}k!(n+k-1)!} x^{2n+2k-1},$$

having simplified $2(n+k)$ against $(n+k)!$. Factoring out x^n and writing $\frac{x^{n+2k-1}}{2^{n+2k-1}} = \left(\frac{x}{2}\right)^{(n-1)+2k}$

gives $x^n \sum_{k \geq 0} \frac{(-1)^k}{k!((n-1)+k)!} \left(\frac{x}{2}\right)^{(n-1)+2k} = x^n J_{n-1}(x)$.

(iii) Expanding the product rule in (i): $-nx^{-n-1}J_n + x^{-n}J'_n = -x^{-n}J_{n+1}$; multiplying by x^n gives $J'_n - \frac{n}{x}J_n = -J_{n+1}$. For $n = 0$ this is $J'_0 = -J_1$.

(iv) Expanding the product rule in (ii): $nx^{n-1}J_n + x^n J'_n = x^n J_{n-1}$, i.e. $J'_n + \frac{n}{x}J_n = J_{n-1}$. Subtracting from this relation (iii) rewritten as $J'_n - \frac{n}{x}J_n = -J_{n+1}$ gives $\frac{2n}{x}J_n = J_{n-1} + J_{n+1}$.

□

Remark 18.8: Comparison with the reference tables. Formulas (iii) and (iv) of Proposition 18.11 are, in that order, equations 10.6.2 and 10.6.1 of the NIST Digital Library of Mathematical Functions, stated there for a generic cylinder function C_ν (i.e. for any linear combination of J_ν and Y_ν) and for real ν ; the identity $J'_0 = -J_1$ is their equation 10.6.3. Here they are proved only for J_n with n an integer, which is all that is needed for the disc, and the proof is self-contained: it is read directly off the series.

Proposition 18.12: The second solution is unbounded at the origin. Let $n \geq 0$ be an integer and let $\delta_n > 0$ be as in Proposition 18.10. Let y be a C^2 solution of Bessel's equation of order n on $(0, \delta_n]$, linearly independent of J_n . Then

$$\lim_{x \rightarrow 0^+} |y(x)| = +\infty.$$

In particular the only solution (up to multiplicative constants) that is bounded on a right-hand neighbourhood of 0 is J_n .

Proof. On $(0, +\infty)$ the equation may be divided by $x^2 \neq 0$ and takes the normal form

$$y'' + \frac{1}{x}y' + \left(1 - \frac{n^2}{x^2}\right)y = 0, \tag{N}$$

with continuous coefficients.

Step 1 — the Wronskian. Let $W := J_n y' - J'_n y$. Differentiating and using (N) for both functions,

$$W' = J_n y'' - J'_n y' = J_n \left(-\frac{1}{x} y' - \left(1 - \frac{n^2}{x^2}\right) y \right) - y' \left(-\frac{1}{x} J'_n - \left(1 - \frac{n^2}{x^2}\right) J_n \right) = -\frac{1}{x} (J_n y' - J'_n y) = -\frac{W}{x}.$$

Hence $(xW)' = W + xW' = W - W = 0$, i.e. $xW(x) = C$ is constant on $(0, \delta_n]$. If $C = 0$ then $W \equiv 0$, and for two solutions of a second-order linear equation an identically vanishing Wronskian is equivalent to linear dependence: excluded by hypothesis. Hence $C \neq 0$ and $W(x) = C/x$.

Step 2 — the quotient. By Proposition 18.10, $J_n > 0$ on $(0, \delta_n]$, so the quotient y/J_n is defined and differentiable there, with

$$\left(\frac{y}{J_n} \right)' = \frac{y' J_n - y J'_n}{J_n^2} = \frac{W}{J_n^2} = \frac{C}{x J_n(x)^2}.$$

Setting $x_0 := \delta_n$, $D := y(x_0)/J_n(x_0)$ and $I(x) := \int_x^{x_0} \frac{ds}{s J_n(s)^2}$, integrating from x to x_0 gives

$$y(x) = J_n(x) \left(D - C I(x) \right), \quad 0 < x \leq x_0.$$

Step 3 — $I(x)$ diverges. By Proposition 18.10, $J_n(s) \leq c_2 s^n$ on $(0, x_0]$, hence $\frac{1}{s J_n(s)^2} \geq \frac{1}{c_2^2 s^{2n+1}}$ and

$$I(x) \geq \frac{1}{c_2^2} \int_x^{x_0} \frac{ds}{s^{2n+1}} = \begin{cases} \frac{1}{c_2^2} \ln \frac{x_0}{x}, & n = 0, \\ \frac{1}{2n c_2^2} (x^{-2n} - x_0^{-2n}), & n \geq 1, \end{cases}$$

and in both cases $I(x) \rightarrow +\infty$ as $x \rightarrow 0^+$.

Step 4 — y is unbounded. From $y = J_n(D - CI)$ it follows, for x small enough that $|C|I(x) > |D|$,

$$|y(x)| \geq J_n(x) (|C|I(x) - |D|) \geq |C|J_n(x)I(x) - |D|J_n(x).$$

The second term is bounded: $J_n(x) \leq c_2 x^n \leq c_2 x_0^n$. The first diverges: using $J_n(x) \geq c_1 x^n$ and the estimates of Step 3,

$$J_n(x)I(x) \geq \begin{cases} \frac{c_1}{c_2^2} \ln \frac{x_0}{x} \rightarrow +\infty, & n = 0, \\ \frac{c_1}{2n c_2^2} (x^{-2n} - x_0^{-2n}) \rightarrow +\infty, & n \geq 1. \end{cases}$$

Hence $|y(x)| \rightarrow +\infty$.

Conclusion. The solution space of (N) on $(0, \delta_n]$ has dimension 2; if z is bounded on a right-hand neighbourhood of 0, then z cannot be independent of J_n (otherwise it would be unbounded), so $z = \alpha J_n$ for some $\alpha \in \mathbb{R}$. $\square$

***Remark 18.9:** Why the drum does not "blow up" at the centre. Proposition 18.12 is, for the membrane, what Theorem 18.2 was for the Dirichlet problem: the filter that discards half of the solutions. In the Laplace case the discarded solution was explicit (r^{-n} , or $\ln r$); here it is not, and it is known under the name of Bessel function of the second kind Y_n ,*

whose behaviour at the origin is $Y_0(x) \sim \frac{2}{\pi} \ln x$ and $Y_\nu(x) \sim -\frac{1}{\pi} \Gamma(\nu) \left(\frac{x}{2}\right)^{-\nu}$ for $\nu > 0$ (NIST DLMF, equations 10.7.1 and 10.7.4). We shall not need it: Proposition 18.12 proves what is needed — that any solution independent of J_n is unbounded — without constructing Y_n .

Lemma 18.8: Liouville form of Bessel's equation. Let $R \in C^2((0, +\infty))$ and set $w(x) := \sqrt{x} R(x)$. Then R solves Bessel's equation of order n if and only if w solves

$$w''(x) + q_n(x) w(x) = 0, \quad q_n(x) := 1 - \frac{n^2 - \frac{1}{4}}{x^2}, \quad x > 0.$$

Proof. Since $x > 0$, the correspondence $R \leftrightarrow w = \sqrt{x} R$ is a bijection between C^2 functions on $(0, +\infty)$, with inverse $R = x^{-1/2} w$. Differentiating:

$$R = x^{-1/2} w, \quad R' = -\frac{1}{2} x^{-3/2} w + x^{-1/2} w', \quad R'' = \frac{3}{4} x^{-5/2} w - x^{-3/2} w' + x^{-1/2} w''.$$

(The second derivative is obtained by differentiating again: $\frac{d}{dx}(-\frac{1}{2} x^{-3/2} w) = \frac{3}{4} x^{-5/2} w - \frac{1}{2} x^{-3/2} w'$ and $\frac{d}{dx}(x^{-1/2} w') = -\frac{1}{2} x^{-3/2} w' + x^{-1/2} w''$; adding gives the result.) Substituting into Bessel's equation:

$$x^2 R'' + x R' + (x^2 - n^2) R = \frac{3}{4} x^{-1/2} w - x^{1/2} w' + x^{3/2} w'' - \frac{1}{2} x^{-1/2} w + x^{1/2} w' + (x^2 - n^2) x^{-1/2} w.$$

The two terms in w' cancel; collecting terms,

$$= x^{3/2} w'' + \left(\frac{3}{4} - \frac{1}{2}\right) x^{-1/2} w + x^{3/2} w - n^2 x^{-1/2} w = x^{3/2} \left[w'' + w + \left(\frac{1}{4} - n^2\right) x^{-2} w \right] = x^{3/2} [w'' + q_n w].$$

Since $x^{3/2} \neq 0$, the vanishing of the left-hand side is equivalent to $w'' + q_n w = 0$. $\square$

Lemma 18.9: Sturm comparison.

- (i) Let $m > 0$, $a < b$ with $b - a \geq \pi/m$, and let q be continuous on $[a, b]$ with $q(x) \geq m^2$ for every $x \in [a, b]$. Then every nontrivial solution $w \in C^2([a, b])$ of $w'' + qw = 0$ has at least one zero in the interval $[a, a + \pi/m]$.
- (ii) Let $M > 0$, $\alpha < \beta$, and let q be continuous on $[\alpha, \beta]$ with $q(x) \leq M^2$. If $w \in C^2([\alpha, \beta])$ solves $w'' + qw = 0$, vanishes at α and β , and does not vanish on (α, β) , then $\beta - \alpha \geq \pi/M$.

Proof. Part (i). Suppose towards a contradiction that w has no zeros in $[a, a + \pi/m]$. Since w is continuous, it has constant sign there; replacing w with $-w$ if necessary (which solves the same equation), we may assume $w > 0$ on $[a, a + \pi/m]$.

Step 1 — the comparison function. Let

$$v(x) := \sin(m(x - a)),$$

which solves $v'' + m^2 v = 0$, vanishes at $x = a$ and at $x = a + \pi/m$, and is ≥ 0 on $[a, a + \pi/m]$. Moreover $v'(a) = m > 0$ and $v'(a + \pi/m) = m \cos \pi = -m < 0$.

Step 2 — the Wronskian increases. Let $W := wv' - w'v$. Then

$$W' = wv'' - w''v = w(-m^2 v) - (-qw)v = (q - m^2) w v \geq 0 \quad \text{on } [a, a + \pi/m],$$

because $q \geq m^2$, $w > 0$ and $v \geq 0$. Hence W is nondecreasing on $[a, a + \pi/m]$.

Step 3 — contradiction. At the endpoints, using $v(a) = v(a + \pi/m) = 0$:

$$W(a) = w(a) v'(a) = m w(a) > 0, \quad W\left(a + \frac{\pi}{m}\right) = w\left(a + \frac{\pi}{m}\right) v'\left(a + \frac{\pi}{m}\right) = -m w\left(a + \frac{\pi}{m}\right) < 0.$$

But W is nondecreasing, so $W(a + \pi/m) \geq W(a) > 0$: a contradiction. Hence w has a zero in $[a, a + \pi/m]$.

Part (ii). Suppose towards a contradiction that $\beta - \alpha < \pi/M$. Since w does not vanish on (α, β) , it has constant sign there; replacing w with $-w$ if necessary, assume $w > 0$ on (α, β) . Let

$$v(x) := \sin(M(x - \alpha)),$$

which solves $v'' + M^2v = 0$, vanishes at α and is strictly positive on $(\alpha, \alpha + \pi/M) \supseteq (\alpha, \beta]$, because $\beta < \alpha + \pi/M$. Setting $W := wv' - w'v$, one has

$$W' = wv'' - w''v = w(-M^2v) - (-qw)v = (q - M^2)wv \leq 0 \quad \text{on } [\alpha, \beta],$$

because $q \leq M^2$, $w \geq 0$ and $v \geq 0$ there: hence W is nonincreasing. Now $W(\alpha) = w(\alpha)v'(\alpha) - w'(\alpha)v(\alpha) = 0$, because $w(\alpha) = 0$ and $v(\alpha) = 0$. On the other hand $w(\beta) = 0$ gives $W(\beta) = -w'(\beta)v(\beta)$, with $v(\beta) > 0$ and $w'(\beta) < 0$ — indeed $w > 0$ immediately to the left of β and $w(\beta) = 0$ force $w'(\beta) \leq 0$, and $w'(\beta) = 0$ would give $w \equiv 0$ by uniqueness for the Cauchy problem. Hence $W(\beta) > 0 = W(\alpha)$, contradicting monotonicity: a contradiction. $\square$

Theorem 18.10: The zeros of J_n : existence, infinitude, simplicity. Let $n \geq 0$ be an integer. Then:

- (i) setting $x_n := \max\{\delta_n, \sqrt{2 \max\{n^2 - \frac{1}{4}, 0\}}\}$, every interval $[\alpha, \alpha + \pi\sqrt{2}]$ with $\alpha \geq x_n$ contains at least one zero of J_n ;
- (ii) J_n has infinitely many zeros in $(0, +\infty)$, forming a strictly increasing sequence $0 < j_{n,1} < j_{n,2} < \dots \rightarrow +\infty$ with no accumulation points in $(0, +\infty)$;
- (iii) every positive zero is simple: if $J_n(\rho) = 0$ with $\rho > 0$, then $J'_n(\rho) \neq 0$; moreover $J'_n(\rho) = -J_{n+1}(\rho)$;
- (iv) for $n \geq 1$, two consecutive positive zeros are at distance at least π : $j_{n,k+1} - j_{n,k} \geq \pi$ for every $k \geq 1$.

Proof. Step 1 — (i). Let $w(x) = \sqrt{x} J_n(x)$: by Lemma 18.8 and Theorem 18.9, w solves $w'' + q_n w = 0$ with $q_n(x) = 1 - (n^2 - \frac{1}{4})x^{-2}$. For $x \geq x_n$:

- if $n = 0$, then $n^2 - \frac{1}{4} = -\frac{1}{4} < 0$ and $q_0(x) = 1 + \frac{1}{4x^2} \geq 1 > \frac{1}{2}$;
- if $n \geq 1$, then $n^2 - \frac{1}{4} > 0$ and $x^2 \geq 2(n^2 - \frac{1}{4})$ gives $\frac{n^2 - \frac{1}{4}}{x^2} \leq \frac{1}{2}$, hence $q_n(x) \geq \frac{1}{2}$.

In both cases $q_n \geq m^2$ with $m = 1/\sqrt{2}$, and $\pi/m = \pi\sqrt{2}$. Moreover $w \not\equiv 0$ because $J_n > 0$ on $(0, \delta_n]$ (Proposition 18.10). Lemma 18.9(i), applied on $[\alpha, \alpha + \pi\sqrt{2}]$, gives a zero of w , hence of J_n (since $\sqrt{x} \neq 0$).

Step 2 — (iii). Let $\rho > 0$ with $J_n(\rho) = 0$ and suppose towards a contradiction that $J'_n(\rho) = 0$. On the open set $(0, +\infty)$, Bessel's equation, divided by $x^2 \neq 0$, is a second-order linear equation with continuous coefficients; by the existence-and-uniqueness theorem for the Cauchy problem, the only solution with data $y(\rho) = y'(\rho) = 0$ is the one identically zero. Hence $J_n \equiv 0$ on $(0, +\infty)$, contradicting $J_n > 0$ on $(0, \delta_n]$. The formula $J'_n(\rho) = -J_{n+1}(\rho)$ follows from Proposition 18.11(iii) with $J_n(\rho) = 0$.

Step 3 — (ii). The positive zeros have no accumulation points in $(0, +\infty)$: if distinct zeros $\rho_k \rightarrow \rho > 0$, then by continuity $J_n(\rho) = 0$ and, by Rolle's theorem applied between ρ_k and ρ_{k+1} , there are points σ_k between them with $J'_n(\sigma_k) = 0$ and $\sigma_k \rightarrow \rho$; by continuity $J'_n(\rho) = 0$, contradicting Step 2. Moreover there are no zeros in $(0, \delta_n]$. It follows that the set of positive zeros is discrete and closed in $(0, +\infty)$, with a positive minimum in every bounded subset: it may therefore be enumerated in increasing order, $j_{n,1} < j_{n,2} < \dots$. By Step 1 there is at least one in $[x_n + k\pi\sqrt{2}, x_n + (k+1)\pi\sqrt{2}]$ for every $k \geq 0$: they are therefore infinitely many and the sequence tends to $+\infty$.

Step 4 — (iv). Let $n \geq 1$, so that $n^2 - \frac{1}{4} > 0$ and $q_n(x) = 1 - (n^2 - \frac{1}{4})x^{-2} \leq 1 = M^2$ for every $x > 0$. Let $j_{n,k} < j_{n,k+1}$ be two consecutive zeros: the function $w = \sqrt{x} J_n$ vanishes at both and does not vanish between them. By Lemma 18.9(ii) applied on $[j_{n,k}, j_{n,k+1}]$ with $M = 1$ one gets $j_{n,k+1} - j_{n,k} \geq \pi$. $\square$

Remark 18.10: The two spacing estimates, and why $n = 0$ is an exception. Combining (i) and (iv) of Theorem 18.10, for $n \geq 1$ and large enough zeros the distance between two consecutive zeros lies between π and $\pi\sqrt{2} = 4.4428829$. For $n = 0$ only the upper estimate holds: indeed $q_0(x) = 1 + \frac{1}{4x^2} > 1$, and part (ii) of Lemma 18.9 does not apply with $M = 1$. And indeed the lower estimate π is false for $n = 0$: $j_{0,2} - j_{0,1} = 3.1152526 < \pi = 3.1415927$ (Observation 18.13). The sign of $n^2 - \frac{1}{4}$ decides which way the inequality goes; it is the same quantity that appears in the Liouville form of Lemma 18.8.

Proposition 18.13: A rigorous enclosure of the first zero of J_0 . The first positive zero of J_0 satisfies

$$2.40 < j_{0,1} < 2.41.$$

Proof. Step 1 — the series is alternating with decreasing terms. For $0 < x \leq 2.41$ set $t_k := \frac{(x/2)^{2k}}{(k!)^2} > 0$, so that $J_0(x) = \sum_{k \geq 0} (-1)^k t_k$. The ratio $\frac{t_{k+1}}{t_k} = \frac{(x/2)^2}{(k+1)^2}$ is $\leq \frac{(1.205)^2}{4} < 1$ for every $k \geq 1$: hence, from $k = 1$ on, the terms strictly decrease and tend to 0. By Leibniz's criterion, truncating the series after the term of index 7 the error is bounded in absolute value by the first omitted term, t_8 :

$$\left| J_0(x) - \sum_{k=0}^7 (-1)^k t_k \right| \leq t_8.$$

Step 2 — the sign at $x = 2.40 = \frac{12}{5}$. Computing the partial sum in exact rational arithmetic (Python script with the `Fraction` class, executed) one gets

$$\sum_{k=0}^7 (-1)^k t_k = 0.002507672\dots, \quad t_8 = 1.137 \cdot 10^{-8},$$

whence

$$J_0(2.40) \in [0.0025076607, 0.0025076835],$$

in particular $J_0(2.40) > 0$.

Step 3 — the sign at $x = 2.41 = \frac{241}{100}$. In the same way

$$\sum_{k=0}^7 (-1)^k t_k = -0.002683412\dots, \quad t_8 = 1.215 \cdot 10^{-8}, \quad J_0(2.41) \in [-0.0026834250, -0.0026834007],$$

in particular $J_0(2.41) < 0$.

Step 4 — the intermediate value theorem. J_0 is continuous (Theorem 18.8) and changes sign between 2.40 and 2.41: hence there is $\rho \in (2.40; 2.41)$ with $J_0(\rho) = 0$.

Step 5 — it is the first zero. We show that $J_0 > 0$ on $(0; 2.41]$, so that $\rho = j_{0,1}$. By Proposition 18.11(iii), $J'_0 = -J_1$; it therefore suffices to prove that $J_1 > 0$ on $(0; 2.41]$, because then J_0 is strictly decreasing there and, starting from $J_0(0) = 1$, cannot vanish before ρ . Now

$$J_1(x) = \frac{x}{2} \sum_{k \geq 0} \frac{(-1)^k}{k!(k+1)!} \left(\frac{x}{2}\right)^{2k},$$

an alternating series whose terms $s_k = \frac{(x/2)^{2k}}{k!(k+1)!}$ have ratio $\frac{s_{k+1}}{s_k} = \frac{(x/2)^2}{(k+1)(k+2)} \leq \frac{(1.205)^2}{2} = 0.7260125 < 1$ for every $k \geq 0$ and $0 < x \leq 2.41$: the sequence is thus strictly decreasing from $k = 0$ on, and by Leibniz's criterion the sum lies between the first and second partial sums, in particular

$$J_1(x) \geq \frac{x}{2}(s_0 - s_1) = \frac{x}{2} \left(1 - \frac{(x/2)^2}{2} \right) \geq \frac{x}{2}(1 - 0.7260125) = 0.2739875 \cdot \frac{x}{2} > 0.$$

Hence J_0 is strictly decreasing on $(0; 2.41]$ and ρ is its first zero. $\square$

Theorem 18.11: Orthogonality and norm of the radial eigenfunctions. Let $n \geq 0$ be an integer and let $j_{n,k}$ be the positive zeros of J_n . Then, for $k \neq l$,

$$\int_0^1 J_n(j_{n,k} r) J_n(j_{n,l} r) r dr = 0,$$

and for every $k \geq 1$

$$\int_0^1 J_n(j_{n,k} r)^2 r dr = \frac{1}{2} J_n'(j_{n,k})^2 = \frac{1}{2} J_{n+1}(j_{n,k})^2.$$

Proof. For $\alpha > 0$ set $y_\alpha(r) := J_n(\alpha r)$. From Theorem 18.9 with $x = \alpha r$ it follows (see Step 4 of the proof of Lemma 18.7, read backwards)

$$r^2 y_\alpha'' + r y_\alpha' + (\alpha^2 r^2 - n^2) y_\alpha = 0,$$

which, divided by $r > 0$, may be written in self-adjoint form as

$$(r y_\alpha')' + \left(\alpha^2 r - \frac{n^2}{r} \right) y_\alpha = 0, \quad r > 0. \quad (\text{SL})$$

Step 1 — orthogonality. Let $\alpha = j_{n,k}$, $\beta = j_{n,l}$ with $k \neq l$, so $\alpha \neq \beta$ and $\alpha^2 \neq \beta^2$. Multiply (SL) by y_β , the analogous equation for y_β by y_α , and subtract:

$$y_\beta (r y_\alpha')' - y_\alpha (r y_\beta')' + (\alpha^2 - \beta^2) r y_\alpha y_\beta = 0.$$

The first group is the derivative of $r(y_\alpha' y_\beta - y_\alpha y_\beta')$: indeed

$$\frac{d}{dr} [r(y_\alpha' y_\beta - y_\alpha y_\beta')] = (r y_\alpha')' y_\beta + r y_\alpha' y_\beta' - r y_\alpha' y_\beta' - (r y_\beta')' y_\alpha.$$

Integrating on $[\varepsilon, 1]$ with $0 < \varepsilon < 1$,

$$\left[r(y_\alpha' y_\beta - y_\alpha y_\beta') \right]_\varepsilon^1 + (\alpha^2 - \beta^2) \int_\varepsilon^1 r y_\alpha y_\beta dr = 0.$$

At $r = 1$ one has $y_\alpha(1) = J_n(\alpha) = 0$ and $y_\beta(1) = J_n(\beta) = 0$, so the boundary term vanishes. At $r = \varepsilon$ the term is $\varepsilon(y_\alpha' y_\beta - y_\alpha y_\beta')(\varepsilon)$, which tends to 0 as $\varepsilon \rightarrow 0^+$ because $y_\alpha, y_\beta, y_\alpha', y_\beta'$ are continuous on $[0, 1]$ (Theorem 18.8) and hence bounded, while the factor ε tends to 0. Passing to the limit, $(\alpha^2 - \beta^2) \int_0^1 r y_\alpha y_\beta dr = 0$, and since $\alpha^2 \neq \beta^2$ the integral is zero.

Step 2 — the norm. Let $\alpha = j_{n,k}$ and $y = y_\alpha$. Multiply (SL) by $2ry'$:

$$2 (ry') (ry')' + 2(\alpha^2 r^2 - n^2) y y' = 0,$$

having written $2ry' \cdot (\alpha^2 r - \frac{n^2}{r})y = 2(\alpha^2 r^2 - n^2)yy'$. Now $2(ry')(ry')' = \frac{d}{dr}[(ry')^2]$ and $2yy' = \frac{d}{dr}[y^2]$, hence

$$\frac{d}{dr}[(ry')^2] + (\alpha^2 r^2 - n^2) \frac{d}{dr}[y^2] = 0.$$

Integrate on $[\varepsilon, 1]$ and integrate the second term by parts:

$$[(ry')^2]_{\varepsilon}^1 + [(\alpha^2 r^2 - n^2)y^2]_{\varepsilon}^1 - \int_{\varepsilon}^1 2\alpha^2 r y^2 dr = 0.$$

Let $\varepsilon \rightarrow 0^+$. The contributions at $r = \varepsilon$ vanish: $(\varepsilon y'(\varepsilon))^2 \rightarrow 0$ because y' is bounded near 0, and $(\alpha^2 \varepsilon^2 - n^2)y(\varepsilon)^2 \rightarrow -n^2 y(0)^2 = 0$, since $y(0) = J_n(0)$ equals 0 for $n \geq 1$ and the factor n^2 is zero for $n = 0$. At $r = 1$ one has $y(1) = J_n(\alpha) = 0$, so the second boundary term is zero, while the first equals $y'(1)^2 = (\alpha J'_n(\alpha))^2$. What remains is

$$\alpha^2 J'_n(\alpha)^2 = 2\alpha^2 \int_0^1 r y^2 dr, \quad \text{i.e.} \quad \int_0^1 J_n(\alpha r)^2 r dr = \frac{1}{2} J'_n(\alpha)^2.$$

Finally $J'_n(\alpha) = -J_{n+1}(\alpha)$ by Theorem 18.10(iii), whence $J'_n(\alpha)^2 = J_{n+1}(\alpha)^2$. $\square$

Remark 18.11: Comparison with the DLMF formulation and numerical check.

Theorem 18.11 is, for $\nu = n$ an integer, equation 10.22.37 of the NIST Digital Library of Mathematical Functions, which states it for $\nu > -1$ in the form $\int_0^1 t J_{\nu}(j_{\nu,\ell} t) J_{\nu}(j_{\nu,m} t) dt = \frac{1}{2} (J'_{\nu}(j_{\nu,\ell}))^2 \delta_{\ell,m}$; the proof given here is self-contained.

Numerical check (Python script executed). With Simpson's rule on 20 000 subintervals of $[0, 1]$:

	$n = 0$	$n = 1$
$\int_0^1 J_n(j_{n,1} r) J_n(j_{n,2} r) r dr$	$2.0 \cdot 10^{-16}$	$-1.4 \cdot 10^{-16}$
$\int_0^1 J_n(j_{n,1} r)^2 r dr$	0.1347570620	0.0811075654
$\frac{1}{2} J_{n+1}(j_{n,1})^2$	0.1347570620	0.0811075654

The cross integrals are zero to machine precision and the norms agree with the theoretical value to ten decimal places. ✓

18.8. Vibration modes, Bessel zeros, and frequencies

All the pieces are ready: separation has reduced the problem to Bessel's equation, regularity at the origin has selected J_n , and the boundary condition $u = 0$ on ∂D_a will now select the admissible values of λ . The result is the list of the drum's normal modes, and with it the list of its frequencies.

Theorem 18.12: The normal modes of the circular membrane. Let $a > 0$, $c > 0$, $n \geq 0$ an integer, $k \geq 1$, and set

$$\alpha_{n,k} := \frac{j_{n,k}}{a}, \quad \lambda_{n,k} := \alpha_{n,k}^2.$$

Then:

- (i) the function $V(r, \theta) = J_n(\alpha_{n,k} r) \cos n\theta$ (and likewise with $\sin n\theta$) extends to a function of class C^∞ on all of $\mathbb{R}^2$;
- (ii) $\Delta V + \lambda_{n,k} V = 0$ on $\mathbb{R}^2$;
- (iii) $V = 0$ on ∂D_a ; and conversely, if $\alpha > 0$ is such that $J_n(\alpha a) \neq 0$, the corresponding V does not vanish identically on ∂D_a : the only admissible values of α are therefore $\alpha_{n,k}$,

Figure 18.3: The functions J_0 (solid) and J_1 (dashed) on $[0, 12]$, sampled with step 0.25 from the series of Definition 18.7 and checked point by point against an independent multiple-precision implementation (the digits agree to eight decimal places throughout). The filled disks on the axis are the first four zeros of J_0 (2.404826; 5.520078; 8.653728; 11.791534), the open circles the first three of J_1 (3.831706; 7.015587; 10.173468). The existence of infinitely many zeros, all simple, is Theorem 18.10; the interlacing $j_{0,1} < j_{1,1} < j_{0,2} < \dots$ and the spacing approaching π are visible in the picture but are not proved here: see Observation 18.13.

$$k \geq 1;$$

(iv) for every $A, B, C, D \in \mathbb{R}$ the function

$$u(r, \theta, t) = J_n(\alpha_{n,k} r) (A \cos n\theta + B \sin n\theta) (C \cos(c \alpha_{n,k} t) + D \sin(c \alpha_{n,k} t))$$

solves the membrane problem of Definition 18.5, and is periodic in t with period $2\pi/(c\alpha_{n,k})$.

Proof. Write $\alpha = \alpha_{n,k}$ for brevity.

Step 1 — (i): the structure of the series. Factoring out $(x/2)^n$ in Definition 18.7,

$$J_n(x) = \left(\frac{x}{2}\right)^n G_n(x^2), \quad G_n(\omega) := \sum_{k \geq 0} \frac{(-1)^k}{4^k k! (n+k)!} \omega^k,$$

and the series defining G_n has infinite radius of convergence (same ratio test as in Step 1 of the proof of Theorem 18.8): G_n is therefore a C^∞ function on all of $\mathbb{R}$. It follows, with $x = \alpha r$ and $r^2 = x_1^2 + x_2^2$ (writing (x_1, x_2) for the point of the plane),

$$J_n(\alpha r) \cos n\theta = \left(\frac{\alpha}{2}\right)^n \underbrace{r^n \cos n\theta}_{=\operatorname{Re}(z^n)} G_n(\alpha^2(x_1^2 + x_2^2)),$$

where $z = x_1 + ix_2$. Now $\operatorname{Re}(z^n)$ is a homogeneous polynomial of degree n in (x_1, x_2) , and $G_n(\alpha^2(x_1^2 + x_2^2))$ is the composition of a C^∞ function with a polynomial: the product is C^∞ on $\mathbb{R}^2$ and agrees with $J_n(\alpha r) \cos n\theta$ for $r > 0$. The same holds with $\operatorname{Im}(z^n) = r^n \sin n\theta$.

Step 2 — (ii) away from the origin. For $r > 0$, with $R(r) = J_n(\alpha r)$ and $\Theta(\theta) = \cos n\theta$, Theorem 18.1 gives

$$\Delta V = \left(R'' + \frac{1}{r}R' - \frac{n^2}{r^2}R\right)\Theta = \frac{1}{r^2}(r^2R'' + rR' - n^2R)\Theta.$$

Now $R'(r) = \alpha J'_n(\alpha r)$ and $R''(r) = \alpha^2 J''_n(\alpha r)$, so, setting $x = \alpha r$,

$$r^2 R'' + r R' - n^2 R = x^2 J''_n(x) + x J'_n(x) - n^2 J_n(x) \stackrel{\text{Thm. 18.9}}{=} -x^2 J_n(x) = -\alpha^2 r^2 J_n(\alpha r).$$

Hence $\Delta V = -\alpha^2 R\Theta = -\alpha^2 V$ for every $r > 0$.

Step 3 — (ii) at the origin. By Step 1 the function V is C^∞ on $\mathbb{R}^2$, so ΔV and $-\alpha^2 V$ are both continuous on $\mathbb{R}^2$; by Step 2 they agree on $\mathbb{R}^2 \setminus \{(0, 0)\}$, which is dense in $\mathbb{R}^2$. Two continuous functions that agree on a dense set agree everywhere: hence $\Delta V + \alpha^2 V = 0$ at the origin as well.

Step 4 — (iii). On ∂D_a one has $r = a$, hence $V = J_n(\alpha a) \cos n\theta = J_n(j_{n,k}) \cos n\theta = 0$, because $j_{n,k}$ is a zero of J_n . Conversely, if $J_n(\alpha a) \neq 0$ then $V(a, \theta) = J_n(\alpha a) \cos n\theta$ is not identically zero (it vanishes only at the $2n$ points where $\cos n\theta = 0$); hence the admissible values of $\alpha > 0$ are exactly those with $\alpha a \in \{j_{n,1}, j_{n,2}, \dots\}$, the set of positive zeros of J_n , which Theorem 18.10 describes.

Step 5 — (iv). Let $T(t) = C \cos(cat) + D \sin(cat)$; then $T'' = -c^2 \alpha^2 T$. With $u = T \cdot V$ (where V is the combination with A, B , still C^∞ and a solution of $\Delta V = -\alpha^2 V$ by linearity),

$$u_{tt} = T''V = -c^2 \alpha^2 TV = c^2 T(\Delta V) = c^2 \Delta u.$$

The boundary condition holds by Step 4, and $u \in C^\infty(\mathbb{R}^2 \times \mathbb{R})$ by Step 1. Finally T has period $2\pi/(c\alpha)$, hence so does u . $\square$

Definition 18.8: Eigenvalues, eigenfunctions, and frequencies of the drum. With the notation of Theorem 18.12, the number $\lambda_{n,k} = (j_{n,k}/a)^2$ is called the **eigenvalue** of the Laplacian on the disc D_a with Dirichlet condition, and V the corresponding **eigenfunction**. The **angular frequency** and the **frequency** of the mode (n, k) are

$$\omega_{n,k} = c \frac{j_{n,k}}{a}, \quad f_{n,k} = \frac{\omega_{n,k}}{2\pi} = \frac{c j_{n,k}}{2\pi a} \quad [\text{Hz}].$$

The **nodal lines** of the mode are the set of points of $\overline{D_a}$ where the eigenfunction vanishes: the $k - 1$ circles $r = a j_{n,l}/j_{n,k}$ with $1 \leq l \leq k - 1$ and, for $n \geq 1$, the n diameters on which the angular factor vanishes.

Remark 18.12: Where the numbers come from: what the DLMF really contains.

Here it must be stated precisely what is imported and what is computed.

What the DLMF contains. The NIST Digital Library of Mathematical Functions, Chapter 10, §10.21, fixes the notation $j_{\nu,m}$ for the m -th positive zero of J_ν , proves its distribution and interlacing properties (§10.21(i)), and gives McMahon's asymptotic expansion for large zeros (equation 10.21.19). §10.21 does not contain a numerical table of the zeros: the tables are catalogued in §10.75, subsection "Real Zeros", which lists — among others — the British Association for the Advancement of Science (1937), $j_{0,m}$ and $j_{1,m}$ for $m = 1, \dots, 150$ with 10 decimal digits; Olver (1960), $j_{n,m}$ for $n = 0(\frac{1}{2})20$, $m = 1, \dots, 50$, with 8 digits; Abramowitz and Stegun (1964), $j_{n,m}$ for $n = 0(1)8$, $m = 1(1)20$, with 5 digits (10 for $n = 0$); Heller (1976), $j_{0,m}$ and $j_{1,m}$ for $m = 1(1)100$ with 25 digits; Wills et al. (1982), $j_{0,m}$ and $j_{1,m}$ for $m = 1(1)30$ with 35 digits. All of these details were verified online on 6 September 2026 (see the Sources environment).

What we do here. We do not report figures read from a table we have not seen: the values of Example 18.5 are recomputed by two independent methods and compared with the DLMF's asymptotic expansion. The only imported element is that expansion (Observation 18.13), which we use only as a third check and never as a definition.

Remark 18.13: McMahon's expansion: what we import. Imported, not proved. The NIST DLMF, equation 10.21.19, states that for fixed $\nu \geq 0$ and $m \rightarrow \infty$

$$j_{\nu,m} \sim a - \frac{\mu - 1}{8a} - \frac{4(\mu - 1)(7\mu - 31)}{3(8a)^3} - \frac{32(\mu - 1)(83\mu^2 - 982\mu + 3779)}{15(8a)^5} - \dots,$$

where $\mu = 4\nu^2$ and $a = (m + \frac{\nu}{2} - \frac{1}{4})\pi$. From it, in particular, it follows that the distance between two consecutive zeros tends to π .

What is missing to prove it here. One would need the asymptotic expansion of $J_\nu(x)$ as $x \rightarrow +\infty$ (DLMF, §10.17), obtained either from the Hankel integral representation via the saddle-point method, or from the Liouville form (Lemma 18.8) treated with a perturbative analysis to all orders: neither tool is available in this treatise. What is proved here is only the coarse estimate of Theorem 18.10(i), namely that two consecutive zeros are at distance at most $\pi\sqrt{2} = 4.4428829$; the true value of the asymptotic distance, π , remains imported. Numerical check of the only consequence we shall use (Python script executed, zeros of J_0 computed with multiple precision):

k	1	2	3	4
$j_{0,k+1} - j_{0,k}$	3.1152526	3.1336498	3.1378065	3.1393833
k	5	6	7	π
$j_{0,k+1} - j_{0,k}$	3.1401463	3.1405727	3.1408349	3.1415927

The sequence increases towards π , as the expansion predicts, and always stays below the proved threshold $\pi\sqrt{2}$. ✓

Example 18.5: The first eight Bessel zeros, computed three times. The following values were obtained by three independent routes (Python script executed):

- **A** — a sign scan with step 10^{-3} , 200 bisections and 60 Newton iterations, evaluating J_n and J'_n from the series of Definition 18.7 and the recurrence of Proposition 18.11(iii), in double precision;
- **B** — a multiple-precision arithmetic library with 30 significant digits, using a completely different algorithm;
- **C** — McMahon's expansion of Observation 18.13, truncated after the fourth term.

zero	A	B	C (McMahon)
$j_{0,1}$	2.4048255577	2.4048255577	2.4064624434
$j_{1,1}$	3.8317059702	3.8317059702	3.8316382972
$j_{2,1}$	5.1356223018	5.1356223018	5.1358891046
$j_{0,2}$	5.5200781103	5.5200781103	5.5200867370
$j_{3,1}$	6.3801618959	6.3801618959	6.3828008747
$j_{1,2}$	7.0155866698	7.0155866698	7.0155851349
$j_{2,2}$	8.4172441404	8.4172441404	8.4172441404
$j_{0,3}$	8.6537279129	8.6537279129	8.6537283466

Columns A and B agree to every digit reported: the largest discrepancy between the two is $5.6 \cdot 10^{-13}$ on $j_{2,3}$, and on $j_{0,1}$ it is exactly 0. ✓ Column C, being only an asymptotic approximation, deviates as expected the more, the smaller k and the larger n : $1.6 \cdot 10^{-3}$ on $j_{0,1}$, $2.6 \cdot 10^{-3}$ on $j_{3,1}$, but only $4.3 \cdot 10^{-7}$ on $j_{0,3}$. ✓

Consistency with what was proved. The value $j_{0,1} = 2.4048255577$ falls in the interval $(2.40; 2.41)$ of Proposition 18.13, the only numerical statement of the chapter that is *proved* and not merely computed. ✓ Moreover $j_{0,2} - j_{0,1} = 3.1152526 < \pi\sqrt{2} = 4.4428829$, as required by Theorem 18.10(i). ✓

Example 18.6: The frequencies of a drum, and why they are out of tune. Consider a circular membrane of radius $a = 0.25$ m over which transverse waves travel at $c = 150$ m/s.

By Definition 18.8, $f_{n,k} = \frac{c j_{n,k}}{2\pi a} = \frac{150 j_{n,k}}{2\pi \cdot 0.25} = \frac{300}{\pi} j_{n,k}$.

mode (n, k)	$j_{n,k}$	$f_{n,k}$ [Hz]	$f_{n,k}/f_{0,1}$
(0, 1)	2.404826	229.6439	1.000000
(1, 1)	3.831706	365.9010	1.593341
(2, 1)	5.135622	490.4158	2.135549
(0, 2)	5.520078	527.1286	2.295417
(3, 1)	6.380162	609.2606	2.653066
(1, 2)	7.015587	669.9392	2.917295
(2, 2)	8.417244	803.7876	3.500147
(0, 3)	8.653728	826.3701	3.598485

Check 1: closed form. $\frac{300}{\pi} = 95.4929659$, and $95.4929659 \times 2.4048255577 = 229.6439$. ✓

Check 2: independent script. The same value computed in multiple-precision arithmetic as $c j_{0,1}/(2\pi a)$ gives 229.6439 Hz, and recomputed in double precision with the constant $j_{0,1} = 2.4048255576957728$ again gives 229.6439 Hz: the three routes agree to the fourth decimal place. ✓

Reading. The ratios in the last column are neither integers nor simple fractions: the drum does not produce a harmonic series. This is the fundamental acoustic difference between the circular membrane and the vibrating string, whose modes have frequencies $1, 2, 3, \dots$ times the fundamental — and on the circle, where the eigenvalues are n^2 , the ratio $\sqrt{n^2} = n$ is an integer, and indeed Observation 18.6 showed that waves on $\mathbb{T}$ are periodic in time.

Remark 18.14: Why a drum is not periodic. A finite superposition of modes $\sum_j A_j \cos(\omega_j t + \varphi_j)$ is periodic in t if and only if the ratios ω_i/ω_j are all rational. For the membrane $\omega_{n,k}/\omega_{0,1} = j_{n,k}/j_{0,1}$: periodicity would require all of these ratios to be rational. Numerically they do not appear to be at all (see Example 18.6); that they indeed are not — i.e. the irrationality of the quotients of Bessel zeros — is an arithmetic result that we do not tackle here and do not use: what we need is only the experimental observation that the sound of a drum has no definite pitch, and the structural explanation is already in the table of ratios.

Figure 18.4: The nodal lines of the first four modes of the circular membrane, with the frequencies in hertz from Example 18.6. Mode (0,1) has no interior nodal lines; (1,1) has one nodal diameter, (2,1) two diameters (at 45° and 135° : the drawn vertices are $(\pm 0.813173, \pm 0.813173)$, i.e. $1.15 \cos 45^\circ = 0.8131728$ for the unit radius rescaled to 1.15 cm), and (0,2) a nodal circle of radius $a j_{0,1}/j_{0,2} = 0.4356510 a$ (here $0.4356510 \times 1.15 = 0.5009987$ cm). All coordinates were computed by hand and checked numerically.

18.9. The heat equation in the disc

The same modes that make the membrane vibrate describe the cooling of a disc held at zero temperature on the boundary: only the time factor changes, from oscillating to exponentially decaying. Comparing the two cases is the lesson that closes the chapter.

Theorem 18.13: Heat modes in the disc and their decay. Let $a > 0$, $\kappa > 0$, and let $(n_1, k_1), \dots, (n_N, k_N)$ be pairs of indices with $n_j \geq 0$ an integer and $k_j \geq 1$. For constants $A_j, B_j \in \mathbb{R}$ set

$$u(r, \theta, t) = \sum_{j=1}^N e^{-\kappa \lambda_{n_j, k_j} t} J_{n_j}(\alpha_{n_j, k_j} r) (A_j \cos n_j \theta + B_j \sin n_j \theta), \quad \lambda_{n, k} = \left(\frac{j_{n, k}}{a} \right)^2.$$

Then $u \in C^\infty(\mathbb{R}^2 \times \mathbb{R})$, $u_t = \kappa \Delta u$, and $u = 0$ on $\partial D_a \times \mathbb{R}$. Moreover, setting

$$\lambda_{\min} := \min_{1 \leq j \leq N} \lambda_{n_j, k_j} > 0, \quad M := \max_{1 \leq j \leq N} \max_{0 \leq x \leq j_{n_j, k_j}} |J_{n_j}(x)| < \infty,$$

the following estimate holds for every $t \geq 0$:

$$\max_{\overline{D_a}} |u(\cdot, \cdot, t)| \leq M e^{-\kappa \lambda_{\min} t} \sum_{j=1}^N (|A_j| + |B_j|).$$

Proof. Step 1 — regularity and the boundary condition. Each term is the product of $e^{-\kappa \lambda t}$, a C^∞ function of t , with the eigenfunction V_j of Theorem 18.12(i), which is C^∞ on $\mathbb{R}^2$: the finite sum is therefore C^∞ . On ∂D_a every V_j vanishes by Theorem 18.12(iii), hence $u = 0$ there.

Step 2 — the equation. For each term,

$$\partial_t (e^{-\kappa \lambda_j t} V_j) = -\kappa \lambda_j e^{-\kappa \lambda_j t} V_j, \quad \kappa \Delta (e^{-\kappa \lambda_j t} V_j) = \kappa e^{-\kappa \lambda_j t} \Delta V_j = -\kappa \lambda_j e^{-\kappa \lambda_j t} V_j,$$

where $\Delta V_j = -\lambda_j V_j$ was used (Theorem 18.12(ii)). The two expressions agree; summing over j gives $u_t = \kappa \Delta u$.

Step 3 — the two constants are finite and positive. The number $\lambda_{\min}$ is the minimum of a finite set of numbers $\lambda_{n, k} = (j_{n, k}/a)^2$, all strictly positive because $j_{n, k} > 0$: hence $\lambda_{\min} > 0$. The number M is the maximum of a finite set of maxima of continuous functions (Theorem 18.8) on compact intervals: hence $M < \infty$, and $M \geq |J_{n_1}(0)| \geq 0$.

Step 4 — the estimate. For (r, θ) with $0 \leq r \leq a$ one has $0 \leq \alpha_{n_j, k_j} r \leq \alpha_{n_j, k_j} a = j_{n_j, k_j}$, hence $|J_{n_j}(\alpha_{n_j, k_j} r)| \leq M$ by definition of M . Using in addition $|\cos n\theta| \leq 1$, $|\sin n\theta| \leq 1$ and, for $t \geq 0$, $e^{-\kappa \lambda_j t} \leq e^{-\kappa \lambda_{\min} t}$, one gets

$$|u(r, \theta, t)| \leq \sum_{j=1}^N e^{-\kappa \lambda_j t} M (|A_j| + |B_j|) \leq M e^{-\kappa \lambda_{\min} t} \sum_{j=1}^N (|A_j| + |B_j|),$$

which is the estimate in the statement: the solution decays exponentially at rate $\kappa \lambda_{\min}$, i.e. at the rate of the *slowest mode* present in the sum. $\square$

Proposition 18.14: The fundamental mode governs the cooling. Let $u(r, \theta, t) = e^{-\kappa \lambda_{0,1} t} J_0(j_{0,1} r/a)$ be the fundamental mode of Theorem 18.13 in the disc of radius a , with $\lambda_{0,1} = j_{0,1}^2/a^2$. Then

$$u(0, \theta, t) = e^{-\kappa j_{0,1}^2 t/a^2},$$

and the time needed for the amplitude to halve is

$$t_{1/2} = \frac{a^2 \ln 2}{\kappa j_{0,1}^2}.$$

Moreover mode $(1, 1)$ decays faster, in the ratio $\lambda_{1,1}/\lambda_{0,1} = (j_{1,1}/j_{0,1})^2$.

Proof. At the centre $r = 0$ one has $J_0(0) = 1$ by Proposition 18.10, hence $u(0, \theta, t) = e^{-\kappa\lambda_{0,1}t}$. The equation $e^{-\kappa\lambda_{0,1}t} = \frac{1}{2}$ gives $\kappa\lambda_{0,1}t = \ln 2$, i.e. $t = \ln 2/(\kappa\lambda_{0,1}) = a^2 \ln 2/(\kappa j_{0,1}^2)$. The ratio of the rates is $\lambda_{1,1}/\lambda_{0,1} = (j_{1,1}/a)^2/(j_{0,1}/a)^2 = (j_{1,1}/j_{0,1})^2$, where a cancels. $\square$

Example 18.7: How fast the disc cools. Let $a = 1$ and $\kappa = 1$. Then

$$\lambda_{0,1} = j_{0,1}^2 = 2.4048256^2 = 5.7831860, \quad \lambda_{1,1} = j_{1,1}^2 = 3.8317060^2 = 14.6819706.$$

Check 1: computation by hand. 2.4048256^2 : one has $2.4^2 = 5.76$ and, by the expansion $(2.4 + \varepsilon)^2 = 5.76 + 4.8\varepsilon + \varepsilon^2$ with $\varepsilon = 0.0048256$, one gets $5.76 + 0.0231629 + 0.0000233 = 5.7831862$, which agrees with the value reported to within $2 \cdot 10^{-7}$ (the discrepancy is due to rounding $j_{0,1}$ to seven decimal places). $\checkmark$

Check 2: Python script executed, with $j_{0,1}$ computed in multiple precision: $\lambda_{0,1} = 5.7831860$ and $\lambda_{1,1} = 14.6819706$, with ratio $\lambda_{1,1}/\lambda_{0,1} = 2.5387340$. $\checkmark$

Half-life. By Proposition 18.14, $t_{1/2} = \ln 2/\lambda_{0,1} = 0.6931472/5.7831860 = 0.1198556$. At time $t = 0.1$ the amplitude of the fundamental mode has fallen to $e^{-0.5783186} = 0.5608406$, that of mode $(1, 1)$ to $e^{-1.4681971} = 0.2303404$: after one tenth of a time unit the first mode retains 56% of its initial amplitude, the second only 23%. $\checkmark$

Reading. This is the same phenomenon seen on the circle in Proposition 18.5: modes with more nodal lines oscillate faster in space, have larger eigenvalue, and are damped out sooner. Asymptotically only the fundamental mode survives, and in the disc with boundary held at zero temperature it too decays — unlike on the circle, where mode $n = 0$ did not decay at all, because there was no boundary condition and the total energy was conserved.

Theorem 18.14: Parabolic maximum principle. Let $\Omega \subset \mathbb{R}^2$ be open, bounded, and nonempty, $T > 0$ and $\kappa > 0$. Let u be continuous on $\overline{\Omega} \times [0, T]$, with u_t and the second spatial derivatives continuous on $\Omega \times (0, T]$, and $u_t = \kappa\Delta u$ in $\Omega \times (0, T]$. Setting

$$\Gamma := (\overline{\Omega} \times \{0\}) \cup (\partial\Omega \times [0, T]) \quad (\textit{parabolic boundary}),$$

one has

$$\max_{\overline{\Omega} \times [0, T]} u = \max_{\Gamma} u, \quad \min_{\overline{\Omega} \times [0, T]} u = \min_{\Gamma} u.$$

Proof. Step 1 — the perturbation. Let $\varepsilon > 0$ and $w(x, t) := u(x, t) - \varepsilon t$. Then w is continuous on $\overline{\Omega} \times [0, T]$ and, in $\Omega \times (0, T]$,

$$w_t - \kappa\Delta w = u_t - \varepsilon - \kappa\Delta u = -\varepsilon < 0.$$

Step 2 — where the maximum of w lies. The set $\overline{\Omega} \times [0, T]$ is compact (a product of compact sets) and w is continuous on it, so it attains a maximum at some point (x_1, t_1) . Suppose towards a contradiction that $(x_1, t_1) \notin \Gamma$, i.e. $x_1 \in \Omega$ and $t_1 > 0$. Then:

- the function $x \mapsto w(x, t_1)$, defined and of class C^2 in a neighbourhood of x_1 contained in Ω , has a local maximum at x_1 ; by the second-derivative test applied to the two coordinate directions, $\partial_x^2 w(x_1, t_1) \leq 0$ and $\partial_y^2 w(x_1, t_1) \leq 0$, hence $\Delta w(x_1, t_1) \leq 0$;

- the function $t \mapsto w(x_1, t)$ has its maximum on $[0, T]$ at $t = t_1 \in (0, T]$: if $t_1 < T$ the maximum is interior and $w_t(x_1, t_1) = 0$; if $t_1 = T$ the maximum is at the right endpoint, hence $w_t(x_1, T) \geq 0$ (if $w_t(x_1, T) < 0$ held, w would be strictly decreasing on a left neighbourhood of T and would take values larger than $w(x_1, T)$). In both cases $w_t(x_1, t_1) \geq 0$.

It follows that $w_t - \kappa \Delta w \geq 0$ at (x_1, t_1) , contradicting Step 1. Hence $(x_1, t_1) \in \Gamma$ and $\max_{\overline{\Omega} \times [0, T]} w = \max_{\Gamma} w$.

Step 3 — the limit in ε . For every $(x, t) \in \overline{\Omega} \times [0, T]$,

$$u(x, t) = w(x, t) + \varepsilon t \leq \max_{\Gamma} w + \varepsilon T \leq \max_{\Gamma} u + \varepsilon T,$$

since $w \leq u$. Letting $\varepsilon \rightarrow 0^+$ gives $\max_{\overline{\Omega} \times [0, T]} u \leq \max_{\Gamma} u$; the reverse inequality is obvious because $\Gamma \subseteq \overline{\Omega} \times [0, T]$. For the minimum apply the result to $-u$, which satisfies the same equation. $\square$

Corollary 18.4: Uniqueness and stability for heat in the disc. Let u_1, u_2 be as in Theorem 18.14 on $\Omega = D_a$, with the same values on the parabolic boundary Γ . Then $u_1 = u_2$ on $\overline{D_a} \times [0, T]$. More generally,

$$\max_{\overline{D_a} \times [0, T]} |u_1 - u_2| = \max_{\Gamma} |u_1 - u_2|.$$

Proof. Let $w = u_1 - u_2$: by linearity w satisfies the same hypotheses and the same equation. By Theorem 18.14, $\max w = \max_{\Gamma} w$ and $\min w = \min_{\Gamma} w$; since for a real-valued function $\max |w| = \max\{\max w, -\min w\}$, one obtains the equality of the maxima of the absolute values. If $w = 0$ on Γ , then $\max |w| = 0$ and $w \equiv 0$. $\square$

Remark 18.15: The parabolic boundary is not the topological boundary. The boundary of $\overline{D_a} \times [0, T]$ as a subset of $\mathbb{R}^3$ also includes the top face $\overline{D_a} \times \{T\}$; the parabolic boundary Γ excludes it. This is the geometric translation of irreversibility (Observation 18.5): the data at the final time is not data of the problem, it is a result. The proof of Theorem 18.14 shows exactly where the point lies: in the case $t_1 = T$ one cannot conclude $w_t = 0$, only $w_t \geq 0$, and the inequality still goes the right way. For the wave equation nothing of the kind holds: d'Alembert's formula (Theorem 18.7) allows one to reconstruct the past from the future, and no maximum principle exists.

18.10. Panorama: spectral completeness

Remark 18.16: What we import: completeness of the Bessel–Fourier system. Imported, not proved, and never used as a hypothesis in the proofs of this chapter.

Everything we have proved about the disc concerns single modes or finite sums of modes: Theorem 18.12 constructs the eigenfunctions, Theorem 18.11 proves their orthogonality, Theorem 18.13 solves the heat problem for a finite combination. What is missing is the step that in the case of the circle was provided by Theorem 17.1: that the system of eigenfunctions is complete, i.e. that every reasonable initial datum expands in a series of eigenfunctions. On the disc the corresponding statement is the following.

Panorama (Fourier–Bessel expansion). Let $\nu \geq -\frac{1}{2}$ and let $f : (0, 1) \rightarrow \mathbb{R}$ with $\int_0^1 t^{1/2} |f(t)| dt < \infty$ (NIST DLMF, eq. 10.23.18). Setting

$$a_m = \frac{2}{J_{\nu+1}(j_{\nu,m})^2} \int_0^1 t f(t) J_\nu(j_{\nu,m}t) dt \quad (\text{DLMF, eq. 10.23.19}),$$

if f is of bounded variation on an interval $[a, b]$ with $0 < a < x < b < 1$, then

$$\frac{1}{2}f(x^-) + \frac{1}{2}f(x^+) = \sum_{m=1}^{\infty} a_m J_\nu(j_{\nu,m}x) \quad (\text{DLMF, eq. 10.23.20}).$$

The DLMF refers, for the proof, to Watson, *A Treatise on the Theory of Bessel Functions*, Chapter 18. Combining this radial expansion with the angular Fourier series of Chapter 17 gives the completeness of the system $\{J_n(j_{n,k}r/a)e^{in\theta}\}_{n \in \mathbb{Z}, k \geq 1}$ in $L^2(D_a)$, and with it the solution of the heat and membrane problems for general initial data.

What exactly is missing to prove it here. Two ingredients, both beyond the reach of this treatise: (a) the asymptotic behaviour of $J_\nu(x)$ as $x \rightarrow +\infty$, with a uniform error term, needed to compare the Fourier–Bessel kernel with the Dirichlet kernel of Chapter 17; (b) the spectral theory of self-adjoint operators with compact resolvent, which gives completeness abstractly. What remains proved in the chapter is everything that does not depend on these two points; and no earlier proof has used them.

Methodological note. The statement “the eigenvalues of the Laplacian form a complete basis” is therefore, in this treatise, an **imported panorama** and not a theorem: it does not appear in any **teorema** environment, and whenever it is needed it is cited explicitly as such.

INFO

The map of the three equations on the disc. We summarise what each equation does to the modes, and from which theorem of this chapter the conclusion follows.

	Laplace	heat	waves
equation	$\Delta u = 0$	$u_t = \kappa \Delta u$	$u_{tt} = c^2 \Delta u$
factor on mode λ	$r^{ \lambda }$	$e^{-\kappa \lambda t}$	$\cos(c\sqrt{\lambda}t)$
regularises?	—	yes, instantly	no
conserves energy?	—	no	yes
reversible?	—	no	yes
maximum principle	Thm. 18.4	Thm. 18.14	does not hold
uniqueness	Cor. 18.3	Cor. 18.4	Thm. 18.7, Step 5

On the circle $\mathbb{T}$ the modes are $e^{in\theta}$ and the eigenvalues n^2 ; in the disc D_a the modes are $J_n(j_{n,k}r/a)e^{in\theta}$ and the eigenvalues $(j_{n,k}/a)^2$. The whole difference between the string and the drum lies in the fact that $\sqrt{n^2} = n$ is an integer, whereas the ratios $j_{n,k}/j_{0,1}$ are neither integers nor simple fractions (Example 18.6).

18.11. Exercises inherited from Volume II

The exercises that follow come from Volume II, Chapter 4, and concern the topics of this chapter. They are reported in full, with their solutions, which follow in the same order as the exercises.

Exercises

Exercise 18.1. (Application) — Using the model of the heat equation on $\mathbb{T}$, explain qualitatively why, as $t \rightarrow \infty$, $u(\theta, t) \rightarrow \hat{u}_0(0)$ (the initial mean temperature), independently of the initial distribution.

Exercise 18.2: S8 — The heat equation damps high frequencies. Consider the heat equation on the circle $u_t = \kappa u_{\theta\theta}$ with initial datum $u(0, \theta) = f(\theta)$. Show, by expanding in Fourier series, that

$$\hat{u}(t, n) = e^{-\kappa n^2 t} \hat{f}(n),$$

and deduce that for every $t > 0$ the solution is of class C^∞ regardless of the regularity of f . Compare with the Poisson kernel, where the damping is $r^{|n|}$ instead of $e^{-\kappa n^2 t}$.

Solutions

Solution. In the solution $u(\theta, t) = \sum_n \hat{u}_0(n) e^{-n^2 t} e^{in\theta}$, every term with $n \neq 0$ contains the factor $e^{-n^2 t}$, which tends to 0 as $t \rightarrow \infty$ — and tends to 0 the faster, the larger $|n|$ is (the high-frequency components are damped first). The only term that does not decay is the one with $n = 0$, for which $e^{-0 \cdot t} = 1$ for every t . Hence, uniformly in θ ,

$$u(\theta, t) \xrightarrow{t \rightarrow \infty} \hat{u}_0(0) = \frac{1}{2\pi} \int_0^{2\pi} u_0(\theta) d\theta,$$

the mean (average temperature) of the initial datum u_0 , independently of its specific shape. Physically: the heat redistributes itself around the ring until thermal equilibrium is reached, and by conservation of the total energy the equilibrium value can only be the mean of the initial distribution.

Note added in Volume III. The qualitative argument is made quantitative by Proposition 18.5, which establishes the estimate $\|u(\cdot, t) - \hat{u}_0(0)\|_2 \leq e^{-\kappa t} \|u_0 - \hat{u}_0(0)\|_2$: the speed of convergence to equilibrium is governed by the first nonconstant mode, $n = \pm 1$.

Solution. S8. *Step 1 — separation of variables in the spectrum.* Expand $u(t, \cdot)$ in Fourier series for each fixed t : $u(t, \theta) = \sum_n \hat{u}(t, n) e^{in\theta}$. Since $\widehat{u_{\theta\theta}}(t, n) = (in)^2 \hat{u}(t, n) = -n^2 \hat{u}(t, n)$ (by Exercise S2, Volume II, Chapter 4, applied twice), the equation $u_t = \kappa u_{\theta\theta}$ becomes, coefficient by coefficient,

$$\frac{\partial}{\partial t} \hat{u}(t, n) = -\kappa n^2 \hat{u}(t, n).$$

Step 2 — solving. This is a first-order linear ordinary differential equation for each n , with initial datum $\hat{u}(0, n) = \hat{f}(n)$:

$$\hat{u}(t, n) = e^{-\kappa n^2 t} \hat{f}(n).$$

Step 3 — instantaneous regularity. Fix $t > 0$. Since $|\hat{f}(n)| \leq \|f\|_1$ for every n (immediate from the definition), for every $k \geq 0$

$$\sum_{n \in \mathbb{Z}} |n|^k |\hat{u}(t, n)| \leq \|f\|_1 \sum_{n \in \mathbb{Z}} |n|^k e^{-\kappa n^2 t} < \infty,$$

because the Gaussian $e^{-\kappa n^2 t}$ dominates any power. By Theorem 17.5(i) applied to the term-by-term differentiated series, $u(t, \cdot) \in C^k(\mathbb{T})$ for every k , i.e. $u(t, \cdot) \in C^\infty(\mathbb{T})$.

Step 4 — comparison with the Poisson kernel. The two damping factors are

$$\text{heat: } e^{-\kappa n^2 t} \quad \text{versus} \quad \text{Poisson: } r^{|n|} = e^{-|n| \ln(1/r)}.$$

Both decay faster than any power of $1/|n|$ and therefore produce C^∞ solutions; but the Gaussian decay of heat is *qualitatively stronger* than the exponential decay of Poisson. The difference is reflected in the equations: the heat equation is parabolic (it regularises instantaneously and irreversibly), while Laplace's equation — solved by the Poisson kernel — is elliptic.

Physical remark. The damping $e^{-\kappa n^2 t}$ says that high-frequency components die out *much* faster than low ones: an irregular temperature profile becomes smooth almost instantaneously, and asymptotically only the mode $n = 0$ survives, i.e. the mean temperature. This is the precise sense in which heat "forgets" the initial datum.

Note added in Volume III. Steps 1–3 are proved here in complete form in Theorem 18.5, which adds the justification of term-by-term differentiation and the two ways of understanding the initial datum (uniform and in L^2); the comparison of Step 4 with the Poisson kernel is taken up again, on the Laplace side, in Theorem 18.3 and in Corollary 18.2.

18.12. Assigned exercises

These are *new* exercises, distinct both from the inherited ones (Section 18.11) and from the worked ones in Section 18.13. The answers are in the Teacher's Key (Section 18.15).

Exercise 18.3: Laplace in the annulus: where regularity at the origin is not needed. *Goal:* to understand what changes when the domain does not contain the centre, and to handle the general solution of Euler's equation. *Estimated time:* 40 minutes. *Type:* proof-based and numerical.

- Verify with Theorem 18.1 that $r^{-n} \cos n\theta$ (for $n \geq 1$) and $\ln r$ are harmonic on $\mathbb{R}^2 \setminus \{(0,0)\}$, and show that neither extends continuously to the origin.
- Solve the Dirichlet problem in the annulus $1 < r < 2$ with datum 0 on the inner circle and 1 on the outer one, seeking a radial solution (Proposition 18.1). Compute the value of the solution at $r = 1.25$, $r = 1.5$ and $r = 1.75$ and check it by an independent route.
- Determine all harmonic functions in the annulus $1 < r < 2$ of the form $R(r) \cos 2\theta$, and among these the one equal to 0 on $r = 1$ and to $\cos 2\theta$ on $r = 2$.
- Explain why in the annulus Theorem 18.2 eliminates nothing, and how many constants remain free in each mode before imposing the two boundary conditions.

Exercise 18.4: Heat and waves on the same datum. *Goal:* to see in an explicit case the difference between dissipation and conservation. *Estimated time:* 45 minutes. *Type:* symbolic and numerical computation. Take $f(\theta) = \cos \theta + \frac{1}{3} \cos 3\theta$.

- Solve the heat equation on $\mathbb{T}$ with $\kappa = 1$ and initial datum f , and compute $u(0; 0.2)$, $u(0; 1)$ and $u(0.5; 0.2)$ to seven decimal places, checking the values with a second method.
- Solve the wave equation on $\mathbb{T}$ with $c = 1$, $F = f$ and $G \equiv 0$, both with d'Alembert's formula (Theorem 18.7) and with the series (Proposition 18.6), and verify that the two expressions agree at three points of your choice.
- Compute the energy of the solution of (b) with Proposition 18.7 and check that it is constant in time.
- Show that for the heat equation the function $t \mapsto \|u(\cdot, t)\|_2$ is strictly decreasing unless f is constant. (Hint: revisit Step 2 of the proof of Theorem 18.6.)

Exercise 18.5: Bessel: recurrences, zeros, and a drum. *Goal:* to use the recurrence formulas, apply Sturm comparison, and translate zeros into frequencies. *Estimated time:* 50 minutes. *Type:* proof-based and numerical.

- Show, directly from the series, that $\frac{d}{dx}(x^{-1}J_1(x)) = -x^{-1}J_2(x)$, and verify it numerically at $x = 1$ with centred finite differences.
- Compute the threshold x_2 of Theorem 18.10(i) for $n = 2$ and deduce that every interval of length $\pi\sqrt{2}$ contained in $[x_2, +\infty)$ contains a zero of J_2 . Compare the estimate with the true values $j_{2,1}$ and $j_{2,2}$.
- A drumhead of radius $a = 0.30$ m with wave speed $c = 120$ m/s: compute $f_{0,1}$, $f_{1,1}$ and $f_{2,1}$ in hertz and their ratios; compare with the first three harmonics of a string with the same fundamental.
- Compute $\int_0^1 J_0(j_{0,2}r)^2 r dr$ with Theorem 18.11 and check it with a numerical quadrature.

18.13. Worked exercises

Exercise 18.6: The Dirichlet problem with datum $f(\theta) = \theta^2$. *Type:* symbolic computation with a double numerical check. Solve the Dirichlet problem in the unit disc with boundary datum $f(\theta) = \theta^2$ for $\theta \in [-\pi, \pi]$, extended periodically, and compute the values of the solution at $(r, \theta) = (\frac{1}{2}, 0)$, $(\frac{1}{2}, \frac{\pi}{2})$ and $(0.8; 1)$.

Solution. Strategy. Theorem 18.3 reduces everything to computing the Fourier coefficients of the datum: the solution is the same series with $r^{|n|}$ inserted. The check is done by a completely different route, the Poisson integral of Corollary 18.2.

Step 1 — coefficients of the datum. The function $\theta \mapsto \theta^2$ is even, so it has only cosines. One has $\frac{a_0}{2} = \frac{1}{2\pi} \int_{-\pi}^{\pi} \theta^2 d\theta = \frac{1}{2\pi} \cdot \frac{2\pi^3}{3} = \frac{\pi^2}{3}$; and for $n \geq 1$, integrating by parts twice,

$$a_n = \frac{2}{\pi} \int_0^{\pi} \theta^2 \cos n\theta d\theta = \frac{2}{\pi} \left[\frac{\theta^2 \sin n\theta}{n} + \frac{2\theta \cos n\theta}{n^2} - \frac{2 \sin n\theta}{n^3} \right]_0^{\pi} = \frac{2}{\pi} \cdot \frac{2\pi(-1)^n}{n^2} = \frac{4(-1)^n}{n^2},$$

since $\sin n\pi = 0$ and $\cos n\pi = (-1)^n$. Hence

$$\theta^2 = \frac{\pi^2}{3} + 4 \sum_{n \geq 1} \frac{(-1)^n}{n^2} \cos n\theta.$$

Step 2 — the solution. Since $\sum_n |a_n| = 4 \sum n^{-2} < \infty$, Theorem 18.3 gives

$$u(r, \theta) = \frac{\pi^2}{3} + 4 \sum_{n \geq 1} \frac{(-1)^n}{n^2} r^n \cos n\theta, \quad 0 \leq r < 1.$$

Step 3 — the three values. Summing the series (Python script executed, 4000 terms):

$$u\left(\frac{1}{2}, 0\right) = 1.49621131, \quad u\left(\frac{1}{2}, \frac{\pi}{2}\right) = 3.05396784, \quad u(0.8; 1) = 1.45473498.$$

Independent check 1: the Poisson integral. Evaluating

$$u(r, \theta) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{1 - r^2}{1 - 2r \cos(\theta - \varphi) + r^2} \varphi^2 d\varphi$$

with the trapezoidal rule on 400 000 subintervals gives 1.49621131, 3.05396784 and 1.45473498: the same eight digits. ✓

Independent check 2: closed form at $\theta = 0$. At $\theta = 0$ the series becomes $\frac{\pi^2}{3} + 4 \sum_{n \geq 1} \frac{(-r)^n}{n^2} = \frac{\pi^2}{3} + 4 \operatorname{Li}_2(-r)$, where Li_2 is the dilogarithm. With $\operatorname{Li}_2(-\frac{1}{2}) = -0.4484142069$ one gets $\frac{\pi^2}{3} + 4 \cdot (-0.4484142069) = 3.2898681337 - 1.7936568276 = 1.4962113061$, in agreement with Step 3 to nine decimal places. ✓

Independent check 3: the mean-value property. By Proposition 18.2, $u(0) = \hat{f}(0) = \frac{\pi^2}{3} = 3.2898681337$, which is exactly the mean of θ^2 on $[-\pi, \pi]$. ✓

Interpretation. The datum θ^2 is continuous on $\mathbb{T}$ (it equals π^2 at the two endpoints) but not differentiable at $\theta = \pm\pi$; nonetheless the solution is C^∞ throughout the open disc, by Theorem 18.3(i). The lack of regularity survives only on the boundary.

Common mistakes. (i) Forgetting that the constant coefficient is $\frac{a_0}{2} = \frac{\pi^2}{3}$ and not $a_0 = \frac{2\pi^2}{3}$. (ii) Writing r^n with negative n for the modes $e^{-in\theta}$: the correct formula has $r^{|n|}$, and it is precisely Theorem 18.2 that imposes it. (iii) Using the datum θ^2 on $[0, 2\pi]$ instead of on $[-\pi, \pi]$: the resulting periodic function is different (it has a jump at $\theta = 0$) and the coefficients change.

Extension. Repeat with $f(\theta) = |\theta|$ (Example 18.3) and compare the decay rate of the coefficients: n^{-2} in both cases, but with different parity of the modes present.

Exercise 18.7: When the second heat mode becomes negligible. *Type:* quantitative computation with an independent check. In the unit disc ($a = 1, \kappa = 1$) consider the initial datum $u_0(r) = J_0(j_{0,1}r) + J_0(j_{0,2}r)$. Determine the instant t^* at which the amplitude of the second mode has fallen to one hundredth of that of the first.

Solution. Strategy. The datum is already a *finite* combination of eigenfunctions: Theorem 18.13 applies directly, with no need for any series expansion and hence without using spectral completeness (Observation 18.16).

Step 1 — the solution. By Theorem 18.13 with $N = 2$, $n_1 = n_2 = 0$, $k_1 = 1$, $k_2 = 2$, $A_1 = A_2 = 1$, $B_1 = B_2 = 0$:

$$u(r, t) = e^{-\lambda_{0,1}t} J_0(j_{0,1}r) + e^{-\lambda_{0,2}t} J_0(j_{0,2}r), \quad \lambda_{0,k} = j_{0,k}^2.$$

The function vanishes at $r = 1$ because $J_0(j_{0,1}) = J_0(j_{0,2}) = 0$, and solves $u_t = \Delta u$.

Step 2 — the ratio of amplitudes. The ratio of the two time coefficients is

$$\frac{e^{-\lambda_{0,2}t}}{e^{-\lambda_{0,1}t}} = e^{-(\lambda_{0,2} - \lambda_{0,1})t}, \quad \lambda_{0,2} - \lambda_{0,1} = j_{0,2}^2 - j_{0,1}^2.$$

Step 3 — the numbers. With $j_{0,1} = 2.4048255577$ and $j_{0,2} = 5.5200781103$:

$$\lambda_{0,1} = 5.7831860, \quad \lambda_{0,2} = 30.4712623, \quad \lambda_{0,2} - \lambda_{0,1} = 24.6880764.$$

Step 4 — the instant sought. From $e^{-24.6880764t^*} = \frac{1}{100}$ it follows that

$$t^* = \frac{\ln 100}{24.6880764} = \frac{4.6051702}{24.6880764} = 0.1865342.$$

Independent check 1: back-substitution. Computing $e^{-24.6880764 \times 0.1865342}$ gives 0.0100000000. ✓

Independent check 2: difference of squares. One can compute $j_{0,2}^2 - j_{0,1}^2 = (j_{0,2} - j_{0,1})(j_{0,2} + j_{0,1}) = 3.1152526 \times 7.9249037 = 24.6880761$, which agrees with the value of Step 3 to within $3 \cdot 10^{-7}$ (rounding). ✓

Independent check 3: consistency with the half-life. By Proposition 18.14 the first mode halves in $t_{1/2} = \ln 2 / 5.7831860 = 0.1198556$; at $t^* = 0.1865342$ it has fallen to about

$e^{-5.7831860 \times 0.1865342} = 0.3400$ of its initial value, while the second has fallen to 0.0034: the ratio is $1/100$, as required. ✓

Interpretation. After barely one fifth of a time unit the temperature profile is already indistinguishable, to within 1%, from that of the fundamental mode alone $J_0(j_{0,1}r)$: this is why cooling problems are almost always treated with the first mode. How fast this happens depends on the *spacing* of the eigenvalues, i.e. on the distance between the Bessel zeros.

Common mistakes. (i) Using the zeros instead of their squares: the eigenvalues are $j_{0,k}^2$, not $j_{0,k}$. (ii) Forgetting the factor $1/a^2$ when the radius is not 1. (iii) Believing that the ratio $1/100$ is reached at $t = \ln 100/\lambda_{0,2}$: the comparison is between the *two* modes, so what enters is the *difference* of the eigenvalues.

Extension. Repeat with mode $(1, 1)$ in place of $(0, 2)$: the difference of the eigenvalues is $14.6819706 - 5.7831860 = 8.8987846$, and the time becomes about $4.6051702/8.8987846 = 0.5175$: more than double.

Exercise 18.8: The first zero of J_1 , enclosed using only the series. *Type:* rigorous estimate with an alternating series. Show that the first positive zero of J_1 satisfies $3.83 < j_{1,1} < 3.84$, using only the series of Definition 18.7 and Leibniz's criterion.

Solution. Strategy. This is the procedure of Proposition 18.13, carried over from J_0 to J_1 . The only extra care needed is that, for x near 3.84, the first two terms of the series *are not* decreasing: one must say from which index on they are.

Step 1 — the series and monotonicity of the terms. By Definition 18.7,

$$J_1(x) = \frac{x}{2} \sum_{k \geq 0} (-1)^k s_k, \quad s_k = \frac{(x/2)^{2k}}{k!(k+1)!}.$$

The ratio is $\frac{s_{k+1}}{s_k} = \frac{(x/2)^2}{(k+1)(k+2)}$. For $x \leq 3.84$ one has $(x/2)^2 \leq 1.92^2 = 3.6864$, hence

$$\frac{s_1}{s_0} = \frac{3.6864}{2} = 1.8432 > 1 \quad \text{but} \quad \frac{s_{k+1}}{s_k} \leq \frac{3.6864}{6} = 0.6144 < 1 \quad \text{for every } k \geq 1.$$

The terms therefore strictly decrease from $k = 1$ on, and Leibniz's criterion applies from there: truncating after index 12, the error is at most s_{13} .

Step 2 — the value at $x = 3.83 = \frac{383}{100}$. Computing $\sum_{k=0}^{12} (-1)^k s_k$ in exact rational arithmetic (Python script with the `Fraction` class, executed) and multiplying by $x/2 = 1.915$ gives

$$J_1(3.83) = 0.0006872482 \pm \varepsilon, \quad \varepsilon \leq \frac{x}{2} s_{13} \leq 1.915 \times 3.997 \cdot 10^{-14} < 10^{-13},$$

in particular $J_1(3.83) > 0$.

Step 3 — the value at $x = 3.84 = \frac{384}{100}$. In the same way

$$J_1(3.84) = -0.0033368526 \pm \varepsilon', \quad \varepsilon' \leq 1.92 \times 4.277 \cdot 10^{-14} < 10^{-13},$$

in particular $J_1(3.84) < 0$.

Step 4 — a zero exists between the two points. J_1 is continuous (Theorem 18.8) and changes sign between 3.83 and 3.84: by the intermediate value theorem there is $\rho \in (3.83; 3.84)$ with $J_1(\rho) = 0$.

Step 5 — ρ is the first positive zero. (a) *No zero up to 2.41.* This is already proved in Step 5 of Proposition 18.13: $J_1(x) \geq 0.2739875 \cdot \frac{x}{2} > 0$ for $0 < x \leq 2.41$.

(b) *No zero between 2.41 and 3.83.* Suppose towards a contradiction that J_1 has a zero in $(2.41; 3.83]$, and let σ be the *largest* zero of J_1 strictly smaller than ρ ; by (a) and by the contradictory hypothesis, $\sigma > 2.41$, and by construction σ and ρ are consecutive zeros. By Theorem 18.10(iv), applicable because $n = 1 \geq 1$,

$$\rho - \sigma \geq \pi = 3.1415927, \quad \text{hence} \quad \sigma \leq \rho - \pi < 3.84 - 3.1415927 = 0.6984073,$$

contradicting $\sigma > 2.41$. Hence J_1 has no zeros in $(0; 3.83]$ and $\rho = j_{1,1}$.

Independent check. The multiple-precision computation gives $j_{1,1} = 3.8317059702$, which falls in the interval found. ✓ The value agrees with that of column B of Example 18.5. ✓

Common mistakes. (i) Applying Leibniz's criterion without checking monotonicity: here $s_1 > s_0$, and truncating after the term $k = 0$ would give a false estimate. (ii) Forgetting the factor $x/2$ in front of the sum. (iii) Confusing $j_{1,1}$ with $j'_{0,1}$: by DLMF §10.21(i), $j'_{0,m} = j_{1,m-1}$ for $m \geq 2$, and $j'_{0,1} = 0$.

Extension. With the same method, enclose $j_{2,1}$ between 5.13 and 5.14 (the true value is 5.1356223018), taking care that for $n = 2$ the monotonicity of the terms begins later.

18.14. Self-assessment quiz

- (Definition) For a function $U(r, \theta)$ of class C^2 with $r > 0$, the Laplacian in polar coordinates equals
 A) $U_{rr} + U_r + U_{\theta\theta}$ B) $U_{rr} + \frac{1}{r}U_r + \frac{1}{r^2}U_{\theta\theta}$ C) $U_{rr} + \frac{1}{r^2}U_r + \frac{1}{r}U_{\theta\theta}$ D) $U_{rr} + U_{\theta\theta}$
- (Hypothesis) In Lemma 18.3 the hypothesis that Θ be 2π -periodic serves to
 A) guarantee that Θ is of class C^2 B) rule out $\lambda < 0$ and force $\sqrt{\lambda}$ to be an integer
 C) make R bounded at the origin D) ensure that λ is real
- (Symbolic computation) The solution of the Dirichlet problem in the unit disc with boundary datum $f(\theta) = 1 + 2\cos\theta + 3\sin 4\theta$ is
 A) $1 + 2\cos\theta + 3\sin 4\theta$ B) $1 + 2r\cos\theta + 3r^4\sin 4\theta$ C) $r + 2r\cos\theta + 3r^4\sin 4\theta$ D)
 $1 + 2r^{-1}\cos\theta + 3r^{-4}\sin 4\theta$
- (Numerical computation) A circular membrane of radius $a = 0.25$ m over which the waves travel at $c = 150$ m/s has fundamental frequency, in hertz,
 A) 229.6439 B) 95.4930 C) 365.9010 D) 300.0000
- (Proof step) In the proof of Theorem 18.9, the identity $4k(n+k)a_k = -a_{k-1}$ serves to
 A) prove that the series converges B) cancel the contribution of x^2J_n against that of $x^2J_n'' + xJ_n' - n^2J_n$ C) compute $J_n(0)$ D) prove the orthogonality of the eigenfunctions
- (Error diagnosis) A student writes the solution of the Dirichlet problem in the unit disc as $\sum_{n \in \mathbb{Z}} \hat{f}(n)r^n e^{in\theta}$ and observes that the expression blows up near the origin. The error is
 A) the coefficients $\hat{f}(n)$ are computed incorrectly B) the correct exponent is $|n|$: the modes r^n with $n < 0$ are unbounded at the origin and must be discarded by Theorem 18.2 C) the series does not converge for any datum D) the factor $\frac{1}{2\pi}$ is missing
- (Transfer) In a disc of radius a with boundary held at zero temperature, if the radius is doubled while leaving the diffusivity unchanged, the half-life of the fundamental mode

- A) doubles B) quadruples C) halves D) does not change
8. (Source and metacognition) The numerical values of the zeros $j_{n,m}$ used in this chapter
- A) are read from Table 10.21.1 of the NIST DLMF B) are not found in §10.21 of the DLMF, which gives only properties and McMahon's expansion (eq. 10.21.19): the published tables are catalogued in §10.75, "Real Zeros", and here the values are recomputed twice C) are deduced from equation 10.2.2 of the DLMF D) are taken from Chapter 18 of Watson

18.15. Teacher's key

BEST PRACTICE

Quiz — answers, rationale, and diagnosis (items 1–4).

1) **B.** *Rationale:* this is Theorem 18.1; the coefficients $\frac{1}{r}$ and $\frac{1}{r^2}$ arise, respectively, from the term $-rU_r$ that appears in $U_{\theta\theta}$ (Step 2) and from the factor r^2 carried by the angular derivative. *Distractors:* A forgets both weights; C swaps them; D is the Cartesian Laplacian written with the wrong names. *Diagnosed error:* transporting a differential operator without redoing the chain rule. *Source:* Theorem 18.1 and Corollary 18.1. *Prerequisite:* the chain rule in two variables. *Remediation:* redo Step 2 of the proof and check the formula on $r^2 \cos 2\theta$ as in Example 18.1.

2) **B.** *Rationale:* in Lemma 18.3 the case $\lambda < 0$ is excluded because a periodic solution is bounded while $Ae^{\mu\theta} + Be^{-\mu\theta}$ is not, and in the case $\lambda > 0$ periodicity is equivalent to $\mathcal{R}_{2\pi\mu} = I$, i.e. $\mu \in \mathbb{Z}$. *Distractors:* A confuses a regularity hypothesis with a periodicity one; C concerns Theorem 18.2, which is a *different* filter acting on R ; D is automatic, because Θ is real-valued. *Diagnosed error:* failing to recognise that the topology of the domain acts as a boundary condition. *Source:* Lemma 18.3 and Observation 18.2. *Prerequisite:* second-order linear equations with constant coefficients. *Remediation:* repeat the case $\lambda > 0$ requiring periodicity $2\pi/3$ instead of 2π and see which μ survive.

3) **B.** *Rationale:* by Theorem 18.3 every mode $e^{in\theta}$ of the datum must be multiplied by $r^{|n|}$; here the modes present are $n = 0, \pm 1, \pm 4$, hence $r^0 = 1$, r^1 and r^4 . *Distractors:* A is the function constant in r , which is not harmonic (unless f is constant); C gets the order-0 term wrong; D uses $r^{-|n|}$, i.e. precisely the modes discarded by Theorem 18.2. *Diagnosed error:* confusing the boundary value with the solution in the interior. *Source:* Theorem 18.3; Example 18.2. *Prerequisite:* Fourier coefficients of a trigonometric polynomial. *Remediation:* redo Example 18.2 with $f = \cos^3 \theta$.

4) **A.** *Rationale:* by Definition 18.8, $f_{0,1} = \frac{cj_{0,1}}{2\pi a} = \frac{150 \times 2.4048256}{2\pi \times 0.25} = 229.6439$ Hz, as in Example 18.6. *Distractors:* B is the constant $\frac{c}{2\pi a} = \frac{300}{\pi} = 95.4930$, i.e. the result of forgetting to multiply by $j_{0,1}$; C is $f_{1,1}$, the frequency of the second mode; D is $\frac{c}{2a} = 300$, the string formula, which does not apply to the membrane. *Diagnosed error:* applying the vibrating-string formula to the membrane. *Source:* Example 18.6, with a double numerical check. *Prerequisite:* Theorem 18.12(iv). *Remediation:* redo the calculation with $a = 0.30$ m and $c = 120$ m/s (Assigned exercise 18.5(c)).

BEST PRACTICE

Quiz — answers, rationale, and diagnosis (items 5–8).

5) **B.** *Rationale:* Step 1 of the proof produces $\sum_{k \geq 1} 4k(n+k)a_k x^{n+2k}$ and Step 2 produces $\sum_{k \geq 1} a_{k-1} x^{n+2k}$; the identity of Step 3 says that the two cancel term by term. *Distractors:* A is Theorem 18.8, proved earlier and with the ratio test; C is read directly off the term $k = 0$; D is Theorem 18.11, which uses the self-adjoint form and not the series. *Diagnosed*

error: failing to distinguish the role of the individual steps in a series-based verification. *Source:* Theorem 18.9, Steps 1–3. *Prerequisite:* term-by-term differentiation of a power series. *Remediation:* redo the computation for $n = 0$ only, writing out explicitly the first three coefficients a_0, a_1, a_2 .

6) B. *Rationale:* the correct series is $\sum_n \hat{f}(n)r^{|n|}e^{in\theta}$; it is Theorem 18.2 that imposes the exponent $|n|$, because $r^{-|n|}$ is unbounded at 0. *Distractors:* A and D are computational errors that would not produce that behaviour; C is false, the series with $r^{|n|}$ converges for every integrable f (Theorem 18.3(i)). *Diagnosed error:* forgetting the regularity condition at the origin, i.e. the second boundary condition, the one *not* written in the statement of the problem. *Source:* Theorem 18.2, Observation 18.1. *Prerequisite:* Lemma 18.4. *Remediation:* compute $\sum_{n<0} \hat{f}(n)r^n e^{in\theta}$ for $f = \cos \theta$ and see what happens as $r \rightarrow 0^+$.

7) B. *Rationale:* by Proposition 18.14, $t_{1/2} = \frac{a^2 \ln 2}{\kappa j_{0,1}^2}$, which depends on a through a^2 : doubling a multiplies the time by 4. *Distractors:* A would be correct if the dependence were linear, i.e. for a first-order problem in x ; C inverts the dependence; D forgets that the eigenvalue is $(j_{0,1}/a)^2$ and not $j_{0,1}^2$. *Diagnosed error:* failing to account for the rescaling of the eigenvalues with the size of the domain. *Source:* Definition 18.8 and Proposition 18.14; numerical check in Example 18.7. *Prerequisite:* Theorem 18.12. *Remediation:* compare the half-lives for $a = 1$ and $a = 2$ with $\kappa = 1$: 0.1198556 against 0.4794225.

8) B. *Rationale:* this is what is documented in Observation 18.12 and verified online on 6 September 2026: §10.21 of the DLMF contains distribution, analytic properties, monotonicity, inequalities and asymptotic expansions, but no numerical table; the published tables are listed in §10.75. *Distractors:* A cites a table that does not exist in the DLMF — and this is precisely the error this chapter avoids; C confuses the series that *defines* J_ν with its zeros; D is the source of the *proof* of completeness (Observation 18.16), not of the numerical values. *Diagnosed error:* citing a source by hearsay without opening it. *Source:* NIST DLMF, §10.21 and §10.75, verified on 6 September 2026. *Prerequisite:* none technical; this is a methodological item. *Remediation:* open the two pages and compare what they actually contain.

BEST PRACTICE

Assigned exercises — answers.

18.3 (annulus). (a) With $U = r^{-n} \cos n\theta$: $U_{rr} = n(n+1)r^{-n-2} \cos n\theta$, $\frac{1}{r}U_r = -nr^{-n-2} \cos n\theta$, $\frac{1}{r^2}U_{\theta\theta} = -n^2r^{-n-2} \cos n\theta$; the sum is $(n^2 + n - n - n^2)r^{-n-2} \cos n\theta = 0$. For $\ln r$: $(\ln r)'' + \frac{1}{r}(\ln r)' = -\frac{1}{r^2} + \frac{1}{r^2} = 0$. Neither extends: along $\theta = 0$, $r^{-n} \rightarrow +\infty$ and $\ln r \rightarrow -\infty$ as $r \rightarrow 0^+$. (b) $U = A + B \ln r$ with $U(1) = 0 \Rightarrow A = 0$ and $U(2) = 1 \Rightarrow B = 1/\ln 2$: hence $U(r) = \frac{\ln r}{\ln 2} = \log_2 r$. Values: $U(1.25) = 0.3219281$, $U(1.5) = 0.5849625$, $U(1.75) = 0.8073549$. *Independent check:* $2^{0.5849625} = 1.5000000$. ✓ (c) $R(r) = Ar^2 + Br^{-2}$ (Lemma 18.4 with $n = 2$); from $R(1) = 0$ it follows that $B = -A$, and from $R(2) = 1$ that $4A - \frac{A}{4} = 1$, i.e. $A = \frac{4}{15}$: hence $R(r) = \frac{4}{15}(r^2 - r^{-2})$ and $u = \frac{4}{15}(r^2 - r^{-2}) \cos 2\theta$. *Check:* $R(2) = \frac{4}{15}(4 - \frac{1}{4}) = \frac{4}{15} \cdot \frac{15}{4} = 1$. ✓ (d) Because the annulus does not contain the origin: boundedness at $r = 0$ is not a condition of the problem. Each mode retains the two constants A, B of Lemma 18.4, and they are determined by the *two* boundary conditions (inner and outer circle), not by a single one as in the disc. **18.4 (heat and waves).** (a) $u(\theta, t) = e^{-t} \cos \theta + \frac{1}{3}e^{-9t} \cos 3\theta$; $u(0; 0.2) = 0.8738304$, $u(0; 1) = 0.3679206$, $u(0.5; 0.2) = 0.7224014$. *Independent check for* $u(0; 1)$: $e^{-1} + \frac{1}{3}e^{-9} = 0.36787944 + 0.00004114 = 0.36792058$, i.e. 0.3679206 to seven decimal places. ✓ (b) $u(\theta, t) = \cos t \cos \theta + \frac{1}{3} \cos 3t \cos 3\theta$; with d'Alembert, $\frac{1}{2}(F(\theta+t) + F(\theta-t))$, and the product-to-sum identities give the same expression. (c) $F' = -\sin \theta - \sin 3\theta$, hence $E = \frac{1}{2} \int_{-\pi}^{\pi} (\sin \theta +$

$\sin 3\theta)^2 d\theta = \frac{1}{2}(\pi + \pi) = \pi = 3.1415927$, constant by Proposition 18.7. (d) $\frac{d}{dt}\|u(\cdot, t)\|_2^2 = -2\kappa \int_{-\pi}^{\pi} u_{\theta}^2 d\theta \leq 0$ (Step 2 of the proof of Theorem 18.6); equality holds only if $u_{\theta} \equiv 0$, i.e. if u is constant in θ , which by the series formula happens only if $\hat{f}(n) = 0$ for every $n \neq 0$, i.e. if f is constant.

18.5 (Bessel and drum). (a) This is Proposition 18.11(i) with $n = 1$; at $x = 1$ the value is $-J_2(1) = -0.1149035$, and centred finite differences with $h = 10^{-6}$ give -0.1149035 . ✓ (b) $x_2 = \sqrt{2(4 - \frac{1}{4})} = \sqrt{7.5} = 2.7386128$; every interval of length $\pi\sqrt{2} = 4.4428829$ contained in $[2.7386128, +\infty)$ contains a zero of J_2 . Indeed $j_{2,1} = 5.1356223 \in [2.7386128; 7.1814957]$ and $j_{2,2} = 8.4172441 \in [5.1356223; 9.5785052]$. ✓ Moreover $j_{2,2} - j_{2,1} = 3.2816218 \geq \pi$, as required by Theorem 18.10(iv). (c) $f_{n,k} = \frac{120 j_{n,k}}{2\pi \cdot 0.30} = \frac{200}{\pi} j_{n,k}$: $f_{0,1} = 153.0959$ Hz, $f_{1,1} = 243.9340$ Hz, $f_{2,1} = 326.9439$ Hz, with ratios 1, 1.593341, 2.135549. A string with the same fundamental would give 153.0959, 306.1918, 459.2877 Hz: the drum is markedly "flatter" on the second mode and "sharper" in an irregular way on the third. (d) By Theorem 18.11, $\int_0^1 J_0(j_{0,2}r)^2 r dr = \frac{1}{2}J_1(j_{0,2})^2 = 0.0578900693$; Simpson's quadrature on 20 000 subintervals gives 0.0578900693. ✓

18.16. Chapter formulary

Polar Laplacian and harmonic modes.

$$\Delta u = U_{rr} + \frac{1}{r}U_r + \frac{1}{r^2}U_{\theta\theta} = \frac{1}{r}(rU_r)_r + \frac{1}{r^2}U_{\theta\theta}; \quad \det D\Phi = r, \quad dA = r dr d\theta.$$

Regular harmonic modes: $1, r^n \cos n\theta, r^n \sin n\theta$; discarded singular modes: $\ln r, r^{-n} \cos n\theta, r^{-n} \sin n\theta$. Radial harmonics: $A + B \ln r$. Euler's equation: $r^2 R'' + rR' - n^2 R = 0 \Rightarrow R = Ar^n + Br^{-n}$ ($n \geq 1$).

Dirichlet problem in the disc D_a .

$$u(r, \theta) = \sum_{n \in \mathbb{Z}} \hat{f}(n) \left(\frac{r}{a}\right)^{|n|} e^{in\theta} = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{a^2 - r^2}{a^2 - 2ar \cos(\theta - \varphi) + r^2} f(\varphi) d\varphi.$$

Mean value: $\frac{1}{2\pi} \int_{-\pi}^{\pi} u(r, \theta) d\theta = \hat{f}(0) = u(0)$. Maximum: $\max_{\overline{\Omega}} u = \max_{\partial\Omega} u$; uniqueness and stability: $\max_{\overline{\Omega}} |u_1 - u_2| = \max_{\partial\Omega} |f_1 - f_2|$.

Heat and waves on the circle.

$$u_t = \kappa u_{\theta\theta} : \quad u(\theta, t) = \sum_{n \in \mathbb{Z}} \hat{f}(n) e^{-\kappa n^2 t} e^{in\theta} = (f * H_t)(\theta), \quad H_t(\theta) = \frac{1}{2\pi} \sum_{n \in \mathbb{Z}} e^{-\kappa n^2 t} e^{in\theta}.$$

$$\|u(\cdot, t) - \hat{f}(0)\|_2 \leq e^{-\kappa t} \|f - \hat{f}(0)\|_2; \quad \min f \leq u \leq \max f.$$

$$u_{tt} = c^2 u_{\theta\theta} : \quad u(\theta, t) = \frac{F(\theta + ct) + F(\theta - ct)}{2} + \frac{1}{2c} \int_{\theta-ct}^{\theta+ct} G,$$

$$u = \hat{F}(0) + \hat{G}(0)t + \sum_{n \neq 0} \left(\hat{F}(n) \cos cnt + \frac{\hat{G}(n)}{cn} \sin cnt \right) e^{in\theta}, \quad E = \frac{1}{2} \int_{-\pi}^{\pi} (u_t^2 + c^2 u_{\theta}^2) = \text{const.}$$

Bessel.

$$x^2 y'' + xy' + (x^2 - n^2)y = 0; \quad J_n(x) = \sum_{k \geq 0} \frac{(-1)^k}{k! (n+k)!} \left(\frac{x}{2}\right)^{n+2k}.$$

$$(x^{-n} J_n)' = -x^{-n} J_{n+1}, \quad (x^n J_n)' = x^n J_{n-1}, \quad J_{n-1} + J_{n+1} = \frac{2n}{x} J_n, \quad J_0' = -J_1.$$

$$J_n(x) \sim \frac{1}{n!} \left(\frac{x}{2}\right)^n \quad (x \rightarrow 0); \quad w = \sqrt{x} J_n \Rightarrow w'' + \left(1 - \frac{n^2 - \frac{1}{4}}{x^2}\right) w = 0.$$

$$\int_0^1 J_n(j_{n,k} r) J_n(j_{n,l} r) r dr = \frac{\delta_{kl}}{2} J_{n+1}(j_{n,k})^2; \quad 2.40 < j_{0,1} < 2.41; \quad j_{n,k+1} - j_{n,k} \leq \pi\sqrt{2} \quad (j_{n,k} \geq x_n),$$

Membrane and heat in the disc D_a ; the numerical values of the chapter.

$$\lambda_{n,k} = \left(\frac{j_{n,k}}{a}\right)^2, \quad V_{n,k} = J_n\left(\frac{j_{n,k}}{a} r\right) e^{in\theta}, \quad f_{n,k} = \frac{c j_{n,k}}{2\pi a}, \quad t_{1/2} = \frac{a^2 \ln 2}{\kappa j_{0,1}^2}.$$

(n, k)	(0, 1)	(1, 1)	(2, 1)	(0, 2)	(3, 1)	(1, 2)	(2, 2)	(0, 3)
$j_{n,k}$	2.404826	3.831706	5.135622	5.520078	6.380162	7.015587	8.417244	8.653728
$j_{n,k}/j_{0,1}$	1.000000	1.593341	2.135549	2.295417	2.653066	2.917295	3.500147	3.598485
$j_{0,1}^2 = 5.7831860, \quad j_{1,1}^2 = 14.6819706, \quad j_{0,2}^2 = 30.4712623; \quad \frac{1}{2} J_1(j_{0,1})^2 = 0.1347570620.$								

Sources and bibliography

- [1] NIST Digital Library of Mathematical Functions, <https://dlmf.nist.gov/>, Chapter 10 "Bessel Functions", §10.2 "Definitions": equation 10.2.1 (Bessel's differential equation) and equation 10.2.2 (ascending series defining J_ν), source of Definition 18.6 and of Definition 18.7. Verified on 6 September 2026.
- [2] NIST Digital Library of Mathematical Functions, Chapter 10, §10.6 "Recurrence Relations and Derivatives": equations 10.6.1, 10.6.2 and 10.6.3 ($J_0' = -J_1$), compared with Proposition 18.11 (Observation 18.8). Verified on 6 September 2026.
- [3] NIST Digital Library of Mathematical Functions, Chapter 10, §10.7 "Limiting Forms": equations 10.7.1 ($J_0(z) \rightarrow 1$, $Y_0(z) \sim \frac{2}{\pi} \ln z$), 10.7.3 ($J_\nu(z) \sim (\frac{1}{2}z)^\nu / \Gamma(\nu+1)$) and 10.7.4 ($Y_\nu(z) \sim -\frac{1}{\pi} \Gamma(\nu) (\frac{1}{2}z)^{-\nu}$), cited in Observation 18.9 for the behaviour of the second solution. Verified on 6 September 2026.
- [4] NIST Digital Library of Mathematical Functions, Chapter 10, §10.21 "Zeros": §10.21(i) "Distribution" (notation $j_{\nu,m}$, simplicity and interlacing of the zeros, relation $j_{0,m}' = j_{1,m-1}$ for $m \geq 2$) and §10.21(vi) "McMahon's Asymptotic Expansions for Large Zeros", equation 10.21.19 with $\mu = 4\nu^2$ and $a = (m + \frac{\nu}{2} - \frac{1}{4})\pi$: this is the only *imported* part of the chapter, declared in Observation 18.13. **§10.21 does not contain any numerical table of zeros**: see Observation 18.12. Verified on 6 September 2026.
- [5] NIST Digital Library of Mathematical Functions, Chapter 10, §10.22 "Integrals": equation 10.22.37, orthogonality relation $\int_0^1 t J_\nu(j_{\nu,\ell} t) J_\nu(j_{\nu,m} t) dt = \frac{1}{2} (J_\nu'(j_{\nu,\ell}))^2 \delta_{\ell,m}$ for $\nu > -1$, compared with Theorem 18.11 (proved here independently for $\nu = n$ an integer). Verified on 6 September 2026.
- [6] NIST Digital Library of Mathematical Functions, Chapter 10, §10.23(iii) "Fourier–Bessel

Expansion": equations 10.23.18, 10.23.19 and 10.23.20 (hypothesis $\int_0^1 t^{1/2}|f(t)| dt < \infty$, coefficients a_m , convergence to the half-sum of the one-sided limits for f of bounded variation). This is the statement reported as an **imported panorama** in Observation 18.16. Verified on 6 September 2026.

- [7] NIST Digital Library of Mathematical Functions, Chapter 10, §10.75 "Tables", subsection "Real Zeros": catalogue of the published tables of the zeros $j_{n,m}$ — British Association for the Advancement of Science (1937), 10 decimal digits for $m \leq 150$; F. W. J. Olver (1960), 8 digits; M. Abramowitz and I. A. Stegun (1964), 5 digits (10 for $n = 0$); Heller (1976), 25 digits; Wills et al. (1982), 35 digits. Source of Observation 18.12. Verified on 6 September 2026.
- [8] G. N. Watson, *A Treatise on the Theory of Bessel Functions*, 2nd edition, Cambridge University Press, Cambridge, 1944. Chapter 18, on Fourier–Bessel and Dini series: this is the source to which the NIST DLMF refers for the proof of the expansion of §10.23(iii), i.e. for the panorama of Observation 18.16. The reference is the one explicitly given by the DLMF, §10.23(iii), verified on 6 September 2026; Watson’s volume was not consulted directly and no page number is attributed here.
- [9] W. A. Strauss, *Partial Differential Equations: An Introduction*, 2nd edition, John Wiley & Sons, Hoboken (New Jersey), 2008. Elementary reference treatment of separation of variables in the disc, the heat and wave equations, and the circular membrane. *Verification note*: the bibliographic data are those given in the drafting mandate; as of 6 September 2026 it was not possible to verify the volume’s table of contents online, and for this reason no chapter, section, or page number is cited. No statement of the chapter depends on this source.
- [10] L. C. Evans, *Partial Differential Equations*, 2nd edition, Graduate Studies in Mathematics, American Mathematical Society, Providence (Rhode Island), 2010. Advanced reference treatment of the elliptic and parabolic maximum principle and of the spectral theory of the Laplacian. *Verification note*: as for the previous entry, the bibliographic data are those given in the mandate; the table of contents could not be verified online as of 6 September 2026 and no chapter, section, or page number is cited. The proofs of Theorems 18.4 and 18.14 given here are self-contained and complete.
- [11] Internal references within the treatise: Chapter 17 for the Fourier coefficients (Definition 17.1), orthonormality (Proposition 17.1), L^2 convergence and Parseval’s identity (Theorem 17.1), uniform convergence (Theorem 17.5), and the Poisson kernel with Abel summation (Definition 17.4, Theorem 17.8); Chapter 16 for the Poisson formula and the Dirichlet problem in the disc; Chapter 12 for the circle as the quotient $\mathbb{R}/2\pi\mathbb{Z}$; Chapter 6 for the polar form and the powers z^n ; Chapter 15 for the Cauchy–Riemann equations and the harmonicity of the real part of a holomorphic function.
- [12] Numerical checks: all values in the chapter were recomputed with Python scripts executed on 6 September 2026, in three independent modes — ascending series in double precision with bisection and Newton’s method; multiple-precision arithmetic with 30 digits; exact rational arithmetic (**Fraction** class) for the enclosures of Proposition 18.13 and of Worked exercise 18.8. The discrepancies between the methods are reported in the text next to each value.

Part C

Transforms

The Fourier transform

The Fourier series decomposes a periodic function into a discrete sum of harmonics, because the circle $\mathbb{T}$ is compact and its dual is $\mathbb{Z}$. When the period grows without bound, the admissible frequencies become denser, the sum turns into an integral, and in place of a sequence of coefficients there appears a *function* of the frequency: the Fourier transform. The circle does not disappear in this passage, it hides inside it: the only ingredient of the definition is the character $t \mapsto e^{-2\pi i \xi t}$, that is, a point running around the unit circle at constant angular velocity, and every property of the transform — translation that becomes a phase factor, convolution that becomes a product, the Dirac comb that is its own transform — is a consequence of the functional equation $e^{i(\alpha+\beta)} = e^{i\alpha}e^{i\beta}$ that lives on the circle.

This chapter proves the theory from beginning to end, in *a single convention*, fixed in the box below and never abandoned. It starts from the well-posed definition of the transform on L^1 (Proposition 19.1, Theorem 19.1) and from the dictionary that translates the formulas into the other conventions in use (Remark 19.1); it proves the algebraic properties (Theorem 19.3), the two differentiation rules (Lemma 19.1 and Lemma 19.2), the convolution theorem (Theorem 19.4) with the corollary on autocorrelation (Corollary 19.1), and the Riemann–Lebesgue lemma (Theorem 19.5). Next come the three explicit computations that support everything else: the Gaussian (Theorem 19.6), the rectangle (Proposition 19.2), and the triangle, obtained by convolution (Proposition 19.3). On the Schwartz class we prove the inversion formula (Theorem 19.8), which is then extended to L^1 (Theorem 19.9), and the Plancherel theorem (Theorem 19.10); from there, periodization (Theorem 19.11), the Poisson summation formula (Theorem 19.12) with Jacobi’s identity (Corollary 19.5), and the uncertainty principle (Theorem 19.13) with the case of equality for the Gaussian. A separate section introduces *tempered distributions*, the delta and the Dirac comb (Theorem 19.14), never treating the delta as a function — indeed proving that it cannot be one (Proposition 19.8). The chapter closes with the table of transforms, of which *every row* is proved or derived from the preceding properties (Theorem 19.15).

The material that the executive plan moved here from Volume II (Chapter 4, §9) is preserved in full — heuristic remark, definition, statement, proof, worked example, figure, exercise and solution — in Section 19.2 and Section 19.14. That material uses the angular-frequency convention ω ; Remark 19.3 builds the bridge between the two notations, and Remark 19.4 states exactly which points of the inherited statement were left as a sketch and where they are proved in full.

INFO

Level and prerequisites. Level **C** (undergraduate), with two passages of level **D** (inversion on $\mathcal{S}$ with the Gaussian kernel, and the definition of the transform of a tempered distribution).

Internal prerequisites. Complex exponential, Euler’s formulas and polar form (Volume II, Chapter 3, and Chapter 6); Fourier series on the circle, coefficients, Parseval’s identity, uniqueness of the coefficients (Chapter 17, in particular Theorem 17.1 and Corollary 17.2); periodic convolution and summation kernels (Chapter 17, Definition 17.3 and Definition 17.4); integrals of complex-valued functions of a real variable (Volume II, Chapter 2).

External prerequisites, assumed and not reproved:

- Lebesgue measure theory on the line: measurability, integral, translation invariance and behaviour under dilation;
- Lebesgue's dominated convergence theorem and absolute continuity of the integral (if $g \in L^1$, then $\int_E |g| \rightarrow 0$ as $|E| \rightarrow 0$);
- Tonelli's and Fubini's theorems for measurable functions on $\mathbb{R}^2$;
- density of $C_c(\mathbb{R})$ (continuous functions of compact support) in $L^1(\mathbb{R})$, and density of the Schwartz class in $L^2(\mathbb{R})$;
- Riesz's theorem: from a sequence converging in L^1 one can extract a subsequence converging almost everywhere;
- the change-of-variables formula in polar coordinates in the plane;
- the Cauchy–Schwarz inequality in L^2 , with the case of equality.

Everything else is proved here.

What one learns. How to choose a convention and translate any formula into the others without getting the factors of 2π wrong; how to derive a new transform from a known one using translation, modulation, scaling and convolution instead of redoing the integral; how to compute the transform of the Gaussian in full by solving a first-order differential equation; why inversion needs a stable class of functions and how the Gaussian kernel produces it; how to read Plancherel as an isometry and Poisson as the equality between a sum in time and a sum in frequency; how to recognise that the Dirac delta is a functional and not a function, and how to work with it safely.

Warning. Conventions of this chapter.

- **A single convention.** Throughout the chapter, except in Section 19.2 and Section 19.14 (where the text inherited from Volume II is reported intact), the Fourier transform is

$$\hat{f}(\xi) = \int_{-\infty}^{+\infty} f(t) e^{-2\pi i \xi t} dt,$$

with exponent $-2\pi i \xi t$ and *no* factor in front of the integral. The variable t is time, ξ is *frequency* (cycles per unit of time), not the angular frequency. Remark 19.1 gives the dictionary for the other conventions.

- $\mathcal{F}f = \hat{f}$; $\mathcal{F}^{-1}h(x) = \int h(\xi) e^{2\pi i x \xi} d\xi$; $Rf(t) = f(-t)$ is the reflection, $\tau_h f(t) = f(t - h)$ the translation, $\bar{f}(t) = \overline{f(-t)}$.
- **Normalised sinc:** $\text{sinc } x = \frac{\sin \pi x}{\pi x}$ for $x \neq 0$ and $\text{sinc } 0 = 1$. *Warning:* in Section 19.2, which reproduces the text of Volume II, the *unnormalised* version $\text{sinc}(x) = \sin(x)/x$ appears instead; the two are related by $\text{sinc } x = \text{sinc}(\pi x)$ and must not be confused.
- $\Pi(t) = 1$ for $|t| < \frac{1}{2}$, $\Pi(\pm \frac{1}{2}) = \frac{1}{2}$, $\Pi(t) = 0$ elsewhere; $\Lambda(t) = \max(0, 1 - |t|)$; $u(t) = 1$ for $t > 0$ and 0 for $t < 0$ is the step function.
- $L^1 = L^1(\mathbb{R})$ and $L^2 = L^2(\mathbb{R})$ with respect to Lebesgue measure, $\|f\|_1 = \int |f|$, $\|f\|_2 = (\int |f|^2)^{1/2}$, $\|f\|_\infty = \sup |f|$; $\mathcal{S}$ is the Schwartz class (Definition 19.5) and $\mathcal{S}'$ the space of tempered distributions (Definition 19.7).
- All integrals without endpoints are taken over the whole of $\mathbb{R}$.
- Numerical values are rounded to the seventh decimal place and computed twice by independent methods: a closed formula and a Python script that was run.

19.1. A single convention, and the dictionary of the others

Definition 19.1: Fourier transform on $L^1(\mathbb{R})$. Let $f \in L^1(\mathbb{R})$. Its **Fourier transform** is the function $\hat{f} = \mathcal{F}f : \mathbb{R} \rightarrow \mathbb{C}$ defined by

$$\hat{f}(\xi) = \int_{-\infty}^{+\infty} f(t) e^{-2\pi i \xi t} dt, \quad \xi \in \mathbb{R}.$$

The function $\mathcal{F}^{-1}h(x) = \int h(\xi) e^{2\pi i x \xi} d\xi$, defined for $h \in L^1(\mathbb{R})$, is called the **inverse transform** (the name is justified by Theorem 19.8 and Theorem 19.9).

Proposition 19.1: The transform is well defined and bounded. For every $f \in L^1(\mathbb{R})$ and every $\xi \in \mathbb{R}$ the integral of Definition 19.1 converges absolutely, and

$$|\hat{f}(\xi)| \leq \|f\|_1 \quad \text{for every } \xi \in \mathbb{R}, \quad \text{that is} \quad \|\hat{f}\|_\infty \leq \|f\|_1.$$

Moreover $\mathcal{F}$ is linear: $\widehat{\alpha f + \beta g} = \alpha \hat{f} + \beta \hat{g}$ for $\alpha, \beta \in \mathbb{C}$ and $f, g \in L^1$.

Proof. For every t and every ξ we have $|e^{-2\pi i \xi t}| = 1$, because the modulus of $e^{i\theta}$ equals $\cos^2 \theta + \sin^2 \theta = 1$ for every real θ (Volume II, Chapter 3). Hence

$$|f(t)e^{-2\pi i \xi t}| = |f(t)|,$$

and the integrand has integrable modulus: the integral converges absolutely and defines a complex number. From the inequality between the modulus of an integral and the integral of the modulus,

$$|\hat{f}(\xi)| = \left| \int f(t) e^{-2\pi i \xi t} dt \right| \leq \int |f(t) e^{-2\pi i \xi t}| dt = \int |f(t)| dt = \|f\|_1,$$

and the bound does not depend on ξ , which is exactly $\|\hat{f}\|_\infty \leq \|f\|_1$. Linearity is the linearity of the integral: for $\alpha, \beta \in \mathbb{C}$,

$$\int (\alpha f(t) + \beta g(t)) e^{-2\pi i \xi t} dt = \alpha \int f(t) e^{-2\pi i \xi t} dt + \beta \int g(t) e^{-2\pi i \xi t} dt,$$

legitimate because both integrals on the right converge absolutely by the first part. $\square$

Theorem 19.1: $\hat{f}$ is uniformly continuous. If $f \in L^1(\mathbb{R})$, then $\hat{f}$ is uniformly continuous on $\mathbb{R}$.

Proof. Step 1 — a bound independent of ξ . For $\xi, h \in \mathbb{R}$,

$$\hat{f}(\xi + h) - \hat{f}(\xi) = \int f(t) (e^{-2\pi i (\xi + h)t} - e^{-2\pi i \xi t}) dt = \int f(t) e^{-2\pi i \xi t} (e^{-2\pi i h t} - 1) dt,$$

where $e^{-2\pi i \xi t}$ was factored out using $e^{-2\pi i (\xi + h)t} = e^{-2\pi i \xi t} e^{-2\pi i h t}$. Taking moduli and using $|e^{-2\pi i \xi t}| = 1$,

$$|\hat{f}(\xi + h) - \hat{f}(\xi)| \leq \int |f(t)| |e^{-2\pi i h t} - 1| dt =: \omega(h),$$

and the right-hand side *does not depend on ξ* .

Step 2 — $\omega(h) \rightarrow 0$ as $h \rightarrow 0$. Let (h_k) be any sequence with $h_k \rightarrow 0$. For each fixed t , $e^{-2\pi i h_k t} \rightarrow e^0 = 1$ by continuity of the exponential, so the integrand $|f(t)| |e^{-2\pi i h_k t} - 1|$ tends to 0 pointwise. Moreover

$$|f(t)| |e^{-2\pi i h_k t} - 1| \leq |f(t)| (|e^{-2\pi i h_k t}| + 1) = 2|f(t)|,$$

and $2|f| \in L^1$. By the dominated convergence theorem $\omega(h_k) \rightarrow 0$. Since the sequence was arbitrary, $\omega(h) \rightarrow 0$ as $h \rightarrow 0$.

Step 3 — conclusion. Given $\varepsilon > 0$, by Step 2 there is $\delta > 0$ such that $\omega(h) < \varepsilon$ for $|h| < \delta$; by Step 1, for every ξ and every $|h| < \delta$ we have $|\hat{f}(\xi + h) - \hat{f}(\xi)| < \varepsilon$. The δ does not depend on ξ : continuity is uniform. $\square$

Remark 19.1: The dictionary of conventions. Three conventions circulate in the literature, all legitimate, differing in the variable chosen (frequency ξ or angular frequency $\omega = 2\pi\xi$) and in how the factor 2π is split between the transform and the inverse transform. The table compares them and gives, row by row, the form each formula of the chapter takes in each of the three; in what follows we use only column (A).

	(A) frequency	(B) asym. ang. freq.	(C) sym. ang. freq.
transform	$\int f(t)e^{-2\pi i\xi t} dt$	$\int f(t)e^{-i\omega t} dt$	$\frac{1}{\sqrt{2\pi}} \int f(t)e^{-i\omega t} dt$
inverse transform	$\int \hat{f}(\xi)e^{2\pi i x \xi} d\xi$	$\frac{1}{2\pi} \int \hat{f}_B(\omega)e^{i\omega x} d\omega$	$\frac{1}{\sqrt{2\pi}} \int \hat{f}_C(\omega)e^{i\omega x} d\omega$
link with (A)	—	$\hat{f}_B(\omega) = \hat{f}\left(\frac{\omega}{2\pi}\right)$	$\hat{f}_C(\omega) = \frac{1}{\sqrt{2\pi}} \hat{f}\left(\frac{\omega}{2\pi}\right)$
Plancherel	$\ \hat{f}\ _2^2 = \ f\ _2^2$	$\frac{1}{2\pi} \ \hat{f}_B\ _2^2 = \ f\ _2^2$	$\ \hat{f}_C\ _2^2 = \ f\ _2^2$
convolution	$\widehat{f * g} = \hat{f}\hat{g}$	$\widehat{f * g}_B = \hat{f}_B\hat{g}_B$	$\widehat{f * g}_C = \sqrt{2\pi} \hat{f}_C\hat{g}_C$
derivative	$\widehat{f'} = 2\pi i\xi \hat{f}$	$\widehat{f'}_B = i\omega \hat{f}_B$	$\widehat{f'}_C = i\omega \hat{f}_C$
Gaussian $e^{-\pi t^2}$	$e^{-\pi \xi^2}$	$e^{-\omega^2/(4\pi)}$	$\frac{1}{\sqrt{2\pi}} e^{-\omega^2/(4\pi)}$

The rows “link with (A)” are read as follows: substituting $\omega = 2\pi\xi$ into definition (A) gives exactly (B), and (C) is (B) divided by $\sqrt{2\pi}$. Every other row follows mechanically from this. For example, for convolution in (C): $\widehat{f * g}_C(\omega) = \frac{1}{\sqrt{2\pi}} \widehat{f * g}_B(\omega) = \frac{1}{\sqrt{2\pi}} \hat{f}_B\hat{g}_B = \frac{1}{\sqrt{2\pi}} (\sqrt{2\pi} \hat{f}_C)(\sqrt{2\pi} \hat{g}_C) = \sqrt{2\pi} \hat{f}_C\hat{g}_C$. And for the Gaussian: from Theorem 19.6, $\hat{f}(\xi) = e^{-\pi\xi^2}$, so $\hat{f}_B(\omega) = e^{-\pi(\omega/2\pi)^2} = e^{-\omega^2/(4\pi)}$.

Convention (A) is the one for which the Fourier transform is an isometry of L^2 with no constants (Theorem 19.10), the Dirac comb of step 1 is its own transform (Theorem 19.14), and the Poisson formula carries no factors (Theorem 19.12): this is why we choose it. Convention (B) is the one used in signal engineering and is the one of the text inherited from Volume II (Section 19.2). It is worth noting that even a single source can use both: the NIST Digital Library of Mathematical Functions defines the transform in §1.14(i) with $\mathcal{F}f(x) = \frac{1}{2\pi} \int f(t)e^{ixt} dt$, while the Poisson summation formula of §1.8(iv), equation 1.8.14, is written with $e^{-2\pi i\pi t}$, that is, in our convention (A). This is why declaring the convention at the outset is not pedantry.

The section that follows is the text of Volume II (Chapter 4, §9), reported without removing or summarising anything. It is written in convention (B) of the table above, that is, in angular frequency ω : it should be read bearing the dictionary in mind, and in particular that its $\hat{f}(\omega)$ is our $\hat{f}(\omega/2\pi)$ and its sinc is the unnormalised one. Immediately afterwards, Remark 19.3 translates its main statement row by row into convention (A), and Remark 19.4 states where each point is proved in full.

19.2. From the series to the Fourier transform

The preceding sections deal with *periodic* functions, whose natural domain is the compact circle $\mathbb{T}$. Many signals of engineering interest — a pulse, a transient, the step response — are not periodic. The Fourier transform extends harmonic analysis to this case, and is obtained, heuristically, as the limit of the Fourier series as the period $T \rightarrow \infty$.

Remark 19.2: Heuristic of the limit $T \rightarrow \infty$. For a T -periodic function, the admissible frequencies are $\omega_n = 2\pi n/T$, equally spaced by $\Delta\omega = 2\pi/T$. Defining $\hat{f}_T(\omega_n) := Tc_n$ (where c_n are the Fourier coefficients of period T), the series $f(t) = \sum_n c_n e^{i\omega_n t} = \frac{1}{2\pi} \sum_n \hat{f}_T(\omega_n) e^{i\omega_n t} \Delta\omega$ becomes, as $T \rightarrow \infty$ (so that $\Delta\omega \rightarrow 0$ and the Riemann sum tends to an integral), exactly the transform/inverse-transform pair defined below.

Definition 19.2: Fourier transform. For $f : \mathbb{R} \rightarrow \mathbb{C}$ sufficiently regular (for example $f \in L^1(\mathbb{R})$):

$$\hat{f}(\omega) = \int_{-\infty}^{\infty} f(t) e^{-i\omega t} dt, \quad f(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \hat{f}(\omega) e^{i\omega t} d\omega.$$

Theorem 19.2: Fundamental properties of the Fourier transform. Let f, g be Fourier transformable, $a, t_0, \omega_0 \in \mathbb{R}$. Then:

1. (Linearity) $\widehat{(f + g)}(\omega) = \hat{f}(\omega) + \hat{g}(\omega)$.
2. (Translation) $\widehat{f(\cdot - t_0)}(\omega) = e^{-i\omega t_0} \hat{f}(\omega)$.
3. (Scaling) $\widehat{f(a \cdot)}(\omega) = \frac{1}{|a|} \hat{f}(\omega/a)$, $a \neq 0$.
4. (Convolution) $\widehat{(f * g)}(\omega) = \hat{f}(\omega) \hat{g}(\omega)$, where $(f * g)(t) = \int_{\mathbb{R}} f(\tau) g(t - \tau) d\tau$.
5. (Plancherel) $\int_{\mathbb{R}} |f(t)|^2 dt = \frac{1}{2\pi} \int_{\mathbb{R}} |\hat{f}(\omega)|^2 d\omega$.

Proof. (1) Immediate from the linearity of the integral. (2) With $u = t - t_0$: $\int f(t - t_0) e^{-i\omega t} dt = \int f(u) e^{-i\omega(u+t_0)} du = e^{-i\omega t_0} \hat{f}(\omega)$. (3) With $u = at$ (for $a > 0$; the case $a < 0$ is analogous with the endpoints reversed): $\int f(at) e^{-i\omega t} dt = \frac{1}{a} \int f(u) e^{-i\omega u/a} du = \frac{1}{|a|} \hat{f}(\omega/a)$. (4) $\int (f * g)(t) e^{-i\omega t} dt = \iint f(\tau) g(t - \tau) e^{-i\omega t} d\tau dt$; with $u = t - \tau$ this factors as $[\int f(\tau) e^{-i\omega \tau} d\tau] [\int g(u) e^{-i\omega u} du] = \hat{f}(\omega) \hat{g}(\omega)$. (5) This is the analogue, for non-periodic functions, of Parseval's theorem (Volume II, Chapter 4); it is proved by applying the inversion formula and interchanging the order of integration. $\square$

Worked example — transform of the rectangle function. Let $\Pi(t) = 1$ for $|t| < 1/2$ and $\Pi(t) = 0$ elsewhere. Then

$$\hat{\Pi}(\omega) = \int_{-1/2}^{1/2} e^{-i\omega t} dt = \left[\frac{e^{-i\omega t}}{-i\omega} \right]_{-1/2}^{1/2} = \frac{e^{-i\omega/2} - e^{i\omega/2}}{-i\omega} = \frac{-2i \sin(\omega/2)}{-i\omega} = \frac{\sin(\omega/2)}{\omega/2} = \text{sinc}(\omega/2),$$

with the convention $\text{sinc}(x) = \sin(x)/x$.

Figure 19.1: The Fourier transform of the rectangle $\Pi(t)$ is the function $\text{sinc}(\omega/2)$: a pulse narrow in time has a spectrum broad in frequency, and vice versa (time-frequency uncertainty principle).

Remark 19.3: The bridge between the ω convention and the ξ convention. Definition 19.2 above, inherited from Volume II, is column (B) of the table in Remark 19.1. Writing $\hat{f}_B$ for its transform and $\hat{f}$ for that of Definition 19.1, the substitution $\omega = 2\pi\xi$ in

the integral gives immediately

$$\hat{f}_B(\omega) = \int f(t)e^{-i\omega t} dt = \int f(t)e^{-2\pi i(\omega/2\pi)t} dt = \hat{f}\left(\frac{\omega}{2\pi}\right), \quad \text{that is} \quad \hat{f}(\xi) = \hat{f}_B(2\pi\xi).$$

Translated in this way, the five points of Theorem 19.2 become exactly:

- (1) linearity: identical, and this is Theorem 19.3(i) (already in Proposition 19.1);
- (2) translation: $e^{-i\omega t_0}$ becomes $e^{-2\pi i\xi t_0}$, and this is Theorem 19.3(ii);
- (3) scaling: the formula $\frac{1}{|a|}\hat{f}_B(\omega/a)$ is unchanged in form, and this is Theorem 19.3(iv);
- (4) convolution: identical, and this is Theorem 19.4;
- (5) Plancherel: the factor $\frac{1}{2\pi}$ of the writing in ω disappears in the writing in ξ , because $d\omega = 2\pi d\xi$; the statement with no constants is Theorem 19.10.

The worked example of the rectangle also translates: there one finds $\hat{\Pi}_B(\omega) = \text{sinc}(\omega/2) = \sin(\omega/2)/(\omega/2)$, and with $\omega = 2\pi\xi$ this is $\sin(\pi\xi)/(\pi\xi) = \text{sinc}\xi$, that is, Proposition 19.2. ✓
Numerical check at $\xi = \frac{1}{2}$ (that is, $\omega = \pi$): $\text{sinc}\frac{1}{2} = \frac{2}{\pi} = 0.6366198$, and Simpson quadrature of $\int_{-1/2}^{1/2} \cos(\pi t) dt$ with 200,000 subintervals gives 0.6366198. ✓

Remark 19.4: What the inherited text left as a sketch, and where it is completed.

The proof of Theorem 19.2, as it was written in Volume II, is complete for points (1)–(3); for point (4) it interchanges the order of integration without justifying it, and for point (5) it refers to the inversion formula with the sentence “it is proved by applying the inversion formula and interchanging the order of integration”, which is a sketch and not a proof. Nothing of this has been removed: here we only state where the two points are proved in full.

- The interchange in point (4) is justified by Tonelli’s theorem in Step 1 of the proof of Theorem 19.4, which verifies absolute integrability on $\mathbb{R}^2$ before applying Fubini.
- Point (5) is Theorem 19.10, proved on the Schwartz class with no circularity: the inversion formula (Theorem 19.8) is in turn proved earlier, and does not use Plancherel.
- The inversion formula itself, which Volume II states in Definition 19.2 as part of the “pair”, is a theorem, not a definition: without hypotheses on f the inversion integral may fail to converge. The case of the rectangle shows this: $\hat{\Pi} = \text{sinc}$ is not integrable (Proposition 19.4), and the inversion integral must be understood as a limit of integrals over $[-R, R]$.

19.3. Elementary properties: translation, modulation, scaling, conjugation

The properties that follow are all proved with a change of variable or a property of the complex exponential. They are not a list to memorise: they are the reason why, in the rest of the chapter, we will almost never compute a new integral.

Theorem 19.3: Algebraic properties of the transform. Let $f, g \in L^1(\mathbb{R})$, $\alpha, \beta \in \mathbb{C}$, $t_0, \xi_0 \in \mathbb{R}$ and $a \in \mathbb{R} \setminus \{0\}$. Then, for every $\xi \in \mathbb{R}$:

- (i) (linearity) $\alpha \widehat{f} + \beta \widehat{g}(\xi) = \alpha \hat{f}(\xi) + \beta \hat{g}(\xi)$;
- (ii) (translation) setting $\tau_{t_0} f(t) = f(t - t_0)$, $\widehat{\tau_{t_0} f}(\xi) = e^{-2\pi i \xi t_0} \hat{f}(\xi)$;
- (iii) (modulation) setting $m_{\xi_0} f(t) = e^{2\pi i \xi_0 t} f(t)$, $\widehat{m_{\xi_0} f}(\xi) = \hat{f}(\xi - \xi_0)$;
- (iv) (scaling) setting $d_a f(t) = f(at)$, $\widehat{d_a f}(\xi) = \frac{1}{|a|} \hat{f}\left(\frac{\xi}{a}\right)$;
- (v) (reflection) setting $Rf(t) = f(-t)$, $\widehat{Rf}(\xi) = \hat{f}(-\xi) = R\hat{f}(\xi)$;

(vi) (conjugation) $\widehat{\bar{f}}(\xi) = \overline{\widehat{f}(-\xi)}$.

In particular: if f is real, $\widehat{f}(-\xi) = \overline{\widehat{f}(\xi)}$ (Hermitian symmetry); if f is real and even, $\widehat{f}$ is real and even; if f is real and odd, $\widehat{f}$ is purely imaginary and odd.

Proof. All the functions involved lie in L^1 : for $\tau_{t_0}f$ and Rf by translation and reflection invariance of Lebesgue measure, for $d_a f$ because $\int |f(at)|dt = \frac{1}{|a|}\|f\|_1$, for $m_{\xi_0}f$ and $\bar{f}$ because they have the same modulus as f . Hence all the transforms written above exist by Proposition 19.1.

(i) This is the second part of Proposition 19.1.

(ii) With the substitution $u = t - t_0$ (a translation, $du = dt$):

$$\widehat{\tau_{t_0}f}(\xi) = \int f(t-t_0)e^{-2\pi i\xi t}dt = \int f(u)e^{-2\pi i\xi(u+t_0)}du = e^{-2\pi i\xi t_0} \int f(u)e^{-2\pi i\xi u}du = e^{-2\pi i\xi t_0} \widehat{f}(\xi),$$

where we used $e^{-2\pi i\xi(u+t_0)} = e^{-2\pi i\xi u}e^{-2\pi i\xi t_0}$ and pulled the factor constant in u out of the integral.

(iii) Directly, with no change of variable:

$$\widehat{m_{\xi_0}f}(\xi) = \int e^{2\pi i\xi_0 t} f(t)e^{-2\pi i\xi t}dt = \int f(t)e^{-2\pi i(\xi-\xi_0)t}dt = \widehat{f}(\xi - \xi_0).$$

(iv) First let $a > 0$ and set $u = at$, $du = a dt$; the endpoints $-\infty, +\infty$ keep their order:

$$\widehat{d_a f}(\xi) = \int f(at)e^{-2\pi i\xi t}dt = \frac{1}{a} \int f(u)e^{-2\pi i\xi u/a}du = \frac{1}{a} \widehat{f}\left(\frac{\xi}{a}\right).$$

If instead $a < 0$, the same substitution $u = at$ reverses the order of the endpoints ($t \rightarrow -\infty$ gives $u \rightarrow +\infty$), and restoring the natural order changes the sign:

$$\int f(at)e^{-2\pi i\xi t}dt = \frac{1}{a} \int_{+\infty}^{-\infty} f(u)e^{-2\pi i\xi u/a}du = -\frac{1}{a} \int_{-\infty}^{+\infty} f(u)e^{-2\pi i\xi u/a}du = \frac{1}{|a|} \widehat{f}\left(\frac{\xi}{a}\right),$$

because for $a < 0$ we have $-\frac{1}{a} = \frac{1}{|a|}$. The two cases combine into $1/|a|$.

(v) This is the case $a = -1$ of (iv): $\widehat{Rf}(\xi) = \frac{1}{|-1|} \widehat{f}(-\xi) = \widehat{f}(-\xi)$.

(vi) Using $\overline{e^{i\theta}} = e^{-i\theta}$ and the fact that conjugation commutes with the integral (because it is additive and commutes with limits):

$$\widehat{\bar{f}}(\xi) = \int \overline{f(t)}e^{-2\pi i\xi t}dt = \overline{\int f(t)e^{2\pi i\xi t}dt} = \overline{\int f(t)e^{-2\pi i(-\xi)t}dt} = \overline{\widehat{f}(-\xi)}.$$

Consequences. If f is real, $\bar{f} = f$, and (vi) gives $\widehat{f}(\xi) = \overline{\widehat{f}(-\xi)}$, that is, Hermitian symmetry. If moreover f is even, $Rf = f$ and (v) gives $\widehat{f}(\xi) = \widehat{f}(-\xi)$; combined with Hermitian symmetry, $\widehat{f}(\xi) = \widehat{\bar{f}}(\xi)$, hence $\widehat{f}$ is real (and even). If f is real and odd, $Rf = -f$ and (v) gives $\widehat{f}(-\xi) = -\widehat{f}(\xi)$; with Hermitian symmetry, $\widehat{f}(\xi) = \overline{\widehat{f}(-\xi)} = -\overline{\widehat{f}(\xi)} = -\widehat{f}(\xi)$, that is, $\widehat{f}(\xi) + \widehat{f}(\xi) = 0$: the real part vanishes and $\widehat{f}$ is purely imaginary (and odd). $\square$

Lemma 19.1: Differentiation in the time domain. Let $f : \mathbb{R} \rightarrow \mathbb{C}$ be of class C^1 with $f \in L^1(\mathbb{R})$ and $f' \in L^1(\mathbb{R})$. Then $f(t) \rightarrow 0$ as $|t| \rightarrow \infty$ and

$$\widehat{f'}(\xi) = 2\pi i\xi \widehat{f}(\xi) \quad \text{for every } \xi \in \mathbb{R}.$$

More generally, if $f \in C^k$ and $f, f', \dots, f^{(k)} \in L^1$, then $\widehat{f^{(k)}}(\xi) = (2\pi i \xi)^k \hat{f}(\xi)$ and hence

$$|\hat{f}(\xi)| \leq \frac{\|f^{(k)}\|_1}{(2\pi|\xi|)^k} \quad \text{for } \xi \neq 0.$$

Proof. Step 1 — f has limit 0 at infinity. Since $f \in C^1$, the fundamental theorem of calculus gives $f(T) = f(0) + \int_0^T f'(s) ds$ for every T . Since $f' \in L^1$, the integral $\int_0^T f'$ converges as $T \rightarrow +\infty$ (the function $T \mapsto \int_0^T |f'|$ is increasing and bounded by $\|f'\|_1$, hence the integral of f' converges absolutely). There is thus $L_+ = \lim_{T \rightarrow +\infty} f(T)$. If $L_+ \neq 0$, there would be T_0 with $|f(t)| \geq \frac{|L_+|}{2} > 0$ for every $t \geq T_0$, and then $\int_{T_0}^{+\infty} |f| = +\infty$, contradicting $f \in L^1$. Hence $L_+ = 0$; symmetrically $L_- = \lim_{T \rightarrow -\infty} f(T) = 0$.

Step 2 — integration by parts. The function $t \mapsto f(t)e^{-2\pi i \xi t}$ is of class C^1 and, by the product rule and $\frac{d}{dt}(e^{-2\pi i \xi t}) = -2\pi i \xi e^{-2\pi i \xi t}$,

$$\frac{d}{dt}(f(t)e^{-2\pi i \xi t}) = f'(t)e^{-2\pi i \xi t} - 2\pi i \xi f(t)e^{-2\pi i \xi t}.$$

Integrating this identity over $[-T, T]$ (the fundamental theorem of calculus, applied separately to the real and imaginary parts) and moving the second term to the right:

$$\int_{-T}^T f'(t)e^{-2\pi i \xi t} dt = \left[f(t)e^{-2\pi i \xi t} \right]_{-T}^T + 2\pi i \xi \int_{-T}^T f(t)e^{-2\pi i \xi t} dt.$$

The computation holds for every $\xi \in \mathbb{R}$, including $\xi = 0$, because we never divided by ξ .

Step 3 — the limit $T \rightarrow +\infty$. The boundary term equals $f(T)e^{-2\pi i \xi T} - f(-T)e^{2\pi i \xi T}$ and has modulus $\leq |f(T)| + |f(-T)| \rightarrow 0$ by Step 1. The two integrals converge to $\hat{f}'(\xi)$ and $\hat{f}(\xi)$ because f' and f lie in L^1 (Proposition 19.1). Passing to the limit, $\hat{f}'(\xi) = 2\pi i \xi \hat{f}(\xi)$.

Step 4 — iteration and estimate. If $f \in C^k$ with all derivatives up to order k in L^1 , apply Step 3 to f , then to f' , and so on: by induction on j , $\widehat{f^{(j)}}(\xi) = (2\pi i \xi)^j \hat{f}(\xi)$, since at each step the hypotheses “ $f^{(j)} \in C^1$, $f^{(j)} \in L^1$, $f^{(j+1)} \in L^1$ ” are satisfied. For $j = k$ and $\xi \neq 0$, taking moduli and using $|(2\pi i \xi)^k| = (2\pi|\xi|)^k$ and $|\widehat{f^{(k)}}(\xi)| \leq \|f^{(k)}\|_1$ (Proposition 19.1), one obtains $|\hat{f}(\xi)| \leq \|f^{(k)}\|_1 / (2\pi|\xi|)^k$. $\square$

Lemma 19.2: Differentiation in the frequency domain. Let $f \in L^1(\mathbb{R})$ be such that $t \mapsto tf(t)$ also belongs to $L^1(\mathbb{R})$. Then $\hat{f}$ is differentiable on all of $\mathbb{R}$, its derivative is continuous and

$$\frac{d}{d\xi} \hat{f}(\xi) = (-\widehat{2\pi i t f(t)})(\xi), \quad \text{equivalently} \quad \widehat{(tf(t))}(\xi) = \frac{i}{2\pi} \hat{f}'(\xi).$$

More generally, if $t^j f(t) \in L^1$ for $j = 0, 1, \dots, n$, then $\hat{f} \in C^n$ and $\hat{f}^{(n)}(\xi) = ((-2\pi i t)^n \widehat{f(t)}) (\xi)$.

Proof. Step 0 — an elementary inequality. For every $\theta \in \mathbb{R}$,

$$|e^{i\theta} - 1| = \left| \int_0^\theta i e^{is} ds \right| \leq \left| \int_0^\theta |i e^{is}| ds \right| = |\theta|.$$

Step 1 — the difference quotient. For $h \neq 0$,

$$\frac{\hat{f}(\xi + h) - \hat{f}(\xi)}{h} = \int f(t) e^{-2\pi i \xi t} \frac{e^{-2\pi i h t} - 1}{h} dt,$$

with the same factoring as in Step 1 of the proof of Theorem 19.1.

Step 2 — pointwise limit of the integrand. For fixed t ,

$$\lim_{h \rightarrow 0} \frac{e^{-2\pi i h t} - 1}{h} = \frac{d}{ds} \left(e^{-2\pi i s t} \right) \Big|_{s=0} = -2\pi i t,$$

so the integrand tends pointwise to $-2\pi i t f(t) e^{-2\pi i \xi t}$.

Step 3 — domination. By Step 0 with $\theta = -2\pi h t$,

$$\left| \frac{e^{-2\pi i h t} - 1}{h} \right| \leq \frac{2\pi |h| |t|}{|h|} = 2\pi |t|,$$

hence the modulus of the integrand is $\leq 2\pi |t| |f(t)|$, which by hypothesis is in L^1 and does not depend on h .

Step 4 — conclusion. Taking any sequence $h_k \rightarrow 0$, the dominated convergence theorem gives

$$\lim_k \frac{\hat{f}(\xi + h_k) - \hat{f}(\xi)}{h_k} = \int (-2\pi i t) f(t) e^{-2\pi i \xi t} dt = (\widehat{-2\pi i t f(t)})(\xi),$$

and since the limit does not depend on the sequence, $\hat{f}$ is differentiable at ξ with that derivative. The derivative is the transform of the function $-2\pi i t f(t) \in L^1$, hence it is continuous by Theorem 19.1. The general case is obtained by induction on n : if $t^j f \in L^1$ for $j \leq n$, apply what has just been proved to the function $(-2\pi i t)^{n-1} f(t)$, which lies in L^1 and for which $t \cdot (-2\pi i t)^{n-1} f(t)$ also lies in L^1 . $\square$

***Remark 19.5: Regularity and decay are in balance.** The two preceding lemmas are mirror images of each other, and together they state the fundamental law of Fourier analysis: the more regular f is, the more $\hat{f}$ decays (Lemma 19.1: k integrable derivatives give $|\hat{f}(\xi)| = O(|\xi|^{-k})$), and the more f decays, the more regular $\hat{f}$ is (Lemma 19.2: n finite moments give $\hat{f} \in C^n$). The uncertainty principle (Theorem 19.13) is the quantitative, L^2 version of this balance, and the Schwartz class (Definition 19.5) is the point of equilibrium where both requirements are infinite and the transform never leaves the class.*

19.4. Convolution and autocorrelation

Definition 19.3: Convolution, conjugate reflection, autocorrelation. For measurable $f, g : \mathbb{R} \rightarrow \mathbb{C}$ one sets, when the integral converges absolutely,

$$(f * g)(t) = \int f(\tau) g(t - \tau) d\tau.$$

One also sets $\tilde{f}(t) = \overline{f(-t)}$ (the **conjugate reflection**) and calls the **autocorrelation** of f the function

$$R_f(t) = \int f(s + t) \overline{f(s)} ds.$$

Theorem 19.4: Convolution theorem. Let $f, g \in L^1(\mathbb{R})$. Then:

- (i) for almost every $t \in \mathbb{R}$ the integral defining $(f * g)(t)$ converges absolutely;
- (ii) $f * g \in L^1(\mathbb{R})$ and $\|f * g\|_1 \leq \|f\|_1 \|g\|_1$;
- (iii) $f * g = g * f$ almost everywhere;
- (iv) $\widehat{f * g}(\xi) = \hat{f}(\xi) \hat{g}(\xi)$ for every $\xi \in \mathbb{R}$.

Proof. Step 1 — Tonelli. The function $(t, \tau) \mapsto f(\tau)g(t - \tau)$ is measurable on $\mathbb{R}^2$: $(t, \tau) \mapsto f(\tau)$ is measurable because f is measurable and the projection is continuous, and $(t, \tau) \mapsto g(t - \tau)$ is the composition of g with the linear map $(t, \tau) \mapsto t - \tau$, which preserves Lebesgue measurability, being surjective and linear. Its modulus is non-negative, so by Tonelli's theorem one may integrate in whichever order one likes:

$$\iint |f(\tau)| |g(t - \tau)| dt d\tau = \int |f(\tau)| \left(\int |g(t - \tau)| dt \right) d\tau = \int |f(\tau)| \|g\|_1 d\tau = \|f\|_1 \|g\|_1 < \infty,$$

where the inner integral equals $\|g\|_1$ by translation invariance of Lebesgue measure.

Step 2 — (i) and (ii). Since the double integral of the modulus is finite, by Tonelli's theorem the function $t \mapsto \int |f(\tau)| |g(t - \tau)| d\tau$ is finite for almost every t and has integral $\leq \|f\|_1 \|g\|_1$: this is (i), and together with it

$$\|f * g\|_1 = \int \left| \int f(\tau)g(t - \tau) d\tau \right| dt \leq \iint |f(\tau)| |g(t - \tau)| d\tau dt = \|f\|_1 \|g\|_1,$$

that is, (ii).

Step 3 — (iii). For the t at which the integral converges absolutely, the substitution $\sigma = t - \tau$ (that is, $\tau = t - \sigma$, $d\tau = -d\sigma$ with the endpoints swapped) gives $\int f(\tau)g(t - \tau) d\tau = \int f(t - \sigma)g(\sigma) d\sigma = (g * f)(t)$.

Step 4 — (iv). By Step 1 the function $(t, \tau) \mapsto f(\tau)g(t - \tau)e^{-2\pi i \xi t}$ has modulus $|f(\tau)| |g(t - \tau)|$ integrable on $\mathbb{R}^2$: Fubini's theorem authorises the interchange. Writing $e^{-2\pi i \xi t} = e^{-2\pi i \xi \tau} e^{-2\pi i \xi (t - \tau)}$,

$$\begin{aligned} \widehat{f * g}(\xi) &= \int \left(\int f(\tau)g(t - \tau) d\tau \right) e^{-2\pi i \xi t} dt \\ &= \int f(\tau) e^{-2\pi i \xi \tau} \left(\int g(t - \tau) e^{-2\pi i \xi (t - \tau)} dt \right) d\tau \\ &= \int f(\tau) e^{-2\pi i \xi \tau} \hat{g}(\xi) d\tau = \hat{f}(\xi) \hat{g}(\xi), \end{aligned}$$

where in the inner integral we set $u = t - \tau$ (τ fixed), obtaining $\int g(u) e^{-2\pi i \xi u} du = \hat{g}(\xi)$, independent of τ . $\square$

Corollary 19.1: Autocorrelation and energy spectrum. Let $f \in L^1(\mathbb{R})$. Then $\tilde{f} \in L^1(\mathbb{R})$, $R_f = f * \tilde{f}$ almost everywhere, and

$$\widehat{\tilde{f}}(\xi) = \overline{\hat{f}(\xi)}, \quad \widehat{R_f}(\xi) = |\hat{f}(\xi)|^2.$$

If moreover $f \in L^2(\mathbb{R})$, then $R_f(0) = \|f\|_2^2$.

Proof. Step 1 — $\tilde{f} \in L^1$. $|\tilde{f}(t)| = |f(-t)|$ and reflection preserves Lebesgue measure, hence $\|\tilde{f}\|_1 = \|f\|_1 < \infty$.

Step 2 — $R_f = f * \tilde{f}$. By definition,

$$(f * \tilde{f})(t) = \int f(\tau) \tilde{f}(t - \tau) d\tau = \int f(\tau) \overline{f(\tau - t)} d\tau,$$

having used $\tilde{f}(t - \tau) = \overline{f(-(t - \tau))} = \overline{f(\tau - t)}$. With the substitution $\tau = s + t$ ($d\tau = ds$) this becomes $\int f(s + t) \overline{f(s)} ds = R_f(t)$. By Theorem 19.4(i) the integral converges absolutely for almost every t .

Step 3 — the transform of $\tilde{f}$. With $u = -t$,

$$\widehat{\tilde{f}}(\xi) = \int \overline{f(-t)} e^{-2\pi i \xi t} dt = \int \overline{f(u)} e^{2\pi i \xi u} du = \overline{\int f(u) e^{-2\pi i \xi u} du} = \overline{\hat{f}(\xi)},$$

where the conjugation was pulled out of the integral as in point (vi) of Theorem 19.3.

Step 4 — conclusion. By Theorem 19.4(iv) and Step 3, $\widehat{R_f}(\xi) = \widehat{f * \tilde{f}}(\xi) = \hat{f}(\xi) \overline{\hat{f}(\xi)} = |\hat{f}(\xi)|^2$. Finally, if $f \in L^2$, $R_f(0) = \int f(s) \overline{f(s)} ds = \int |f(s)|^2 ds = \|f\|_2^2$, a finite integral precisely because $f \in L^2$. $\square$

19.5. The Riemann–Lebesgue lemma

Proposition 19.1 says that $\hat{f}$ is bounded and Theorem 19.1 that it is continuous. The result of this section adds the missing piece of information: $\hat{f}$ vanishes at infinity. A preliminary lemma is needed, the continuity of translations in L^1 , which will also be useful later on (Lemma 19.7).

Lemma 19.3: Continuity of translations in L^1 . Let $f \in L^1(\mathbb{R})$ and $\tau_h f(t) = f(t - h)$. Then $\lim_{h \rightarrow 0} \|\tau_h f - f\|_1 = 0$.

Proof. Let $\varepsilon > 0$.

Step 1 — approximation by a continuous function of compact support. By the density of $C_c(\mathbb{R})$ in $L^1(\mathbb{R})$ (a declared prerequisite) there is $g \in C_c(\mathbb{R})$ with $\|f - g\|_1 < \frac{\varepsilon}{3}$. Let $[-M, M]$ be an interval containing the support of g .

Step 2 — the estimate for g . g is continuous with compact support, hence uniformly continuous on $\mathbb{R}$: there is $\delta \in (0, 1]$ such that $|g(s) - g(s')| < \frac{\varepsilon}{3(2M+2)}$ whenever $|s - s'| < \delta$. For $|h| < \delta \leq 1$ the function $\tau_h g - g$ vanishes outside $[-M-1, M+1]$, of length $2M+2$, hence

$$\|\tau_h g - g\|_1 = \int_{-M-1}^{M+1} |g(t-h) - g(t)| dt \leq (2M+2) \cdot \frac{\varepsilon}{3(2M+2)} = \frac{\varepsilon}{3}.$$

Step 3 — the triangle inequality. By translation invariance of Lebesgue measure, $\|\tau_h(f - g)\|_1 = \|f - g\|_1$. Hence, for $|h| < \delta$,

$$\|\tau_h f - f\|_1 \leq \|\tau_h f - \tau_h g\|_1 + \|\tau_h g - g\|_1 + \|g - f\|_1 < \frac{\varepsilon}{3} + \frac{\varepsilon}{3} + \frac{\varepsilon}{3} = \varepsilon.$$

Since ε was arbitrary, the limit is 0. $\square$

Theorem 19.5: Riemann–Lebesgue lemma. Let $f \in L^1(\mathbb{R})$. Then $\lim_{|\xi| \rightarrow \infty} \hat{f}(\xi) = 0$.

Proof. **Step 1 — the half-period trick.** Let $\xi \neq 0$ and set $h = \frac{1}{2\xi}$. Then

$$e^{-2\pi i \xi h} = e^{-2\pi i \xi \cdot \frac{1}{2\xi}} = e^{-\pi i} = -1.$$

With the substitution $t = u + h$ in the integral defining $\hat{f}$,

$$\hat{f}(\xi) = \int f(u+h) e^{-2\pi i \xi (u+h)} du = e^{-2\pi i \xi h} \int f(u+h) e^{-2\pi i \xi u} du = - \int f(u+h) e^{-2\pi i \xi u} du.$$

Step 2 — averaging the two expressions. Adding this equality to the definition $\hat{f}(\xi) = \int f(t) e^{-2\pi i \xi t} dt$ gives

$$2\hat{f}(\xi) = \int [f(t) - f(t+h)] e^{-2\pi i \xi t} dt,$$

and taking moduli (with $|e^{-2\pi i \xi t}| = 1$)

$$|\hat{f}(\xi)| \leq \frac{1}{2} \int |f(t) - f(t+h)| dt = \frac{1}{2} \|\tau_{-h}f - f\|_1.$$

Step 3 — conclusion. As $|\xi| \rightarrow \infty$ we have $h = \frac{1}{2\xi} \rightarrow 0$, hence $-h \rightarrow 0$ and by Lemma 19.3 $\|\tau_{-h}f - f\|_1 \rightarrow 0$. Therefore $|\hat{f}(\xi)| \rightarrow 0$. $\square$

Remark 19.6: Riemann–Lebesgue gives no rate. Theorem 19.5 guarantees vanishing at infinity but no rate: for every sequence $\varepsilon_n \downarrow 0$ there exist functions $f \in L^1$ whose transform decays more slowly than ε_n . A rate is bought only with regularity, and this is Lemma 19.1: k integrable derivatives give $O(|\xi|^{-k})$. The rectangle Π illustrates this well: it is not continuous, and its transform sinc decays like $|\xi|^{-1}$, just enough to tend to zero and not enough to be integrable (Proposition 19.4). The triangle Λ is continuous with derivative of bounded variation, and its transform sinc^2 decays like $|\xi|^{-2}$: integrable.

19.6. The Gaussian, computed in full

Lemma 19.4: The normalised Gauss integral. $\int_{-\infty}^{+\infty} e^{-\pi t^2} dt = 1$.

Proof. Step 1 — finiteness. For $|t| \geq 1$ we have $t^2 \geq |t|$, hence $e^{-\pi t^2} \leq e^{-\pi|t|}$, which is integrable on $\{|t| \geq 1\}$ with integral $\frac{2}{\pi}e^{-\pi}$; on $[-1, 1]$ the function is continuous and bounded by 1. Hence $I := \int e^{-\pi t^2} dt$ is finite, and $I > 0$ because the integrand is positive.

Step 2 — the square as a double integral. The integrand is non-negative and measurable, so by Tonelli's theorem

$$I^2 = \left(\int e^{-\pi x^2} dx \right) \left(\int e^{-\pi y^2} dy \right) = \iint_{\mathbb{R}^2} e^{-\pi(x^2+y^2)} dx dy.$$

Step 3 — polar coordinates. With $x = \rho \cos \theta$, $y = \rho \sin \theta$, $\rho \in [0, +\infty)$, $\theta \in [0, 2\pi)$, whose Jacobian is ρ (a declared prerequisite) and for which $x^2 + y^2 = \rho^2$:

$$I^2 = \int_0^{2\pi} \int_0^{+\infty} e^{-\pi \rho^2} \rho d\rho d\theta = 2\pi \int_0^{+\infty} e^{-\pi \rho^2} \rho d\rho.$$

The antiderivative of $\rho e^{-\pi \rho^2}$ is $-\frac{1}{2\pi} e^{-\pi \rho^2}$, hence

$$\int_0^{+\infty} e^{-\pi \rho^2} \rho d\rho = \left[-\frac{e^{-\pi \rho^2}}{2\pi} \right]_0^{+\infty} = 0 - \left(-\frac{1}{2\pi} \right) = \frac{1}{2\pi},$$

and hence $I^2 = 2\pi \cdot \frac{1}{2\pi} = 1$. Since $I > 0$, $I = 1$.

Independent check. Composite Simpson quadrature on $[-12, 12]$ with 200,000 subintervals: 1.0000000 (the excluded tail is worth less than $2 \int_{12}^{\infty} e^{-\pi t^2} dt < 10^{-16}$). $\checkmark$ $\square$

Lemma 19.5: The second moment of the Gaussian. For every $b > 0$,

$$\int_{-\infty}^{+\infty} e^{-\pi b t^2} dt = \frac{1}{\sqrt{b}}, \quad \int_{-\infty}^{+\infty} t^2 e^{-\pi b t^2} dt = \frac{1}{2\pi b^{3/2}}.$$

Proof. Step 1 — the first integral. With the substitution $u = \sqrt{b}t$, $du = \sqrt{b}dt$, and Lemma 19.4: $\int e^{-\pi b t^2} dt = \frac{1}{\sqrt{b}} \int e^{-\pi u^2} du = \frac{1}{\sqrt{b}}$.

Step 2 — differentiating under the integral sign. Let $\Phi(b) = \int e^{-\pi b t^2} dt$ for $b > 0$. Fix $b_0 > 0$ and set $b \in [\frac{b_0}{2}, 2b_0]$; the difference quotient in b of the integrand equals, by the mean value theorem applied to $b \mapsto e^{-\pi b t^2}$, $-\pi t^2 e^{-\pi \beta t^2}$ for some β between b and b_0 , hence bounded in modulus by $\pi t^2 e^{-\pi b_0 t^2/2}$, an integrable function independent of b . By the dominated convergence theorem one may differentiate under the integral sign:

$$\Phi'(b) = \int \frac{\partial}{\partial b} e^{-\pi b t^2} dt = -\pi \int t^2 e^{-\pi b t^2} dt.$$

Step 3 — conclusion. From Step 1, $\Phi(b) = b^{-1/2}$, hence $\Phi'(b) = -\frac{1}{2}b^{-3/2}$. Equating, $-\pi \int t^2 e^{-\pi b t^2} dt = -\frac{1}{2}b^{-3/2}$, that is, $\int t^2 e^{-\pi b t^2} dt = \frac{1}{2\pi b^{3/2}}$.

Independent check. For $b = 2$ the formula gives $\frac{1}{2\pi \cdot 2^{3/2}} = \frac{1}{4\sqrt{2}\pi} = 0.0562700$; multiplied by $\sqrt{2}$ (the normalising constant used in Theorem 19.13) this gives $\frac{1}{4\pi} = 0.0795775$, and Simpson quadrature of $\int \sqrt{2} t^2 e^{-2\pi t^2} dt$ on $[-12, 12]$ with 200,000 subintervals gives 0.0795775. ✓ □

Theorem 19.6: The Gaussian is its own transform. Let $g(t) = e^{-\pi t^2}$. Then $g \in L^1(\mathbb{R})$ and

$$\hat{g}(\xi) = e^{-\pi \xi^2} = g(\xi) \quad \text{for every } \xi \in \mathbb{R}.$$

Proof. Step 1 — the hypotheses of the two differentiation lemmas. g is of class C^∞ , $g \in L^1$ by Lemma 19.4, and $g'(t) = -2\pi t e^{-\pi t^2}$. The function $t \mapsto tg(t)$ is continuous, hence integrable on $[-1, 1]$; for $|t| \geq 1$ we have $t^2 \geq |t|$ and hence $|t|e^{-\pi t^2} \leq |t|e^{-\pi|t|}$, which is integrable on $\{|t| \geq 1\}$. Hence $tg(t) \in L^1$ and, since $g' = -2\pi tg$, also $g' \in L^1$. The hypotheses of Lemma 19.1 and Lemma 19.2 are thus satisfied.

Step 2 — the differential equation in the time domain. Applying Lemma 19.1 to g :

$$\widehat{g'}(\xi) = 2\pi i \xi \hat{g}(\xi).$$

On the other hand $g'(t) = -2\pi t g(t)$, so by linearity $\widehat{g'}(\xi) = -2\pi \widehat{(tg(t))}(\xi)$. Equating,

$$\widehat{(tg(t))}(\xi) = -i\xi \hat{g}(\xi). \quad (*)$$

Step 3 — the differential equation in the frequency domain. Applying Lemma 19.2 to g :

$$\hat{g'}(\xi) = \widehat{(-2\pi i t g(t))}(\xi) = -2\pi i \widehat{(tg(t))}(\xi) \stackrel{(*)}{=} -2\pi i \cdot (-i\xi \hat{g}(\xi)) = 2\pi i^2 \xi \hat{g}(\xi) = -2\pi \xi \hat{g}(\xi).$$

Step 4 — the initial datum. $\hat{g}(0) = \int e^{-\pi t^2} dt = 1$ by Lemma 19.4.

Step 5 — solving the equation. Let $\Psi(\xi) = \hat{g}(\xi)e^{\pi \xi^2}$. By Step 3, Ψ is differentiable and

$$\Psi'(\xi) = \hat{g'}(\xi)e^{\pi \xi^2} + \hat{g}(\xi) \cdot 2\pi \xi e^{\pi \xi^2} = e^{\pi \xi^2} \left(-2\pi \xi \hat{g}(\xi) + 2\pi \xi \hat{g}(\xi) \right) = 0$$

for every $\xi \in \mathbb{R}$. A complex-valued function with derivative identically zero on $\mathbb{R}$ is constant (its real and imaginary parts are), hence $\Psi(\xi) = \Psi(0) = \hat{g}(0) = 1$, that is, $\hat{g}(\xi) = e^{-\pi \xi^2}$.

Independent check. Simpson quadrature on $[-12, 12]$ with 200,000 subintervals of $\int e^{-\pi t^2} \cos(2\pi \xi t) dt$ (the imaginary part is zero because g is real and even, Theorem 19.3): for $\xi = \frac{1}{2}$ one obtains $0.4559381 = e^{-\pi/4}$; for $\xi = 1$, $0.0432139 = e^{-\pi}$; for $\xi = 2$, $0.0000035 = e^{-4\pi}$. The computed imaginary parts are less than 10^{-16} . ✓ □

Corollary 19.2: Gaussian of arbitrary width. For every $a > 0$,

$$\widehat{(e^{-\pi at^2})}(\xi) = \frac{1}{\sqrt{a}} e^{-\pi \xi^2/a}.$$

In particular, in the parametrisation used in probability,

$$\widehat{(e^{-t^2/(2\sigma^2)})}(\xi) = \sigma\sqrt{2\pi} e^{-2\pi^2\sigma^2\xi^2} \quad (\sigma > 0).$$

Proof. We have $e^{-\pi at^2} = g(\sqrt{a}t) = d_{\sqrt{a}}g(t)$ with $g(t) = e^{-\pi t^2}$, because $\pi(\sqrt{a}t)^2 = \pi at^2$. By Theorem 19.3(iv) with $a \rightsquigarrow \sqrt{a} > 0$ and by Theorem 19.6,

$$\widehat{d_{\sqrt{a}}g}(\xi) = \frac{1}{\sqrt{a}} \hat{g}\left(\frac{\xi}{\sqrt{a}}\right) = \frac{1}{\sqrt{a}} e^{-\pi \xi^2/a}.$$

For the second formula it suffices to identify a : $e^{-t^2/(2\sigma^2)} = e^{-\pi at^2}$ requires $\pi a = \frac{1}{2\sigma^2}$, that is, $a = \frac{1}{2\pi\sigma^2}$. Then $\frac{1}{\sqrt{a}} = \sigma\sqrt{2\pi}$ and $\frac{\pi\xi^2}{a} = \pi\xi^2 \cdot 2\pi\sigma^2 = 2\pi^2\sigma^2\xi^2$.

Independent check. For $a = \delta^{-2}$ one obtains the formula $\widehat{(e^{-\pi t^2/\delta^2})}(\xi) = \delta e^{-\pi\delta^2\xi^2}$, which is the relation used in Lemma 19.7. For $\sigma = 1$ and $\xi = 0$ the second formula gives $\sqrt{2\pi} = 2.5066283$, and the quadrature of $\int e^{-t^2/2} dt$ on $[-16, 16]$ with 200,000 subintervals gives 2.5066283. ✓

19.7. Rectangle, sinc function, and triangle

Definition 19.4: Rectangle, triangle, sinc function. One sets

$$\Pi(t) = \begin{cases} 1 & |t| < \frac{1}{2}, \\ \frac{1}{2} & |t| = \frac{1}{2}, \\ 0 & |t| > \frac{1}{2}, \end{cases} \quad \Lambda(t) = \max(0, 1 - |t|), \quad \text{sinc } x = \begin{cases} \frac{\sin \pi x}{\pi x} & x \neq 0, \\ 1 & x = 0. \end{cases}$$

Π is the **rectangle function** (or window) of width 1, Λ the **triangle function** of base 2, sinc the **normalised sinc function**.

Proposition 19.2: Transform of the rectangle. $\widehat{\Pi}(\xi) = \text{sinc } \xi$ for every $\xi \in \mathbb{R}$.

Proof. $\Pi \in L^1$ with $\|\Pi\|_1 = 1$ (the value at $\pm\frac{1}{2}$ does not affect the integral, being attained on a set of measure zero).

Case $\xi = 0$. $\widehat{\Pi}(0) = \int_{-1/2}^{1/2} 1 dt = 1 = \text{sinc } 0$.

Case $\xi \neq 0$. An antiderivative of $e^{-2\pi i \xi t}$ is $\frac{e^{-2\pi i \xi t}}{-2\pi i \xi}$, hence

$$\widehat{\Pi}(\xi) = \int_{-1/2}^{1/2} e^{-2\pi i \xi t} dt = \left[\frac{e^{-2\pi i \xi t}}{-2\pi i \xi} \right]_{-1/2}^{1/2} = \frac{e^{-\pi i \xi} - e^{\pi i \xi}}{-2\pi i \xi}.$$

By Euler's formula $e^{i\alpha} - e^{-i\alpha} = 2i \sin \alpha$ (Volume II, Chapter 3), with $\alpha = \pi \xi$ we have $e^{-\pi i \xi} - e^{\pi i \xi} = -2i \sin(\pi \xi)$, and hence

$$\widehat{\Pi}(\xi) = \frac{-2i \sin(\pi \xi)}{-2\pi i \xi} = \frac{\sin \pi \xi}{\pi \xi} = \text{sinc } \xi.$$

Independent check. Simpson quadrature of $\int_{-1/2}^{1/2} \cos(2\pi\xi t) dt$ with 200,000 subintervals: $\xi = \frac{1}{4} \rightarrow 0.9003163 = \text{sinc } \frac{1}{4}$; $\xi = \frac{1}{2} \rightarrow 0.6366198 = \frac{2}{\pi}$; $\xi = 1 \rightarrow 0.0000000$; $\xi = \frac{3}{2} \rightarrow -0.2122066 = -\frac{2}{3\pi}$. ✓ □

Proposition 19.3: The triangle by convolution, and its transform. $\Pi * \Pi = \Lambda$ everywhere, and consequently

$$\widehat{\Lambda}(\xi) = (\text{sinc } \xi)^2.$$

Moreover $\Lambda = R_{\Pi}$, the autocorrelation of the rectangle.

Proof. Step 1 — computing the convolution. Since Π equals 1 on $(-\frac{1}{2}, \frac{1}{2})$ and 0 outside (up to a set of measure zero),

$$(\Pi * \Pi)(t) = \int \Pi(\tau)\Pi(t - \tau) d\tau = \left| \left(-\frac{1}{2}, \frac{1}{2}\right) \cap \left(t - \frac{1}{2}, t + \frac{1}{2}\right) \right|,$$

because the integrand equals 1 exactly when $|\tau| < \frac{1}{2}$ and $|t - \tau| < \frac{1}{2}$, that is, $\tau \in (t - \frac{1}{2}, t + \frac{1}{2})$. The intersection of two open intervals is the interval with endpoints $\max(-\frac{1}{2}, t - \frac{1}{2})$ and $\min(\frac{1}{2}, t + \frac{1}{2})$, of length

$$\ell(t) = \min\left(\frac{1}{2}, t + \frac{1}{2}\right) - \max\left(-\frac{1}{2}, t - \frac{1}{2}\right)$$

if positive, and 0 otherwise. Three cases arise.

- $0 \leq t < 1$: then $t + \frac{1}{2} \geq \frac{1}{2}$ and $t - \frac{1}{2} \geq -\frac{1}{2}$, hence $\ell(t) = \frac{1}{2} - (t - \frac{1}{2}) = 1 - t$, which is positive.
- $-1 < t \leq 0$: symmetrically $\ell(t) = (t + \frac{1}{2}) - (-\frac{1}{2}) = 1 + t > 0$.
- $|t| \geq 1$: for $t \geq 1$ we have $t - \frac{1}{2} \geq \frac{1}{2}$, hence the intersection is empty; for $t \leq -1$ we have $t + \frac{1}{2} \leq -\frac{1}{2}$, again empty. In both cases the convolution is 0.

The three cases combine into $(\Pi * \Pi)(t) = \max(0, 1 - |t|) = \Lambda(t)$.

Step 2 — the transform. $\Pi \in L^1$, hence Theorem 19.4(iv) and Proposition 19.2 give

$$\widehat{\Lambda}(\xi) = \widehat{\Pi * \Pi}(\xi) = \widehat{\Pi}(\xi)^2 = (\text{sinc } \xi)^2.$$

Step 3 — the autocorrelation. Π is real and even, hence $\tilde{\Pi}(t) = \overline{\Pi(-t)} = \Pi(t)$, and by Corollary 19.1 $R_{\Pi} = \Pi * \tilde{\Pi} = \Pi * \Pi = \Lambda$; consistently $\widehat{R_{\Pi}} = |\widehat{\Pi}|^2 = \text{sinc}^2$, the same result as in Step 2, since sinc is real.

Independent check. (a) Convolution computed directly as the length of the intersection: $(\Pi * \Pi)(0) = 1.0000000$, $(\Pi * \Pi)(0.25) = 0.7500000$, $(\Pi * \Pi)(0.7) = 0.3000000$, $(\Pi * \Pi)(1.2) = 0.0000000$, against $\Lambda(0) = 1$, $\Lambda(0.25) = 0.75$, $\Lambda(0.7) = 0.3$, $\Lambda(1.2) = 0$. ✓ (b) Simpson quadrature of $\int_{-1}^1 \Lambda(t) \cos(2\pi\xi t) dt$ with 200,000 subintervals: $\xi = \frac{1}{2} \rightarrow 0.4052847 = (\frac{2}{\pi})^2$; $\xi = 1 \rightarrow 0.0000000$; $\xi = 1.3 \rightarrow 0.0392400 = \text{sinc}^2(1.3)$. ✓ (c) Autocorrelation computed numerically: $R_{\Pi}(0.3) = 0.7000000 = \Lambda(0.3)$, $R_{\Pi}(0.9) = 0.1000000 = \Lambda(0.9)$. ✓ □

Proposition 19.4: The sinc function is not integrable, its square is. $\text{sinc} \notin L^1(\mathbb{R})$, whereas $\text{sinc}^2 \in L^1(\mathbb{R})$.

Proof. Step 1 — divergence. For every integer $k \geq 1$ and every $x \in [k, k+1]$ we have $\pi x \leq \pi(k+1)$, hence

$$\int_k^{k+1} |\text{sinc } x| dx = \int_k^{k+1} \frac{|\sin \pi x|}{\pi x} dx \geq \frac{1}{\pi(k+1)} \int_k^{k+1} |\sin \pi x| dx.$$

The last integral does not depend on k , because $|\sin \pi x|$ is periodic with period 1, and equals

$$\int_0^1 |\sin \pi x| dx = \int_0^1 \sin \pi x dx = \left[-\frac{\cos \pi x}{\pi} \right]_0^1 = \frac{2}{\pi}.$$

Hence

$$\int_1^{+\infty} |\operatorname{sinc} x| dx \geq \sum_{k \geq 1} \frac{2}{\pi^2(k+1)} = +\infty,$$

because the harmonic series diverges. Thus $\operatorname{sinc} \notin L^1$.

Step 2 — integrability of the square. $|\operatorname{sinc} x| \leq 1$ everywhere (because $|\sin \theta| \leq |\theta|$), so $\operatorname{sinc}^2 \leq 1$ is integrable on $[-1, 1]$; for $|x| \geq 1$ we have $\operatorname{sinc}^2 x \leq \frac{1}{\pi^2 x^2}$, integrable. Hence $\operatorname{sinc}^2 \in L^1$.

Independent check. The quadrature of $\int_0^R |\operatorname{sinc}|$ grows logarithmically: $R = 10 \rightarrow 1.0528631$, $R = 10^2 \rightarrow 1.5194284$, $R = 10^3 \rightarrow 1.9860293$, $R = 10^4 \rightarrow 2.4526306$. The successive differences are 0.4665653, 0.4666009, 0.4666013, against $\frac{2}{\pi^2} \ln 10 = 0.4666013$: the asymptotic behaviour $\frac{2}{\pi^2} \ln R + \text{const.}$ is confirmed to seven decimal places, and the divergence is logarithmic. ✓ $\square$

19.8. The Schwartz class and the inversion formula

The inversion formula cannot hold for every $f \in L^1$: Proposition 19.4 shows that $\hat{\Pi} = \operatorname{sinc}$ is not integrable, so the integral $\int \hat{\Pi}(\xi) e^{2\pi i x \xi} d\xi$ makes no sense as a Lebesgue integral. We need a class of functions small enough to be stable under $\mathcal{F}$: this is the Schwartz class.

Definition 19.5: Schwartz class. The **Schwartz class** $\mathcal{S} = \mathcal{S}(\mathbb{R})$ is the set of functions $f : \mathbb{R} \rightarrow \mathbb{C}$ of class C^∞ such that, for every pair of integers $m, n \geq 0$,

$$p_{m,n}(f) := \sup_{t \in \mathbb{R}} |t^m f^{(n)}(t)| < \infty.$$

The quantities $p_{m,n}$ are called the **seminorms** of $\mathcal{S}$; one says $f_k \rightarrow f$ in $\mathcal{S}$ if $p_{m,n}(f_k - f) \rightarrow 0$ for every $m, n \geq 0$.

Example 19.1: What lies in $\mathcal{S}$, and what does not. The Gaussian $e^{-\pi t^2}$ lies in $\mathcal{S}$: every derivative of it is $q(t)e^{-\pi t^2}$ with q a polynomial, and $t^m q(t)e^{-\pi t^2} \rightarrow 0$ as $|t| \rightarrow \infty$ because the exponential beats every polynomial. Not in $\mathcal{S}$: the rectangle Π (not continuous), the triangle Λ (not differentiable at $0, \pm 1$), $\frac{1}{1+t^2}$ (decays only like t^{-2} , hence $p_{3,0} = \infty$), and $e^{-|t|}$ (not differentiable at 0).

Proposition 19.5: Elementary stability of $\mathcal{S}$. $\mathcal{S}$ is a complex vector space, closed under differentiation $f \mapsto f'$, under multiplication by a polynomial, and under conjugation. Moreover $\mathcal{S} \subset L^1(\mathbb{R}) \cap L^2(\mathbb{R})$, with

$$\|f\|_1 \leq \pi(p_{0,0}(f) + p_{2,0}(f)), \quad \|f\|_2^2 \leq \pi p_{0,0}(f)(p_{0,0}(f) + p_{2,0}(f)).$$

Proof. Step 1 — vector space. If $f, g \in \mathcal{S}$ and $\alpha, \beta \in \mathbb{C}$, then $\alpha f + \beta g \in C^\infty$ and $p_{m,n}(\alpha f + \beta g) \leq |\alpha|p_{m,n}(f) + |\beta|p_{m,n}(g) < \infty$.

Step 2 — differentiation. $p_{m,n}(f') = p_{m,n+1}(f) < \infty$ for every m, n : $\mathcal{S}$ is closed under differentiation.

Step 3 — multiplication by t . Let $g(t) = tf(t)$. By the Leibniz formula $g^{(n)}(t) = tf^{(n)}(t) + n f^{(n-1)}(t)$ (the further terms vanish because the second derivative of t is zero), hence

$$p_{m,n}(g) \leq p_{m+1,n}(f) + n p_{m,n-1}(f) < \infty.$$

Iterating, $\mathcal{S}$ is closed under multiplication by t^k and hence by any polynomial (by Step 1).

Step 4 — conjugation. $\overline{f^{(n)}} = \overline{f}^{(n)}$ and $|t^m \overline{f^{(n)}}(t)| = |t^m f^{(n)}(t)|$, hence $p_{m,n}(\overline{f}) = p_{m,n}(f)$.

Step 5 — inclusion in L^1 and L^2 . Let $C = p_{0,0}(f) + p_{2,0}(f)$. For every t ,

$$(1+t^2)|f(t)| = |f(t)| + |t^2 f(t)| \leq p_{0,0}(f) + p_{2,0}(f) = C, \quad \text{that is} \quad |f(t)| \leq \frac{C}{1+t^2}.$$

Since $\int \frac{dt}{1+t^2} = [\arctan t]_{-\infty}^{+\infty} = \pi$, one obtains $\|f\|_1 \leq \pi C$. For L^2 : $|f(t)|^2 \leq p_{0,0}(f) |f(t)|$, hence $\|f\|_2^2 \leq p_{0,0}(f) \|f\|_1 \leq \pi p_{0,0}(f) C$. $\square$

Theorem 19.7: $\mathcal{F}$ maps $\mathcal{S}$ into $\mathcal{S}$, continuously. If $f \in \mathcal{S}$, then $\hat{f} \in \mathcal{S}$. More precisely, for every pair $m, n \geq 0$ there is a constant $C_{m,n}$ (depending only on m and n) such that

$$p_{m,n}(\hat{f}) \leq C_{m,n} \max_{\substack{0 \leq j \leq n+2 \\ 0 \leq k \leq m}} p_{j,k}(f) \quad \text{for every } f \in \mathcal{S}.$$

In particular, if $f_\ell \rightarrow 0$ in $\mathcal{S}$ then $\hat{f}_\ell \rightarrow 0$ in $\mathcal{S}$.

Proof. **Step 1 — the derivatives of $\hat{f}$.** By Proposition 19.5, $t^j f(t) \in \mathcal{S} \subset L^1$ for every $j \geq 0$. Lemma 19.2 (the general part) then gives $\hat{f} \in C^\infty$ and

$$\hat{f}^{(n)} = \widehat{g_n}, \quad g_n(t) = (-2\pi i)^n t^n f(t) \in \mathcal{S}.$$

Step 2 — multiplication by ξ^m . $g_n \in \mathcal{S}$ is of class C^∞ and all its derivatives lie in L^1 (Proposition 19.5, Steps 2 and 5), so Lemma 19.1 gives $\widehat{g_n^{(m)}}(\xi) = (2\pi i)^m \widehat{g_n}(\xi)$, that is,

$$\xi^m \hat{f}^{(n)}(\xi) = \frac{1}{(2\pi i)^m} \widehat{g_n^{(m)}}(\xi).$$

Step 3 — the estimate. By Proposition 19.1, $|\widehat{g_n^{(m)}}(\xi)| \leq \|g_n^{(m)}\|_1$, hence

$$p_{m,n}(\hat{f}) = \sup_{\xi} |\xi^m \hat{f}^{(n)}(\xi)| \leq \frac{\|g_n^{(m)}\|_1}{(2\pi)^m} \leq \frac{\pi}{(2\pi)^m} (p_{0,0}(g_n^{(m)}) + p_{2,0}(g_n^{(m)})),$$

where the last inequality is Proposition 19.5, Step 5. By the Leibniz formula applied to $g_n = (-2\pi i)^n t^n f$,

$$g_n^{(m)}(t) = (-2\pi i)^n \sum_{k=0}^{\min(m,n)} \binom{m}{k} \frac{n!}{(n-k)!} t^{n-k} f^{(m-k)}(t),$$

because the k -th derivative of t^n is $\frac{n!}{(n-k)!} t^{n-k}$ and vanishes for $k > n$. Hence, for $r \in \{0, 2\}$,

$$p_{r,0}(g_n^{(m)}) \leq (2\pi)^n \sum_{k=0}^{\min(m,n)} \binom{m}{k} \frac{n!}{(n-k)!} p_{n-k+r, m-k}(f),$$

and all the indices that appear satisfy $n-k+r \leq n+2$ and $m-k \leq m$. Collecting the numerical constants into $C_{m,n}$ gives the inequality in the statement; in particular all the $p_{m,n}(\hat{f})$ are finite, that is, $\hat{f} \in \mathcal{S}$. If $f_\ell \rightarrow 0$ in $\mathcal{S}$, the right-hand side tends to 0 for every m, n , hence $\hat{f}_\ell \rightarrow 0$ in $\mathcal{S}$. $\square$

Lemma 19.6: Multiplication formula. For every $f, g \in L^1(\mathbb{R})$,

$$\int \hat{f}(\xi) g(\xi) d\xi = \int f(t) \hat{g}(t) dt,$$

and the two integrals converge absolutely.

Proof. The function $(t, \xi) \mapsto f(t)g(\xi)e^{-2\pi i t \xi}$ is measurable on $\mathbb{R}^2$ and has modulus $|f(t)||g(\xi)|$; by Tonelli's theorem

$$\iint |f(t)||g(\xi)| dt d\xi = \|f\|_1 \|g\|_1 < \infty.$$

Fubini's theorem then authorises both orders of integration:

$$\int \left(\int f(t) e^{-2\pi i t \xi} dt \right) g(\xi) d\xi = \iint f(t) g(\xi) e^{-2\pi i t \xi} dt d\xi = \int f(t) \left(\int g(\xi) e^{-2\pi i t \xi} d\xi \right) dt,$$

that is, $\int \hat{f}g = \int f\hat{g}$. The absolute convergence of the two integrals follows from $|\hat{f}| \leq \|f\|_1$ and $|\hat{g}| \leq \|g\|_1$ (Proposition 19.1) and from $f, g \in L^1$. $\square$

Lemma 19.7: The Gaussian kernel is an approximate identity. For $\delta > 0$ set

$$K_\delta(u) = \frac{1}{\delta} e^{-\pi u^2 / \delta^2}.$$

Then:

- (i) $K_\delta > 0$, K_δ is even and $\int K_\delta = 1$;
- (ii) setting $G_{x,\delta}(\xi) = e^{2\pi i x \xi} e^{-\pi \delta^2 \xi^2}$, we have $G_{x,\delta} \in \mathcal{S}$ and $\widehat{G_{x,\delta}}(t) = K_\delta(t - x)$;
- (iii) if f is bounded and continuous at x , then $\lim_{\delta \rightarrow 0^+} \int f(t) K_\delta(t - x) dt = f(x)$;
- (iv) if $f \in L^1(\mathbb{R})$, then $\|f * K_\delta - f\|_1 \rightarrow 0$ as $\delta \rightarrow 0^+$.

Proof. (i) Positivity and evenness are evident from the formula; with $u = \delta v$, $\int K_\delta(u) du = \int e^{-\pi v^2} dv = 1$ by Lemma 19.4.

(ii) By Corollary 19.2 with $a = \delta^2$,

$$(\widehat{e^{-\pi \delta^2 \xi^2}})(t) = \frac{1}{\delta} e^{-\pi t^2 / \delta^2} = K_\delta(t),$$

and by modulation (Theorem 19.3(iii), applied in the variable ξ with $\xi_0 = x$) one obtains $\widehat{G_{x,\delta}}(t) = K_\delta(t - x)$. That $G_{x,\delta} \in \mathcal{S}$ follows from Example 19.1 and from the fact that multiplying by $e^{2\pi i x \xi}$, a C^∞ function with all derivatives bounded, does not alter the finiteness of the seminorms (Leibniz formula).

(iii) With the substitution $t = x + \delta v$ ($dt = \delta dv$),

$$\int f(t) K_\delta(t - x) dt = \int f(x + \delta v) e^{-\pi v^2} dv,$$

while by (i) $f(x) = \int f(x) e^{-\pi v^2} dv$. The difference is

$$\int [f(x + \delta v) - f(x)] e^{-\pi v^2} dv.$$

For each fixed v the integrand tends to 0 as $\delta \rightarrow 0^+$, by continuity of f at x ; and it is dominated in modulus by $2\|f\|_\infty e^{-\pi v^2}$, integrable and independent of δ . The dominated convergence theorem (applied to any sequence $\delta_k \rightarrow 0^+$) gives the limit 0.

(iv) Since K_δ is even, $(f * K_\delta)(x) = \int f(x-u)K_\delta(u)du$, and by (i)

$$(f * K_\delta)(x) - f(x) = \int K_\delta(u)[f(x-u) - f(x)] du.$$

Taking moduli and integrating in x , Tonelli's theorem (non-negative integrand) allows the order to be exchanged:

$$\|f * K_\delta - f\|_1 \leq \int K_\delta(u) \left(\int |f(x-u) - f(x)| dx \right) du = \int K_\delta(u) \|\tau_u f - f\|_1 du.$$

With $u = \delta v$ this becomes $\int e^{-\pi v^2} \|\tau_{\delta v} f - f\|_1 dv$. The integrand tends to 0 for every v as $\delta \rightarrow 0^+$ (Lemma 19.3) and is dominated by $2\|f\|_1 e^{-\pi v^2}$, because $\|\tau_u f - f\|_1 \leq 2\|f\|_1$. The dominated convergence theorem concludes the proof. $\square$

Theorem 19.8: Inversion formula on the Schwartz class. Let $f \in \mathcal{S}(\mathbb{R})$. Then, for every $x \in \mathbb{R}$,

$$f(x) = \int_{-\infty}^{+\infty} \hat{f}(\xi) e^{2\pi i x \xi} d\xi = (\mathcal{F}^{-1} \hat{f})(x).$$

Proof. Step 1 — the starting identity. Fix x and $\delta > 0$, and apply Lemma 19.6 to the pair $f \in \mathcal{S} \subset L^1$ and $G_{x,\delta} \in \mathcal{S} \subset L^1$ from Lemma 19.7(ii):

$$\int \hat{f}(\xi) e^{2\pi i x \xi} e^{-\pi \delta^2 \xi^2} d\xi = \int \hat{f}(\xi) G_{x,\delta}(\xi) d\xi = \int f(t) \widehat{G_{x,\delta}}(t) dt = \int f(t) K_\delta(t-x) dt.$$

Step 2 — the limit on the left. By Theorem 19.7 we have $\hat{f} \in \mathcal{S}$, hence $\hat{f} \in L^1$ by Proposition 19.5. The integrand on the left tends pointwise to $\hat{f}(\xi) e^{2\pi i x \xi}$ as $\delta \rightarrow 0^+$ and is dominated in modulus by $|\hat{f}| \in L^1$, independent of δ (because $0 < e^{-\pi \delta^2 \xi^2} \leq 1$). By dominated convergence the left-hand side tends to $\int \hat{f}(\xi) e^{2\pi i x \xi} d\xi$.

Step 3 — the limit on the right. $f \in \mathcal{S}$ is bounded ($p_{0,0}(f) < \infty$) and continuous; by Lemma 19.7(iii) the right-hand side tends to $f(x)$.

Step 4 — conclusion. Two quantities equal for every $\delta > 0$ have the same limit: $f(x) = \int \hat{f}(\xi) e^{2\pi i x \xi} d\xi$. $\square$

Corollary 19.3: $\mathcal{F}$ is a bijection of $\mathcal{S}$, and $\mathcal{F}^4 = \text{id}$. $\mathcal{F} : \mathcal{S} \rightarrow \mathcal{S}$ is bijective; its inverse is $\mathcal{F}^{-1} = R\mathcal{F} = \mathcal{F}R$, where $Rh(x) = h(-x)$. Moreover $\mathcal{F}^2 = R$ and $\mathcal{F}^4 = \text{id}$.

Proof. Step 1 — $\mathcal{F}$ and R commute. By Theorem 19.3(v), $\widehat{Rh} = R\hat{h}$ for every $h \in L^1$: that is, $\mathcal{F}R = R\mathcal{F}$ on L^1 , and in particular on $\mathcal{S}$ (which is closed under reflection, since $p_{m,n}(Rh) = p_{m,n}(h)$).

Step 2 — $\mathcal{F}^2 = R$. Theorem 19.8 says that for $f \in \mathcal{S}$

$$f(x) = \int \hat{f}(\xi) e^{2\pi i x \xi} d\xi = \int \hat{f}(\xi) e^{-2\pi i (-x) \xi} d\xi = (\mathcal{F}\hat{f})(-x) = (R\mathcal{F}^2 f)(x),$$

that is, $R\mathcal{F}^2 = \text{id}$. Applying R on the left and using $R^2 = \text{id}$, one obtains $\mathcal{F}^2 = R$.

Step 3 — conclusion. From $\mathcal{F}^2 = R$ it follows that $\mathcal{F}^4 = R^2 = \text{id}$: hence $\mathcal{F}$ is invertible on $\mathcal{S}$ with inverse $\mathcal{F}^3 = \mathcal{F}^2 \mathcal{F} = R\mathcal{F} = \mathcal{F}R$ (Step 1). In particular $\mathcal{F}$ is injective and surjective on $\mathcal{S}$, and $\mathcal{F}^{-1}h(x) = (\mathcal{F}h)(-x) = \int h(\xi) e^{2\pi i x \xi} d\xi$, which is the formula of Definition 19.1. $\square$

Theorem 19.9: Inversion in L^1 . Let $f \in L^1(\mathbb{R})$ with $\hat{f} \in L^1(\mathbb{R})$. Then the function

$$F(x) = \int \hat{f}(\xi) e^{2\pi i x \xi} d\xi$$

is uniformly continuous and bounded on $\mathbb{R}$, and $f = F$ almost everywhere. In particular, if f is continuous, $f = F$ everywhere.

Proof. **Step 1 — F is continuous and bounded.** $F(x) = \widehat{\hat{f}}(-x)$, and $\widehat{\hat{f}}$ is uniformly continuous and bounded by $\|\hat{f}\|_1$ by Theorem 19.1 and Proposition 19.1; reflection preserves both properties.

Step 2 — the identity with the kernel. As in Step 1 of the proof of Theorem 19.8, Lemma 19.6 applied to $f \in L^1$ and $G_{x,\delta} \in L^1$ gives

$$\int \hat{f}(\xi) e^{2\pi i x \xi} e^{-\pi \delta^2 \xi^2} d\xi = \int f(t) K_\delta(t - x) dt = (f * K_\delta)(x),$$

the last equality because K_δ is even (Lemma 19.7(i)).

Step 3 — the limit on the left. Since $\hat{f} \in L^1$ by hypothesis, the same domination as in Step 2 of the proof of Theorem 19.8 gives, for every x ,

$$\lim_{\delta \rightarrow 0^+} \int \hat{f}(\xi) e^{2\pi i x \xi} e^{-\pi \delta^2 \xi^2} d\xi = F(x).$$

Step 4 — the limit on the right. By Lemma 19.7(iv), $f * K_\delta \rightarrow f$ in L^1 . Choosing a sequence $\delta_k \rightarrow 0^+$, we have $\|f * K_{\delta_k} - f\|_1 \rightarrow 0$; by Riesz's theorem (a declared prerequisite) there is a subsequence δ_{k_j} such that $f * K_{\delta_{k_j}}(x) \rightarrow f(x)$ for almost every x .

Step 5 — conclusion. For almost every x the same sequence of numbers $(f * K_{\delta_{k_j}})(x)$ converges to $F(x)$ (Step 3, which holds for every x) and to $f(x)$ (Step 4): by uniqueness of the limit $f(x) = F(x)$ for almost every x . If f is continuous, $f - F$ is continuous and zero almost everywhere, hence zero everywhere (if it were non-zero at a point, it would be non-zero on a neighbourhood, which has positive measure). $\square$

Remark 19.7: Why the hypothesis $\hat{f} \in L^1$ cannot be dropped. The rectangle Π lies in L^1 but $\hat{\Pi} = \text{sinc} \notin L^1$ (Proposition 19.4): the inversion integral is not defined in the Lebesgue sense. It does exist, however, as a principal value, that is, as $\lim_{R \rightarrow \infty} \int_{-R}^R$, and equals $\Pi(x)$ at points of continuity and $\frac{1}{2}$ at $x = \pm \frac{1}{2}$ — exactly the value that Definition 19.4 assigns at the two jump points. The proof of this fact is the Dirichlet–Jordan theorem applied to the non-periodic case, and is not carried out here: the periodic version is Theorem 17.4 of Chapter 17.

19.9. The Plancherel theorem

Theorem 19.10: Plancherel–Parseval on the Schwartz class. For every $f, g \in \mathcal{S}(\mathbb{R})$,

$$\int f(t) \overline{g(t)} dt = \int \hat{f}(\xi) \overline{\hat{g}(\xi)} d\xi.$$

Proof. **Step 1 — an auxiliary function.** Set $w = \bar{\hat{g}}$. By Theorem 19.7 $\hat{g} \in \mathcal{S}$, and by Proposition 19.5 (Step 4) also $w \in \mathcal{S}$; in particular $w \in L^1$.

Step 2 — the transform of w . Pulling the conjugation out of the integral as in Theorem 19.3(vi),

$$\hat{w}(t) = \int \overline{\hat{g}(\xi)} e^{-2\pi i t \xi} d\xi = \overline{\int \hat{g}(\xi) e^{2\pi i t \xi} d\xi} = \overline{g(t)},$$

where the last step is the inversion formula (Theorem 19.8) applied to $g \in \mathcal{S}$.

Step 3 — the multiplication formula. Applying Lemma 19.6 to the pair $f, w \in L^1$ and using Step 2,

$$\int \hat{f}(\xi) \overline{\hat{g}(\xi)} d\xi = \int \hat{f}(\xi) w(\xi) d\xi = \int f(t) \hat{w}(t) dt = \int f(t) \overline{g(t)} dt.$$

□

Corollary 19.4: $\mathcal{F}$ is an isometry for the L^2 norm. For every $f \in \mathcal{S}(\mathbb{R})$, $\|\hat{f}\|_2 = \|f\|_2$.

Proof. Take $g = f$ in Theorem 19.10:

$$\|f\|_2^2 = \int f \bar{f} = \int \hat{f} \bar{\hat{f}} = \|\hat{f}\|_2^2,$$

and the two norms are non-negative, hence equal. □

Example 19.2: Two sinc integrals, via Plancherel. Π does not lie in $\mathcal{S}$, but it lies in $L^1 \cap L^2$ and Plancherel's identity holds for it equally, as one verifies directly from Corollary 19.1 and Theorem 19.9. Indeed $R_\Pi = \Lambda$ is continuous and $\widehat{R_\Pi} = \text{sinc}^2 \in L^1$ (Proposition 19.4), so Theorem 19.9 applies to R_Π and gives, at $x = 0$,

$$\int \text{sinc}^2 \xi d\xi = R_\Pi(0) = \int |\Pi|^2 = 1.$$

$\Pi * \Lambda = \Pi * \Pi * \Pi$ and $\Lambda * \Lambda$ are treated in the same way: both are continuous, because $(\Pi * \Lambda)(t) = \int_{-1/2}^{1/2} \Lambda(t - \tau) d\tau$ and $(\Lambda * \Lambda)(t) = \int_{-1}^1 \Lambda(\tau) \Lambda(t - \tau) d\tau$ depend continuously on t by the uniform continuity of Λ ; and their transforms, sinc^3 and sinc^4 (Theorem 19.4(iv)), are integrable because $|\text{sinc}| \leq 1$ and $\text{sinc}^2 \in L^1$. Evaluating at 0: $\int \text{sinc}^3 \xi d\xi = (\Pi * \Lambda)(0) = \int_{-1/2}^{1/2} \Lambda(s) ds = 2 \int_0^{1/2} (1-s) ds = \frac{3}{4}$; and from $\Lambda * \Lambda$ evaluated at 0: $\int \text{sinc}^4 \xi d\xi = \int \Lambda(s)^2 ds = 2 \int_0^1 (1-s)^2 ds = \frac{2}{3}$.

Independent checks. Simpson quadrature on $[-3000, 3000]$ with 6,000,000 subintervals: $\int \text{sinc}^3 = 0.7500000$ and $\int \text{sinc}^4 = 0.6666667$. ✓ For $\int \text{sinc}^2$, the same quadrature on $[-4000, 4000]$ with 8,000,000 subintervals gives 0.9999747: the discrepancy $2.5 \cdot 10^{-5}$ is exactly the neglected tail, $2 \int_{4000}^{\infty} \frac{\sin^2 \pi x}{\pi^2 x^2} dx \approx \frac{1}{\pi^2 \cdot 4000} = 2.5 \cdot 10^{-5}$ (the mean value of $\sin^2$ is $\frac{1}{2}$). ✓ Rewritten with $x = \pi \xi$, these three integrals are the classical identities $\int \frac{\sin^2 x}{x^2} dx = \pi$, $\int \frac{\sin^3 x}{x^3} dx = \frac{3\pi}{4} = 2.3561945$ and $\int \frac{\sin^4 x}{x^4} dx = \frac{2\pi}{3} = 2.0943951$, verified numerically with the same parameters. ✓

Remark 19.8: What we import: the extension of Plancherel to L^2 . Corollary 19.4 says that $\mathcal{F}$ preserves the L^2 norm on the Schwartz class. The statement used in practice — there is a unique linear map $\mathcal{F}_2 : L^2(\mathbb{R}) \rightarrow L^2(\mathbb{R})$ that agrees with $\mathcal{F}$ on $\mathcal{S}$, and is a surjective isometry — is obtained by a density argument, and is **imported** here. Precisely, the one fact we do not prove is the density of $\mathcal{S}(\mathbb{R})$ in $L^2(\mathbb{R})$. Given that, the rest is mechanical, and we record it for completeness: if $f \in L^2$ and $(f_k) \subset \mathcal{S}$ with $\|f_k - f\|_2 \rightarrow 0$, then (f_k) is Cauchy in L^2 , hence by Corollary 19.4 so is $(\hat{f}_k)$ ($\|\hat{f}_k - \hat{f}_j\|_2 = \|f_k - f_j\|_2$), and the completeness of

L^2 gives a limit called $\mathcal{F}_2 f$; the limit does not depend on the chosen sequence (interleave two sequences) and norm preservation passes to the limit. Surjectivity follows from $\mathcal{F}(\mathcal{S}) = \mathcal{S}$ (Corollary 19.3) and from the fact that the image of an isometry of a complete space is closed. Hence only density is missing, which is the measure-theory point declared among the external prerequisites; it is found in Rudin, *Real and Complex Analysis*, Chapter 9. Note that $\mathcal{F}_2 f$ is no longer defined by a convergent integral for every $f \in L^2$: for $f \in L^1 \cap L^2$ the two definitions agree, but for $f \in L^2 \setminus L^1$ the integral of Definition 19.1 may fail to converge.

19.10. Periodization and the Poisson summation formula

Definition 19.6: Periodization of a function. Let $f : \mathbb{R} \rightarrow \mathbb{C}$. Its **periodization** of step 1 is

$$(Pf)(t) = \sum_{n \in \mathbb{Z}} f(t + n),$$

defined at the points where the series converges.

Theorem 19.11: The coefficients of the periodization are the samples of the transform. Let $f : \mathbb{R} \rightarrow \mathbb{C}$ be continuous and such that, for some constants $C > 0$ and $\varepsilon > 0$,

$$|f(t)| \leq \frac{C}{(1 + |t|)^{1+\varepsilon}} \quad \text{for every } t \in \mathbb{R}. \quad (\text{H1})$$

Then:

- (i) the series $\sum_n f(t + n)$ converges absolutely and uniformly on every bounded interval, and Pf is continuous and 1-periodic;
- (ii) $f \in L^1(\mathbb{R})$;
- (iii) the Fourier coefficients of Pf with respect to period 1 are the integer samples of $\hat{f}$:

$$c_n(Pf) := \int_0^1 (Pf)(t) e^{-2\pi i n t} dt = \hat{f}(n) \quad \text{for every } n \in \mathbb{Z}.$$

Proof. Step 1 — uniform convergence on $[-1, 2]$. Let $t \in [-1, 2]$ and $|n| \geq 4$. Then $|t + n| \geq |n| - |t| \geq |n| - 2 \geq \frac{|n|}{2}$, hence by (H1)

$$|f(t + n)| \leq \frac{C}{(1 + |n|/2)^{1+\varepsilon}} \leq \frac{C 2^{1+\varepsilon}}{|n|^{1+\varepsilon}}.$$

The series $\sum_{|n| \geq 4} |n|^{-1-\varepsilon}$ converges (comparison with the integral, since $1 + \varepsilon > 1$), so by the Weierstrass criterion the series $\sum_{|n| \geq 4} f(t + n)$ converges absolutely and uniformly on $[-1, 2]$; the seven remaining terms are continuous functions. Hence Pf is defined and continuous on $[-1, 2]$, and in particular on $[0, 1]$.

Step 2 — periodicity. By absolute convergence one may reorder: $(Pf)(t + 1) = \sum_n f(t + 1 + n) = \sum_m f(t + m) = (Pf)(t)$ (setting $m = n + 1$). Hence Pf , continuous on $[-1, 2]$ and 1-periodic, is continuous on all of $\mathbb{R}$; and the argument of Step 1, repeated on $[-M - 1, M + 2]$ for every M , gives uniform convergence on every bounded interval.

Step 3 — (ii). From (H1), $\int |f| \leq C \int \frac{dt}{(1 + |t|)^{1+\varepsilon}} = 2C \int_0^\infty \frac{ds}{(1 + s)^{1+\varepsilon}} = \frac{2C}{\varepsilon} < \infty$.

Step 4 — (iii). The convergence is uniform on $[0, 1]$ (Step 1), and $|e^{-2\pi i n t}| = 1$, so the series and the integral may be interchanged:

$$c_n(Pf) = \int_0^1 \left(\sum_{k \in \mathbb{Z}} f(t+k) \right) e^{-2\pi i n t} dt = \sum_{k \in \mathbb{Z}} \int_0^1 f(t+k) e^{-2\pi i n t} dt.$$

In the k -th integral set $u = t + k$, so that $t = u - k$ and $e^{-2\pi i n t} = e^{-2\pi i n u} e^{2\pi i n k} = e^{-2\pi i n u}$, because $n k \in \mathbb{Z}$ and $e^{2\pi i \ell} = 1$ for every integer ℓ . Hence

$$c_n(Pf) = \sum_{k \in \mathbb{Z}} \int_k^{k+1} f(u) e^{-2\pi i n u} du = \int_{-\infty}^{+\infty} f(u) e^{-2\pi i n u} du = \hat{f}(n),$$

where the last equality is the σ -additivity of the integral over $\mathbb{R} = \bigcup_k [k, k+1)$, legitimate because $f \in L^1$ (Step 3). $\square$

Theorem 19.12: Poisson summation formula. Let $f : \mathbb{R} \rightarrow \mathbb{C}$ be continuous and suppose there exist $C > 0$ and $\varepsilon > 0$ with

$$|f(t)| \leq \frac{C}{(1+|t|)^{1+\varepsilon}} \quad (H1) \quad \text{and} \quad |\hat{f}(\xi)| \leq \frac{C}{(1+|\xi|)^{1+\varepsilon}} \quad (H2)$$

for every $t, \xi \in \mathbb{R}$. Then, for every $t \in \mathbb{R}$,

$$\sum_{n \in \mathbb{Z}} f(t+n) = \sum_{n \in \mathbb{Z}} \hat{f}(n) e^{2\pi i n t},$$

and the two series converge absolutely and uniformly on $\mathbb{R}$. In particular, for $t = 0$,

$$\sum_{n \in \mathbb{Z}} f(n) = \sum_{n \in \mathbb{Z}} \hat{f}(n).$$

Proof. **Step 1 — the right-hand side is a continuous function.** From (H2), $\sum_n |\hat{f}(n)| \leq C \sum_n (1+|n|)^{-1-\varepsilon} < \infty$; since $|\hat{f}(n) e^{2\pi i n t}| = |\hat{f}(n)|$, the Weierstrass criterion gives absolute and uniform convergence on $\mathbb{R}$ of the series $S(t) = \sum_n \hat{f}(n) e^{2\pi i n t}$, which is therefore continuous and 1-periodic.

Step 2 — the coefficients of S . By uniform convergence one may interchange the series and the integral:

$$c_m(S) = \int_0^1 S(t) e^{-2\pi i m t} dt = \sum_{n \in \mathbb{Z}} \hat{f}(n) \int_0^1 e^{2\pi i (n-m)t} dt = \hat{f}(m),$$

because $\int_0^1 e^{2\pi i \ell t} dt$ equals 1 for $\ell = 0$ and $\left[\frac{e^{2\pi i \ell t}}{2\pi i \ell} \right]_0^1 = 0$ for $\ell \in \mathbb{Z} \setminus \{0\}$.

Step 3 — the coefficients of Pf . By Theorem 19.11, Pf is continuous, 1-periodic and $c_m(Pf) = \hat{f}(m)$ for every m .

Step 4 — uniqueness of coefficients. Let $h = Pf - S$: it is continuous, 1-periodic and has all coefficients zero. To compare it with Chapter 17, which works on $\mathbb{T}$ with period 2π , set $H(\theta) = h\left(\frac{\theta}{2\pi}\right)$, a continuous, 2π -periodic function. With the substitution $\theta = 2\pi t$,

$$\hat{H}(n) = \frac{1}{2\pi} \int_0^{2\pi} H(\theta) e^{-in\theta} d\theta = \frac{1}{2\pi} \int_0^1 h(t) e^{-2\pi i n t} 2\pi dt = \int_0^1 h(t) e^{-2\pi i n t} dt = c_n(h) = 0$$

for every $n \in \mathbb{Z}$. Since H is continuous, Corollary 17.2 of Chapter 17 gives $H \equiv 0$, that is, $h \equiv 0$ and $Pf = S$ everywhere. $\square$

Corollary 19.5: Jacobi's identity for the theta function. Setting $\vartheta(a) = \sum_{n \in \mathbb{Z}} e^{-\pi a n^2}$ for $a > 0$, we have

$$\vartheta(a) = \frac{1}{\sqrt{a}} \vartheta\left(\frac{1}{a}\right).$$

Proof. Apply Theorem 19.12 at $t = 0$ to $f(t) = e^{-\pi a t^2}$.

Checking the hypotheses. f is continuous; for (H1), for every $\varepsilon > 0$ there is C with $e^{-\pi a t^2} \leq C(1 + |t|)^{-1-\varepsilon}$, because $(1 + |t|)^{1+\varepsilon} e^{-\pi a t^2} \rightarrow 0$ as $|t| \rightarrow \infty$ and is a continuous function, hence bounded. By Corollary 19.2, $\hat{f}(\xi) = a^{-1/2} e^{-\pi \xi^2/a}$, which satisfies (H2) for the same reason.

Conclusion. The Poisson formula gives

$$\sum_{n \in \mathbb{Z}} e^{-\pi a n^2} = \sum_{n \in \mathbb{Z}} \frac{1}{\sqrt{a}} e^{-\pi n^2/a},$$

that is, $\vartheta(a) = a^{-1/2} \vartheta(1/a)$.

Independent check. Sums truncated at $|n| \leq 60$ (the further terms are less than $e^{-\pi \cdot 3600}$):

a	$\vartheta(a)$	$a^{-1/2} \vartheta(1/a)$
1	1.0864348	1.0864348
2	1.0037349	1.0037349
$\frac{1}{2}$	1.4194955	1.4194955
3	1.0001614	1.0001614

✓ The case $a = 1$ is the fixed point: $\vartheta(1) = 1 + 2e^{-\pi} + 2e^{-4\pi} + \dots = 1 + 2 \cdot 0.0432139 + 2 \cdot 0.0000035 + \dots = 1.0864348$, and the relation $\vartheta(1) = \vartheta(1)$ holds identically. ✓ $\square$

Figure 19.2: Periodization of the Gaussian $f(t) = e^{-\pi t^2}$. The dashed curves are the translates $f(t + n)$ for $n = -1, 0, 1$; the thick curve is their sum over all $n \in \mathbb{Z}$, which is 1-periodic and oscillates between $Pf(\frac{1}{2}) = 0.9135791$ and $Pf(0) = 1.0864348 = \vartheta(1)$. The Poisson formula (Theorem 19.12) says that the Fourier coefficients of this curve are the samples $\hat{f}(n) = e^{-\pi n^2}$: 1 , $e^{-\pi} = 0.0432139$, $e^{-4\pi} = 0.0000035$, $\dots$, and indeed $1 + 2(0.0432139) + 2(0.0000035) = 1.0864348$ and $1 - 2(0.0432139) + 2(0.0000035) = 0.9135791$. ✓

19.11. The uncertainty principle

Theorem 19.13: Uncertainty principle, centered form. Let $f \in \mathcal{S}(\mathbb{R})$ with $\|f\|_2 = 1$. Then

$$\left(\int t^2 |f(t)|^2 dt \right) \left(\int \xi^2 |\hat{f}(\xi)|^2 d\xi \right) \geq \frac{1}{16\pi^2}.$$

Equality holds if and only if $f(t) = A e^{ct^2/2}$ for some real $c < 0$ and $A \in \mathbb{C}$ with $|A|^2 \sqrt{-2\pi/c} = 1$; equivalently, if and only if $f(t) = A e^{-\pi a t^2}$ with $a > 0$ and $|A|^2 = \sqrt{2a}$.

Proof. Step 0 — all quantities are finite. $f \in \mathcal{S}$, so $tf(t)$ and f' lie in $\mathcal{S} \subset L^2$ (Proposition 19.5), and $\hat{f} \in \mathcal{S}$ (Theorem 19.7), so $\xi \hat{f}(\xi) \in L^2$ as well. If $f' \equiv 0$ then f is constant, and the only constant in $L^2(\mathbb{R})$ is 0, which contradicts $\|f\|_2 = 1$: hence $f' \not\equiv 0$. Likewise $tf(t) \not\equiv 0$, otherwise f would vanish away from the origin and hence $\|f\|_2 = 0$.

Step 1 — integration by parts. The function $|f|^2 = f\bar{f}$ is of class C^1 with

$$\frac{d}{dt} |f(t)|^2 = f'(t)\overline{f(t)} + f(t)\overline{f'(t)} = 2\operatorname{Re}(f'(t)\overline{f(t)}).$$

Integrating $1 \cdot |f|^2$ by parts on $[-T, T]$, with t as the primitive of the factor 1:

$$\int_{-T}^T |f(t)|^2 dt = \left[t |f(t)|^2 \right]_{-T}^T - \int_{-T}^T t \cdot 2\operatorname{Re}(f'(t)\bar{f}) dt.$$

The boundary term tends to 0: indeed $|t| |f(t)|^2 = |tf(t)| \cdot |f(t)|$, and for $t \neq 0$ one has $|tf(t)| = \frac{|t^3 f(t)|}{t^2} \leq \frac{p_{3,0}(f)}{t^2} \rightarrow 0$ while $|f(t)| \leq p_{0,0}(f)$ stays bounded. Letting $T \rightarrow +\infty$,

$$1 = \|f\|_2^2 = -2\operatorname{Re} \int_{\mathbb{R}} t f'(t) \overline{f(t)} dt. \quad (**)$$

Step 2 — Cauchy–Schwarz. Since t is real, $tf'(t)\overline{f(t)} = f'(t)\overline{tf(t)}$, that is, the integral in (**) is the scalar product $\langle f', tf \rangle$ in L^2 . Hence

$$1 = |-2\operatorname{Re}\langle f', tf \rangle| \leq 2|\langle f', tf \rangle| \leq 2\|f'\|_2 \|tf\|_2. \quad (***)$$

Step 3 — Plancherel on the derivative. $f \in \mathcal{S}$, so $f' \in \mathcal{S}$ and Lemma 19.1 gives $\widehat{f'}(\xi) = 2\pi i \xi \hat{f}(\xi)$. By Corollary 19.4,

$$\|f'\|_2 = \|\widehat{f'}\|_2 = \|2\pi i \xi \hat{f}(\xi)\|_2 = 2\pi \|\xi \hat{f}\|_2.$$

Step 4 — concluding the inequality. Substituting into (***): $1 \leq 4\pi \|tf\|_2 \|\xi \hat{f}\|_2$, and squaring both sides (both are positive)

$$\|tf\|_2^2 \|\xi \hat{f}\|_2^2 \geq \frac{1}{16\pi^2},$$

which is the claim.

Step 5 — equality implies the Gaussian. If equality holds, then both inequalities of Step 2 are equalities.

- Equality in Cauchy–Schwarz, with $f' \neq 0$ and $tf \neq 0$ (Step 0), means that the two vectors are proportional: there is $c \in \mathbb{C}$ with $f'(t) = c tf(t)$ for every t (the identity holds almost everywhere, but both sides are continuous).
- Then $\langle f', tf \rangle = c \|tf\|_2^2$, and (**) becomes $1 = -2\operatorname{Re}(c) \|tf\|_2^2$, which forces $\operatorname{Re}(c) < 0$. The equality $|-2\operatorname{Re}\langle f', tf \rangle| = 2|\langle f', tf \rangle|$ becomes $2|\operatorname{Re}(c)| \|tf\|_2^2 = 2|c| \|tf\|_2^2$, that is, $|\operatorname{Re}(c)| = |c|$: hence c is real, and negative.

Setting $c < 0$, one has $\frac{d}{dt}(f(t)e^{-ct^2/2}) = e^{-ct^2/2}(f'(t) - ctf(t)) = 0$, hence $f(t) = Ae^{ct^2/2}$ with $A \in \mathbb{C}$: a Gaussian. Setting $a = -\frac{c}{2\pi} > 0$ gives $e^{ct^2/2} = e^{-\pi at^2}$; the condition $\|f\|_2 = 1$ becomes, by Lemma 19.5 with $b = 2a$, $|A|^2 \int e^{-2\pi at^2} dt = |A|^2 (2a)^{-1/2} = 1$, that is, $|A|^2 = \sqrt{2a}$. **Step 6 — the Gaussian achieves equality.** Let $f(t) = Ae^{-\pi at^2}$ with $a > 0$ and $|A|^2 = \sqrt{2a}$. By Lemma 19.5 with $b = 2a$,

$$\int t^2 |f|^2 dt = |A|^2 \int t^2 e^{-2\pi at^2} dt = \sqrt{2a} \cdot \frac{1}{2\pi(2a)^{3/2}} = \frac{1}{2\pi \cdot 2a} = \frac{1}{4\pi a}.$$

By Corollary 19.2, $\hat{f}(\xi) = A a^{-1/2} e^{-\pi \xi^2/a}$, hence, applying the same formula with $a \rightsquigarrow \frac{1}{a}$ and amplitude $Aa^{-1/2}$,

$$\int \xi^2 |\hat{f}|^2 d\xi = \frac{|A|^2}{a} \cdot \frac{1}{2\pi(2/a)^{3/2}} = \frac{\sqrt{2a}}{a} \cdot \frac{a^{3/2}}{2\pi 2^{3/2}} = \frac{\sqrt{2} a^{1/2} a^{1/2}}{2\pi \cdot 2\sqrt{2}} = \frac{a}{4\pi}.$$

The product equals $\frac{1}{4\pi a} \cdot \frac{a}{4\pi} = \frac{1}{16\pi^2}$, *independently of a* : equality is attained.

Independent check. For $a = 1$, that is $f(t) = 2^{1/4} e^{-\pi t^2}$: Simpson quadrature on $[-12, 12]$ with 200,000 subintervals gives $\|f\|_2^2 = 1.0000000$ and $\int t^2 |f|^2 = 0.0795775 = \frac{1}{4\pi}$. Since $\hat{f} = f$ (Theorem 19.6), also $\int \xi^2 |\hat{f}|^2 = 0.0795775$, and the product is $0.0063326 = \frac{1}{16\pi^2}$. ✓ □

Corollary 19.6: General form, with arbitrary centers. Let $f \in \mathcal{S}(\mathbb{R})$ with $\|f\|_2 = 1$ and let $t_0, \xi_0 \in \mathbb{R}$. Then

$$\left(\int (t - t_0)^2 |f(t)|^2 dt \right) \left(\int (\xi - \xi_0)^2 |\hat{f}(\xi)|^2 d\xi \right) \geq \frac{1}{16\pi^2},$$

with equality if and only if $f(t) = A e^{2\pi i \xi_0 t} e^{-\pi a(t-t_0)^2}$ for some $a > 0$ and $|A|^2 = \sqrt{2a}$.

Proof. Step 1 — normalization. Set $g(t) = e^{-2\pi i \xi_0 t} f(t + t_0)$. Then $g \in \mathcal{S}$ (translation and multiplication by a C^∞ function with bounded derivatives) and $|g(t)| = |f(t + t_0)|$, hence $\|g\|_2 = \|f\|_2 = 1$.

Step 2 — the transform of g . Set $h(t) = f(t + t_0) = \tau_{-t_0} f(t)$; Theorem 19.3(ii) with $t_0 \rightsquigarrow -t_0$ gives $\hat{h}(\xi) = e^{2\pi i \xi t_0} \hat{f}(\xi)$. Then $g = e^{-2\pi i \xi_0 t} h = m_{-\xi_0} h$, and Theorem 19.3(iii) gives $\hat{g}(\xi) = \hat{h}(\xi + \xi_0) = e^{2\pi i (\xi + \xi_0) t_0} \hat{f}(\xi + \xi_0)$. In particular $|\hat{g}(\xi)| = |\hat{f}(\xi + \xi_0)|$.

Step 3 — translating the integrals. With the substitutions $s = t + t_0$ and $\eta = \xi + \xi_0$,

$$\int t^2 |g(t)|^2 dt = \int (s - t_0)^2 |f(s)|^2 ds, \quad \int \xi^2 |\hat{g}(\xi)|^2 d\xi = \int (\eta - \xi_0)^2 |\hat{f}(\eta)|^2 d\eta.$$

Applying Theorem 19.13 to g gives the inequality of the statement.

Step 4 — the equality case. Equality for f is equivalent to equality for g , that is, by Theorem 19.13, to $g(t) = Ae^{-\pi at^2}$ with $|A|^2 = \sqrt{2a}$. Inverting the definition of g , $f(s) = e^{2\pi i \xi_0(s-t_0)} g(s - t_0) = Ae^{-2\pi i \xi_0 t_0} e^{2\pi i \xi_0 s} e^{-\pi a(s-t_0)^2}$, which is the form of the statement with A replaced by $Ae^{-2\pi i \xi_0 t_0}$, of equal modulus. □

19.12. Tempered distributions: the delta and the Dirac comb

Three objects that engineering uses constantly — the impulse, the constant, the train of impulses — are not integrable functions, and their "Fourier transform" has no meaning in Definition 19.1. The solution is not to enlarge the notion of function, but to change the object: one passes from pointwise values to *action on a test function*. This section builds the minimal framework needed, and in it the Dirac delta is never a function: it is a functional, and Proposition 19.8 shows that

Figure 19.3: The Gaussians $e^{-\pi at^2}$ for $a = 4$, $a = 1$ and $a = \frac{1}{4}$: same height, widths in ratio 1 : 2 : 4. The transform of the narrowest one ($a = 4$) is $\frac{1}{2}e^{-\pi\xi^2/4}$ (Corollary 19.2), that is, the widest curve of the picture halved in height, and vice versa: narrowing in time widens in frequency, exactly in the proportion fixed by Theorem 19.13, for which the product of the two spreads equals $\frac{1}{16\pi^2} = 0.0063326$ for every a . Check values on the curve $a = 4$: $e^{-4\pi(0.25)^2} = e^{-\pi/4} = 0.4559381$ and $e^{-4\pi(0.5)^2} = e^{-\pi} = 0.0432139$. ✓

it cannot be anything else.

Definition 19.7: Tempered distribution. A **tempered distribution** is a map $T : \mathcal{S}(\mathbb{R}) \rightarrow \mathbb{C}$ such that

- (i) T is linear: $T(\alpha\varphi + \beta\psi) = \alpha T(\varphi) + \beta T(\psi)$ for $\alpha, \beta \in \mathbb{C}$ and $\varphi, \psi \in \mathcal{S}$;
- (ii) T is continuous: if $\varphi_k \rightarrow 0$ in $\mathcal{S}$ (that is, $p_{m,n}(\varphi_k) \rightarrow 0$ for every m, n , Definition 19.5), then $T(\varphi_k) \rightarrow 0$ in $\mathbb{C}$.

The set of tempered distributions is denoted $\mathcal{S}'(\mathbb{R})$, and one writes $\langle T, \varphi \rangle$ instead of $T(\varphi)$. The elements of $\mathcal{S}$ are called **test functions**.

Proposition 19.6: Slowly growing functions are tempered distributions. Let $g : \mathbb{R} \rightarrow \mathbb{C}$ be measurable and such that, for some integer $N \geq 0$,

$$\int \frac{|g(t)|}{(1+|t|)^N} dt < \infty.$$

Then $\langle T_g, \varphi \rangle = \int g(t)\varphi(t) dt$ defines a tempered distribution. In particular every $g \in L^1(\mathbb{R})$ ($N = 0$), every bounded function ($N = 2$), and every polynomial ($N = \deg + 2$) give a tempered distribution.

Proof. Step 1 — a pointwise estimate for test functions. Let $\varphi \in \mathcal{S}$ and $M = N + 2$. Since $1 + |t| \leq 2 \max(1, |t|)$, one has $(1 + |t|)^M \leq 2^M \max(1, |t|^M) \leq 2^M (1 + |t|^M)$, hence

$$(1 + |t|)^M |\varphi(t)| \leq 2^M (|\varphi(t)| + |t|^M |\varphi(t)|) \leq 2^M (p_{0,0}(\varphi) + p_{M,0}(\varphi)) =: A(\varphi),$$

that is, $|\varphi(t)| \leq A(\varphi)(1 + |t|)^{-M}$ for every t .

Step 2 — convergence of the integral. Since $M = N + 2$,

$$\int |g(t)\varphi(t)| dt \leq A(\varphi) \int \frac{|g(t)|}{(1+|t|)^{N+2}} dt \leq A(\varphi) \int \frac{|g(t)|}{(1+|t|)^N} dt < \infty,$$

having used $(1 + |t|)^{N+2} \geq (1 + |t|)^N$. Hence $T_g(\varphi)$ is well defined.

Step 3 — linearity and continuity. Linearity is that of the integral. Writing $B = \int |g|(1 + |t|)^{-N} dt$, Step 2 gives $|\langle T_g, \varphi \rangle| \leq B A(\varphi) = 2^M B (p_{0,0}(\varphi) + p_{M,0}(\varphi))$. If $\varphi_k \rightarrow 0$ in $\mathcal{S}$, then $p_{0,0}(\varphi_k) \rightarrow 0$ and $p_{M,0}(\varphi_k) \rightarrow 0$, hence $\langle T_g, \varphi_k \rangle \rightarrow 0$.

Step 4 — the three cases. If $g \in L^1$, $N = 0$ suffices. If $|g| \leq K$, then $\int \frac{|g|}{(1+|t|)^2} \leq K\pi < \infty$ (see Step 5 of the proof of Proposition 19.5, with $1 + t^2 \leq (1 + |t|)^2$). If g is a polynomial of degree d , then $|g(t)| \leq K(1 + |t|)^d$ for some constant K , and with $N = d + 2$ the integral converges. □

Definition 19.8: Dirac delta. The **Dirac delta** centered at $x_0 \in \mathbb{R}$ is the functional

$$\langle \delta_{x_0}, \varphi \rangle = \varphi(x_0), \quad \varphi \in \mathcal{S}(\mathbb{R});$$

one writes $\delta = \delta_0$.
