Proposition 19.7: δ_{x_0} is a tempered distribution. $\delta_{x_0} \in \mathcal{S}'(\mathbb{R})$ for every $x_0 \in \mathbb{R}$.

Proof. Linearity is immediate: $(\alpha\varphi + \beta\psi)(x_0) = \alpha\varphi(x_0) + \beta\psi(x_0)$. For continuity, $|\langle \delta_{x_0}, \varphi \rangle| = |\varphi(x_0)| \leq \sup_t |\varphi(t)| = p_{0,0}(\varphi)$; hence if $\varphi_k \rightarrow 0$ in $\mathcal{S}$, in particular $p_{0,0}(\varphi_k) \rightarrow 0$ and therefore $\langle \delta_{x_0}, \varphi_k \rangle \rightarrow 0$. $\square$

Proposition 19.8: The delta is not a function. There is no $g \in L^1_{\text{loc}}(\mathbb{R})$ such that $\int |g\varphi| < \infty$ for every $\varphi \in \mathcal{S}(\mathbb{R})$ and

$$\int g(t)\varphi(t) dt = \varphi(0) \quad \text{for every } \varphi \in \mathcal{S}(\mathbb{R}).$$

Proof. Suppose, for contradiction, that such a g exists.

Step 1 — the test family. For $\delta \in (0, 1]$ set $\varphi_\delta(t) = e^{-\pi t^2/\delta^2}$. Each φ_δ lies in $\mathcal{S}$: it is $g(t/\delta)$ with $g(t) = e^{-\pi t^2} \in \mathcal{S}$ (Example 19.1), and $\mathcal{S}$ is stable under dilation, since $p_{m,n}(g(\cdot/\delta)) = \delta^{m-n} p_{m,n}(g)$. Moreover $\varphi_\delta(0) = 1$, hence by hypothesis

$$\int g(t) e^{-\pi t^2/\delta^2} dt = 1 \quad \text{for every } \delta \in (0, 1]. \quad (\dagger)$$

Applying the hypothesis to $\varphi_1(t) = e^{-\pi t^2}$ also gives $B := \int |g(t)| e^{-\pi t^2} dt < \infty$.

Step 2 — the contribution away from the origin. Let $\eta \in (0, 1]$. For $|t| \geq \eta$ and $\delta \in (0, 1]$,

$$e^{-\pi t^2/\delta^2} = e^{-\pi t^2} e^{-\pi t^2(\frac{1}{\delta^2}-1)} \leq e^{-\pi t^2} e^{-\pi \eta^2(\frac{1}{\delta^2}-1)},$$

since $\frac{1}{\delta^2} - 1 \geq 0$ and $t^2 \geq \eta^2$. Hence

$$\left| \int_{|t| \geq \eta} g(t) e^{-\pi t^2/\delta^2} dt \right| \leq e^{-\pi \eta^2(\frac{1}{\delta^2}-1)} \int |g(t)| e^{-\pi t^2} dt = B e^{-\pi \eta^2(\frac{1}{\delta^2}-1)},$$

which tends to 0 as $\delta \rightarrow 0^+$, for fixed η .

Step 3 — the contribution near the origin. Since $g \in L^1([-1, 1])$ (it is locally integrable), absolute continuity of the integral gives $\int_{|t| < \eta} |g| \rightarrow 0$ as $\eta \rightarrow 0^+$. Moreover $e^{-\pi t^2/\delta^2} \leq 1$ everywhere, hence

$$\left| \int_{|t| < \eta} g(t) e^{-\pi t^2/\delta^2} dt \right| \leq \int_{|t| < \eta} |g|.$$

Step 4 — the contradiction. Let $\varepsilon = \frac{1}{2}$. By Step 3 choose $\eta \in (0, 1]$ with $\int_{|t| < \eta} |g| < \frac{1}{4}$; by Step 2, with that η fixed, choose $\delta \in (0, 1]$ with $B e^{-\pi \eta^2(\delta^{-2}-1)} < \frac{1}{4}$. Then, by $(\dagger)$,

$$1 = \left| \int g \varphi_\delta \right| \leq \left| \int_{|t| < \eta} g \varphi_\delta \right| + \left| \int_{|t| \geq \eta} g \varphi_\delta \right| < \frac{1}{4} + \frac{1}{4} = \frac{1}{2},$$

which is absurd. Hence no g of the described type exists. $\square$

Remark 19.9: Why one never writes " $\delta(t)$ ". Proposition 19.8 settles the question: the notation $\delta(t)$, with the "rule" $\delta(t) = 0$ for $t \neq 0$, $\delta(0) = +\infty$ and $\int \delta = 1$, does not define any measurable function — a function that is zero almost everywhere has zero integral, whatever value is assigned to it at the origin. In this chapter δ appears only as a functional, and formulas are always written as pairings: $\langle \delta, \varphi \rangle = \varphi(0)$, never $\int \delta(t)\varphi(t)dt = \varphi(0)$. The integral notation remains a very convenient shorthand and is found everywhere in the technical literature (for instance in Bracewell, Chapter 5, where the "sifting property" is stated in that form), but its meaning is the definition given here, not a Lebesgue integral. The sequence of Gaussian kernels K_δ of Lemma 19.7 is the correct way to "approach" δ : by part (iii) of that lemma, $\int \varphi(t)K_\delta(t)dt \rightarrow \varphi(0) = \langle \delta, \varphi \rangle$ for every $\varphi \in \mathcal{S}$, that is, $T_{K_\delta} \rightarrow \delta$ in the sense of distributions.

Definition 19.9: Fourier transform of a tempered distribution. For $T \in \mathcal{S}'(\mathbb{R})$ one defines $\hat{T} = \mathcal{F}T \in \mathcal{S}'(\mathbb{R})$ by

$$\langle \hat{T}, \varphi \rangle = \langle T, \hat{\varphi} \rangle, \quad \varphi \in \mathcal{S}(\mathbb{R}).$$

Proposition 19.9: The definition is well posed and extends the one on L^1 . For every $T \in \mathcal{S}'(\mathbb{R})$, $\hat{T}$ is a tempered distribution. Moreover, if $f \in L^1(\mathbb{R})$, then $\hat{T}_f = T_{\hat{f}}$: Definition 19.9 extends Definition 19.1.

Proof. **Step 1 — $\hat{T}$ is defined.** By Theorem 19.7, $\varphi \in \mathcal{S}$ implies $\hat{\varphi} \in \mathcal{S}$: the right-hand side makes sense.

Step 2 — linearity. $\varphi \mapsto \hat{\varphi}$ is linear (Proposition 19.1) and T is linear, hence so is the composition.

Step 3 — continuity. If $\varphi_k \rightarrow 0$ in $\mathcal{S}$, the estimate of Theorem 19.7 gives $\hat{\varphi}_k \rightarrow 0$ in $\mathcal{S}$, and continuity of T gives $\langle T, \hat{\varphi}_k \rangle \rightarrow 0$.

Step 4 — consistency with L^1 . Let $f \in L^1$ and $\varphi \in \mathcal{S} \subset L^1$. By Lemma 19.6,

$$\langle \hat{T}_f, \varphi \rangle = \langle T_f, \hat{\varphi} \rangle = \int f(t)\hat{\varphi}(t)dt = \int \hat{f}(\xi)\varphi(\xi)d\xi = \langle T_{\hat{f}}, \varphi \rangle,$$

for every φ : the two functionals coincide. (T_f and $T_{\hat{f}}$ are tempered by Proposition 19.6, the latter because $\hat{f}$ is bounded.) $\square$

Proposition 19.10: $\hat{\delta} = 1$ and $\hat{1} = \delta$. In the sense of Definition 19.9,

$$\hat{\delta} = T_1, \quad \hat{T}_1 = \delta, \quad \text{and more generally} \quad \widehat{\delta_{x_0}} = T_{e_{x_0}} \quad \text{with } e_{x_0}(\xi) = e^{-2\pi i x_0 \xi}.$$

Proof. **Step 1 — $\hat{\delta} = T_1$.** For every $\varphi \in \mathcal{S}$,

$$\langle \hat{\delta}, \varphi \rangle = \langle \delta, \hat{\varphi} \rangle = \hat{\varphi}(0) = \int \varphi(t)e^{-2\pi i \cdot 0 \cdot t}dt = \int \varphi(t)dt = \langle T_1, \varphi \rangle.$$

Step 2 — $\hat{T}_1 = \delta$. The constant function 1 is bounded, hence $T_1 \in \mathcal{S}'$ (Proposition 19.6). For every $\varphi \in \mathcal{S}$,

$$\langle \hat{T}_1, \varphi \rangle = \langle T_1, \hat{\varphi} \rangle = \int \hat{\varphi}(\xi)d\xi = \int \hat{\varphi}(\xi)e^{2\pi i \cdot 0 \cdot \xi}d\xi = \varphi(0) = \langle \delta, \varphi \rangle,$$

where the second-to-last step is the inversion formula (Theorem 19.8) evaluated at $x = 0$.

Step 3 — the translated case. For every $\varphi \in \mathcal{S}$,

$$\langle \widehat{\delta_{x_0}}, \varphi \rangle = \hat{\varphi}(x_0) = \int \varphi(\xi) e^{-2\pi i x_0 \xi} d\xi = \langle T_{e_{x_0}}, \varphi \rangle,$$

and e_{x_0} is bounded, hence tempered. $\square$

Definition 19.10: Dirac comb. The **Dirac comb** of step 1 is the functional

$$\langle \mathbb{I}, \varphi \rangle = \sum_{n \in \mathbb{Z}} \varphi(n), \quad \varphi \in \mathcal{S}(\mathbb{R}),$$

formally the sum $\sum_{n \in \mathbb{Z}} \delta_n$.

Proposition 19.11: The comb is a tempered distribution. $\mathbb{I} \in \mathcal{S}'(\mathbb{R})$.

Proof. **Step 1 — the series converges.** For $\varphi \in \mathcal{S}$ and every t , $(1+t^2)|\varphi(t)| \leq p_{0,0}(\varphi) + p_{2,0}(\varphi) =: C(\varphi)$ (Step 5 of the proof of Proposition 19.5), hence

$$\sum_{n \in \mathbb{Z}} |\varphi(n)| \leq C(\varphi) \sum_{n \in \mathbb{Z}} \frac{1}{1+n^2}.$$

The latter series converges: its terms are $\leq n^{-2}$ for $n \neq 0$. (Its value is $\pi \coth \pi = 3.1533481$, computed in Solved Exercise 19.6.)

Step 2 — linearity and continuity. Linearity is clear. By Step 1, $|\langle \mathbb{I}, \varphi \rangle| \leq 3.16 C(\varphi) = 3.16(p_{0,0}(\varphi) + p_{2,0}(\varphi))$, hence $\varphi_k \rightarrow 0$ in $\mathcal{S}$ implies $\langle \mathbb{I}, \varphi_k \rangle \rightarrow 0$. $\square$

Theorem 19.14: The Dirac comb is its own transform. $\widehat{\mathbb{I}} = \mathbb{I}$.

Proof. **Step 1 — test functions satisfy the hypotheses of Poisson.** Let $\varphi \in \mathcal{S}$. Then φ is continuous and, as in Step 5 of the proof of Proposition 19.5, $|\varphi(t)| \leq \frac{C(\varphi)}{1+t^2} \leq \frac{2C(\varphi)}{(1+|t|)^2}$ (because $(1+|t|)^2 \leq 2(1+t^2)$): this is hypothesis (H1) of Theorem 19.12 with $\varepsilon = 1$. By Theorem 19.7 also $\hat{\varphi} \in \mathcal{S}$, hence the same estimate holds for $\hat{\varphi}$: this is hypothesis (H2).

Step 2 — Poisson at $t = 0$. Theorem 19.12 gives

$$\sum_{n \in \mathbb{Z}} \varphi(n) = \sum_{n \in \mathbb{Z}} \hat{\varphi}(n).$$

Step 3 — conclusion. For every $\varphi \in \mathcal{S}$,

$$\langle \widehat{\mathbb{I}}, \varphi \rangle = \langle \mathbb{I}, \hat{\varphi} \rangle = \sum_{n \in \mathbb{Z}} \hat{\varphi}(n) \stackrel{\text{Step 2}}{=} \sum_{n \in \mathbb{Z}} \varphi(n) = \langle \mathbb{I}, \varphi \rangle,$$

hence the two functionals coincide. $\square$

Remark 19.10: Sampling: what can and cannot be said here. Theorem 19.14 is the algebraic core of sampling theory: multiplying a signal by a comb of step T amounts, in frequency, to convolving its spectrum with a comb of step $1/T$, that is, to periodizing it — which is Theorem 19.11 read the other way. The sampling theorem of Whittaker–Kotel’nikov–Shannon (a signal band-limited to $[-\frac{B}{2}, \frac{B}{2}]$ is reconstructed exactly from its samples taken at step $1/B$, by interpolation with sinc) follows from here, but its complete proof requires the product of a tempered distribution by a slowly growing C^∞ function and the convolution of distributions, which this chapter does not build: it is a **panorama**, not a theorem

proved here. It is found, with the full distributional apparatus, in Bracewell, Chapter 10 "Sampling and Series." Chapter 21 and Chapter 24 take it up again from the point of view of the discrete signal.

19.13. The table of transforms, row by row

Theorem 19.15: Table of Fourier transforms. In the convention $\hat{f}(\xi) = \int f(t)e^{-2\pi i \xi t} dt$ the following equalities hold, for every $\xi \in \mathbb{R}$ and with $a > 0$, $t_0, \xi_0 \in \mathbb{R}$, $\alpha \in \mathbb{R} \setminus \{0\}$:

	$f(t)$	$\hat{f}(\xi)$	where
1	$\Pi(t)$	$\text{sinc } \xi$	Prop. 19.2
2	$\Lambda(t)$	$\text{sinc}^2 \xi$	Prop. 19.3
3	$e^{-\pi t^2}$	$e^{-\pi \xi^2}$	Thm. 19.6
4	$e^{-\pi a t^2}$	$a^{-1/2} e^{-\pi \xi^2 / a}$	Cor. 19.2
5	$t e^{-\pi t^2}$	$-i \xi e^{-\pi \xi^2}$	(a)
6	$e^{-a t }$	$\frac{2a}{a^2 + 4\pi^2 \xi^2}$	(b)
7	$\frac{1}{\pi} \frac{a}{a^2 + t^2}$	$e^{-2\pi a \xi }$	(c)
8	$e^{-at} u(t)$	$\frac{1}{a + 2\pi i \xi}$	(d)
9	$f(t - t_0)$	$e^{-2\pi i \xi t_0} \hat{f}(\xi)$	Thm. 19.3(ii)
10	$e^{2\pi i \xi_0 t} f(t)$	$\hat{f}(\xi - \xi_0)$	Thm. 19.3(iii)
11	$f(\alpha t)$	$ \alpha ^{-1} \hat{f}(\xi/\alpha)$	Thm. 19.3(iv)
12	$f(t) \cos(2\pi \xi_0 t)$	$\frac{1}{2} [\hat{f}(\xi - \xi_0) + \hat{f}(\xi + \xi_0)]$	(e)
13	$\Pi(t) \cos(2\pi \xi_0 t)$	$\frac{1}{2} [\text{sinc}(\xi - \xi_0) + \text{sinc}(\xi + \xi_0)]$	(f)
14	$f'(t)$	$2\pi i \xi \hat{f}(\xi)$	Lem. 19.1
15	$-2\pi i t f(t)$	$\hat{f}'(\xi)$	Lem. 19.2
16	$(f * g)(t)$	$\hat{f}(\xi) \hat{g}(\xi)$	Thm. 19.4(iv)
17	$R_f(t)$	$ \hat{f}(\xi) ^2$	Cor. 19.1
18	δ	1	Prop. 19.10
19	1	δ	Prop. 19.10
20	III	III	Thm. 19.14

Rows 18–20 are to be understood in the sense of Definition 19.9.

Proof. Rows 1–4, 9–11 and 14–20 are exactly the results indicated in the right-hand column, and have already been proved. The six derivations (a)–(f) remain.

(a) — **row 5.** Lemma 19.2 applied to $g(t) = e^{-\pi t^2}$ (the hypotheses are checked in Step 1 of the proof of Theorem 19.6) gives $(\widehat{tg(t)})(\xi) = \frac{i}{2\pi} \hat{g}'(\xi)$. By Theorem 19.6 $\hat{g}(\xi) = e^{-\pi \xi^2}$, whose derivative is $-2\pi \xi e^{-\pi \xi^2}$. Hence

$$(\widehat{te^{-\pi t^2}})(\xi) = \frac{i}{2\pi} (-2\pi \xi e^{-\pi \xi^2}) = -i \xi e^{-\pi \xi^2}.$$

The result is purely imaginary and odd, as it must be by Theorem 19.3, since $te^{-\pi t^2}$ is real and odd. ✓ Numerical check (Simpson on $[-12, 12]$, 400,000 subintervals): $\xi = \frac{1}{2}$ gives $-0.2279691 i$ against $-\frac{1}{2} e^{-\pi/4} = -0.2279691$; $\xi = 1$ gives $-0.0432139 i$ against $-e^{-\pi} = -0.0432139$. ✓

(b) — **row 6.** The function $e^{-a|t|}$ is in L^1 (integral $2/a$) and is even, hence

$$(\widehat{e^{-a|t|}})(\xi) = \int_{-\infty}^0 e^{at} e^{-2\pi i \xi t} dt + \int_0^{+\infty} e^{-at} e^{-2\pi i \xi t} dt = \int_0^{+\infty} e^{-at} (e^{2\pi i \xi t} + e^{-2\pi i \xi t}) dt,$$

having substituted $t \rightarrow -t$ in the first integral. Each of the two summands is computed with the primitive of a complex exponential: for $z \in \mathbb{C}$ with $\operatorname{Re} z > 0$,

$$\int_0^{+\infty} e^{-zt} dt = \left[\frac{e^{-zt}}{-z} \right]_0^{+\infty} = \frac{1}{z},$$

because $|e^{-zt}| = e^{-t \operatorname{Re} z} \rightarrow 0$. With $z = a - 2\pi i \xi$ and $z = a + 2\pi i \xi$ (both with real part $a > 0$),

$$\widehat{(e^{-a|t|})}(\xi) = \frac{1}{a - 2\pi i \xi} + \frac{1}{a + 2\pi i \xi} = \frac{(a + 2\pi i \xi) + (a - 2\pi i \xi)}{a^2 + 4\pi^2 \xi^2} = \frac{2a}{a^2 + 4\pi^2 \xi^2}.$$

This is the translation into convention (A) of the result of Inherited Exercise 19.1, which gives $\frac{2a}{a^2 + \omega^2}$: substituting $\omega = 2\pi \xi$ gives the same formula. ✓ Numerical check (Simpson on $[-80, 80]$, 800,000 subintervals): $a = 1, \xi = 0 \rightarrow 2.0000000$ against 2; $a = 1, \xi = \frac{1}{2} \rightarrow 0.1839993$ against $\frac{2}{1 + \pi^2} = 0.1839993$; $a = 2, \xi = 1 \rightarrow 0.0919997$ against $\frac{4}{4 + 4\pi^2} = 0.0919997$. ✓

(c) — **row 7.** Set $g(t) = e^{-2\pi a|t|}$ and $h(t) = \frac{1}{\pi} \frac{a}{a^2 + t^2}$. By (b) with the parameter $2\pi a$ in place of a ,

$$\hat{g}(\xi) = \frac{2 \cdot 2\pi a}{4\pi^2 a^2 + 4\pi^2 \xi^2} = \frac{4\pi a}{4\pi^2(a^2 + \xi^2)} = \frac{1}{\pi} \frac{a}{a^2 + \xi^2} = h(\xi).$$

Now $g \in L^1$ and $\hat{g} = h \in L^1$ (the integral of h equals $\frac{1}{\pi} [\arctan \frac{\xi}{a}]_{-\infty}^{+\infty} = 1$), and g is continuous: Theorem 19.9 gives, for every x ,

$$g(x) = \int h(\xi) e^{2\pi i x \xi} d\xi = \hat{h}(-x).$$

Since g is even, $\hat{h}(\xi) = g(-\xi) = g(\xi) = e^{-2\pi a|\xi|}$. ✓ Numerical check (Simpson on $[-20,000, 20,000]$, $4 \cdot 10^7$ subintervals): $a = 1, \xi = \frac{1}{2} \rightarrow 0.0432139$ and $a = \frac{1}{2}, \xi = 1 \rightarrow 0.0432139$, both against $e^{-\pi} = 0.0432139$. ✓

(d) — **row 8.** $e^{-at}u(t)$ equals e^{-at} for $t > 0$ and 0 for $t < 0$, and is in L^1 (integral $1/a$). With the same primitive as in (b), with $z = a + 2\pi i \xi$:

$$\widehat{(e^{-at}u(t))}(\xi) = \int_0^{+\infty} e^{-(a+2\pi i \xi)t} dt = \frac{1}{a + 2\pi i \xi}.$$

✓ Numerical check (Simpson on $[0, 80]$, 800,000 subintervals): $a = 1, \xi = 1$ gives $0.0247045 - 0.1552231i$, against $\frac{1}{1+2\pi i} = \frac{1-2\pi i}{1+4\pi^2} = 0.0247045 - 0.1552231i$; $a = 2, \xi = \frac{1}{2}$ gives $0.1442002 - 0.2265092i$, against $\frac{1}{2+\pi i} = \frac{2-\pi i}{4+\pi^2} = 0.1442002 - 0.2265092i$. ✓

(e) — **row 12.** From Euler's formula, $\cos(2\pi \xi_0 t) = \frac{1}{2}(e^{2\pi i \xi_0 t} + e^{-2\pi i \xi_0 t})$, hence by linearity (Proposition 19.1) and modulation (Theorem 19.3(iii), used with ξ_0 and with $-\xi_0$),

$$(f \cos(2\pi \xi_0 \cdot))(\xi) = \frac{1}{2} [\widehat{m_{\xi_0} f}(\xi) + \widehat{m_{-\xi_0} f}(\xi)] = \frac{1}{2} [\hat{f}(\xi - \xi_0) + \hat{f}(\xi + \xi_0)].$$

(f) — **row 13.** This is the case $f = \Pi$ of (e), with $\hat{\Pi} = \operatorname{sinc}$ (Proposition 19.2). ✓ Numerical check with $\xi_0 = 2$ (Simpson on $[-\frac{1}{2}, \frac{1}{2}]$, 400,000 subintervals): $\xi = 1.7 \rightarrow 0.3943971$; $\xi = 2 \rightarrow 0.5000000$; $\xi = 2.4 \rightarrow 0.4128146$; the closed-form values agree to seven decimals with the computed values, and the imaginary parts are below 10^{-16} , as must be the case for a real, even function (Theorem 19.3). ✓ □

Remark 19.11: How the table is used. Rows 9–17 are not transforms: they are rules, and they serve to manufacture new rows without ever redoing an integral. An example, to be worked out with the table alone: the transform of $t e^{-a|t|}$. By row 15, $\widehat{(t e^{-a|t|})}(\xi) =$

$\frac{i}{2\pi} \frac{d}{d\xi} \frac{2a}{a^2 + 4\pi^2 \xi^2} = \frac{i}{2\pi} \cdot \frac{-2a \cdot 8\pi^2 \xi}{(a^2 + 4\pi^2 \xi^2)^2} = \frac{-8\pi i a \xi}{(a^2 + 4\pi^2 \xi^2)^2}$, and the starting function is real and odd, hence the transform must be purely imaginary and odd (Theorem 19.3): it is. ✓ A second example: the transform of $\Pi(\frac{t-3}{2})$, that is, the rectangle of width 2 centered at 3; by rows 11 and 9, $\wedge = 2 e^{-6\pi i \xi} \text{sinc}(2\xi)$, and at $\xi = 0$ it equals 2, which is the area of the window. ✓

19.14. Exercises inherited from Volume II

The exercises that follow come from Volume II, Chapter 4, and concern the topics of this chapter. They are reproduced in full, with their solutions, which follow in the same order as the exercises.

Exercises

Exercise 19.1. Compute the Fourier transform of $f(t) = e^{-a|t|}$, $a > 0$.

Solutions

Solution. We split the integral into $t < 0$ and $t > 0$, where $|t| = -t$ and $|t| = t$ respectively:

$$\hat{f}(\omega) = \int_{-\infty}^0 e^{at} e^{-i\omega t} dt + \int_0^{\infty} e^{-at} e^{-i\omega t} dt = \int_{-\infty}^0 e^{(a-i\omega)t} dt + \int_0^{\infty} e^{-(a+i\omega)t} dt.$$

The first integral (with $a > 0$, it is convenient to substitute $t \rightarrow -t$ to bring it to an integral over $[0, \infty)$):

$$\int_{-\infty}^0 e^{(a-i\omega)t} dt = \int_0^{\infty} e^{-(a-i\omega)t} dt = \frac{1}{a - i\omega},$$

and the second is $\frac{1}{a + i\omega}$ (standard integral of a decreasing exponential, convergent because $a > 0$). Adding:

$$\hat{f}(\omega) = \frac{1}{a - i\omega} + \frac{1}{a + i\omega} = \frac{(a + i\omega) + (a - i\omega)}{a^2 + \omega^2} = \frac{2a}{a^2 + \omega^2}.$$

This is the celebrated "Lorentzian" spectrum, which appears wherever exponential relaxations occur: RC circuits, radioactive decays, damped spectral lines.

19.15. Assigned exercises

These are *new* exercises, distinct both from the inherited one (Section 19.14) and from those solved in Section 19.16. The answers are in the Teacher's Key (Section 19.18).

Exercise 19.2: Translating a table between the three conventions. *Goal:* handle the dictionary of Remark 19.1 without getting a single factor of 2π wrong, and understand what changes and what does not. *Estimated time:* 40 minutes. *Type:* symbolic and numerical computation.

- Write row 6 of the table (Theorem 19.15), $\widehat{e^{-a|t|}}(\xi) = \frac{2a}{a^2 + 4\pi^2 \xi^2}$, in conventions (B) and (C).
- Verify Plancherel's identity for $f(t) = e^{-a|t|}$ in convention (A), that is, compute separately $\int |f|^2 dt$ and $\int |\hat{f}|^2 d\xi$ and show that they coincide. (Hint: one needs

$\int_{-\infty}^{+\infty} \frac{du}{(a^2+u^2)^2} = \frac{\pi}{2a^3}$, obtained with the substitution $u = a \tan \theta$.)

- (c) Repeat the computation of (b) in convention (B) and verify that the factor $\frac{1}{2\pi}$ announced by the table appears.
- (d) Explain why in convention (A) the sinc function that appears is the *normalized* one $\frac{\sin \pi \xi}{\pi \xi}$ and in (B) the unnormalized one $\frac{\sin(\omega/2)}{\omega/2}$, and state where the zeros are in the two cases.

Exercise 19.3: Convolutions of the rectangle and sinc integrals. *Goal:* use convolution as a machine for manufacturing integral identities. *Estimated time:* 45 minutes. *Type:* symbolic computation with numerical check.

- (a) Compute explicitly $(\Pi * \Lambda)(t)$ for every $t \in \mathbb{R}$ (it is a piecewise function on $[-\frac{3}{2}, \frac{3}{2}]$, polynomial of degree 2 on each piece) and verify that $(\Pi * \Lambda)(0) = \frac{3}{4}$ and $(\Pi * \Lambda)(\pm \frac{3}{2}) = 0$.
- (b) Deduce from this, with Theorem 19.9, $\int \text{sinc}^3 \xi \, d\xi = \frac{3}{4}$ and hence $\int_{-\infty}^{+\infty} \frac{\sin^3 x}{x^3} \, dx = \frac{3\pi}{4}$.
- (c) Compute $R_\Lambda = \Lambda * \Lambda$ at $t = 0$ and deduce $\int \text{sinc}^4 \xi \, d\xi = \frac{2}{3}$.
- (d) Why does the same method *not* allow computing $\int \text{sinc} \xi \, d\xi$? What does the principal value $\lim_{R \rightarrow \infty} \int_{-R}^R \text{sinc}$ equal instead, and which result of the chapter suggests it?

Exercise 19.4: Poisson, the theta function, and the comb. *Goal:* verify the hypotheses of Poisson before using it, and derive two classical identities from it. *Estimated time:* 45 minutes. *Type:* proof-based and numerical.

- (a) Verify that $f(t) = e^{-2\pi a|t|}$, with $a > 0$, satisfies hypotheses (H1) and (H2) of Theorem 19.12, exhibiting in each case the constant C and the exponent ε .
- (b) Apply Poisson at $t = 0$ and deduce $\sum_{n \in \mathbb{Z}} \frac{1}{a^2 + n^2} = \frac{\pi}{a} \coth(\pi a)$. Compute both sides for $a = \frac{1}{2}$ and $a = 2$ and compare them to seven decimal places.
- (c) Using the expansion $\coth x = \frac{1}{x} + \frac{x}{3} + O(x^3)$ as $x \rightarrow 0$ (which follows from the series for $\sinh$ and $\cosh$), let $a \rightarrow 0^+$ in the identity of (b) and deduce $\sum_{n \geq 1} \frac{1}{n^2} = \frac{\pi^2}{6}$.
- (d) Verify directly, without using Theorem 19.14, that $\langle \mathbb{I}, \varphi \rangle = \langle \mathbb{I}, \hat{\varphi} \rangle$ for $\varphi(t) = e^{-\pi t^2}$, and explain why this particular case does *not* prove the theorem.

19.16. Solved exercises

Exercise 19.5: What is $\int_{-\infty}^{+\infty} \frac{\sin^4 x}{x^4} \, dx$? *Type:* computation via Plancherel with two independent checks. Compute the real integral $J = \int_{-\infty}^{+\infty} \frac{\sin^4 x}{x^4} \, dx$ and give its value in closed form and to seven decimal places.

Solution. Strategy. The integrand is the fourth power of a sinc function, and sinc is the transform of Π : the fourth power in frequency is the product of two squares, that is, the transform of a convolution of two triangles. Plancherel's theorem converts the integral of sinc^4 into an integral of Λ^2 , which is a polynomial.

Step 1 — rewriting in the normalized variable. With the substitution $x = \pi \xi$, $dx = \pi \, d\xi$,

$$J = \int \frac{\sin^4(\pi \xi)}{(\pi \xi)^4} \pi \, d\xi = \pi \int (\text{sinc} \, \xi)^4 \, d\xi.$$

It thus suffices to compute $I_4 = \int \text{sinc}^4 \xi \, d\xi$.

Step 2 — $\text{sinc}^2 = \hat{\Lambda}$. By Proposition 19.3, $\hat{\Lambda} = \text{sinc}^2$; since Λ is real and even, $\hat{\Lambda}$ is real (Theorem 19.3), and $|\hat{\Lambda}|^2 = \text{sinc}^4$.

Step 3 — **Plancherel's identity for Λ .** Λ does not lie in $\mathcal{S}$, so Theorem 19.10 does not apply directly. One uses autocorrelation instead: $\Lambda \in L^1$ and $R_\Lambda = \Lambda * \tilde{\Lambda} = \Lambda * \Lambda$ (because Λ is real and even) is continuous, with $\widehat{R_\Lambda} = |\hat{\Lambda}|^2 = \text{sinc}^4 \in L^1$ (because $|\text{sinc}| \leq 1$ and $\text{sinc}^2 \in L^1$, Proposition 19.4). Theorem 19.9 applies to R_Λ and gives, at $x = 0$,

$$I_4 = \int \text{sinc}^4 \xi \, d\xi = R_\Lambda(0) = \int \Lambda(s)^2 \, ds.$$

Step 4 — **the integral of the polynomial.** Λ^2 is even, hence

$$\int \Lambda(s)^2 \, ds = 2 \int_0^1 (1-s)^2 \, ds = 2 \left[-\frac{(1-s)^3}{3} \right]_0^1 = 2 \cdot \frac{1}{3} = \frac{2}{3}.$$

Step 5 — **conclusion.**

$$J = \pi \cdot \frac{2}{3} = \boxed{\frac{2\pi}{3} = 2.0943951}.$$

Independent check 1: direct quadrature. Composite Simpson on $[-3000, 3000]$ with 6,000,000 subintervals applied to $\frac{\sin^4 x}{x^4}$: 2.0943951, with a discrepancy of $9 \cdot 10^{-12}$ from the closed form. ✓

Independent check 2: the same quadrature on the normalized form. The same scheme applied to sinc^4 gives 0.6666667 = $\frac{2}{3}$ (discrepancy $9 \cdot 10^{-14}$), and $\pi \cdot \frac{2}{3} = 2.0943951$. ✓

Interpretation. The integral is nothing but the *energy* of the triangle, read in frequency: $\int |\hat{\Lambda}|^2 = \int \Lambda^2$. And the triangle is the rectangle convolved with itself, hence the chain $\Pi \rightarrow \Lambda \rightarrow \Lambda * \Lambda$ produces, evaluated at 0, the sequence $\int \text{sinc}^2 = 1$, $\int \text{sinc}^3 = \frac{3}{4}$, $\int \text{sinc}^4 = \frac{2}{3}$: each additional convolution lowers the value, because it widens the support while keeping the area fixed.

Typical errors. (1) Confusing normalized and unnormalized sinc and forgetting the factor π of Step 1: one gets $\frac{2}{3}$ instead of $\frac{2\pi}{3}$. (2) Applying Theorem 19.10 to Λ , which is not in $\mathcal{S}$, without passing through autocorrelation. (3) Believing that $\int \text{sinc}^4 = (\int \text{sinc}^2)^2$: the integral is not multiplicative.

Extension. With $\Pi * \Pi * \Pi$ in place of $\Lambda * \Lambda$ one obtains $\int \text{sinc}^3 = \frac{3}{4}$, that is, $\int \frac{\sin^3 x}{x^3} \, dx = \frac{3\pi}{4} = 2.3561945$ (checked numerically with the same parameters, discrepancy $5 \cdot 10^{-11}$). ✓ The method stops at $\int \text{sinc}$: Proposition 19.4 says that integral does not exist in the sense of Lebesgue.

Exercise 19.6: Summing $\sum_{n \in \mathbb{Z}} \frac{1}{1+n^2}$ with the Poisson formula. *Type:* application of Poisson with explicit verification of the hypotheses. Compute, for $a > 0$, the sum $\Sigma(a) = \sum_{n \in \mathbb{Z}} \frac{1}{a^2 + n^2}$, and in particular $\Sigma(1)$.

Solution. Strategy. The function to be summed is, up to a constant, row 7 of the table (Theorem 19.15): it is the transform of a two-sided exponential. The Poisson formula turns the sum of the samples of $\hat{f}$ into the sum of the samples of f , and the latter is a geometric series.

Step 1 — the right pair. Take $f(t) = e^{-2\pi a|t|}$. By part (c) of the proof of Theorem 19.15,

$$\hat{f}(\xi) = \frac{1}{\pi} \frac{a}{a^2 + \xi^2},$$

hence $\sum_n \hat{f}(n) = \frac{a}{\pi} \Sigma(a)$: summing $\hat{f}$ over the integers is exactly the problem.

Step 2 — checking the hypotheses of Poisson. f is continuous on all of $\mathbb{R}$ (even at 0, where it has a corner but not a jump). For (H1): $e^{-2\pi a|t|}$ decays exponentially, and the function $(1 + |t|)^2 e^{-2\pi a|t|}$ is continuous and tends to 0 at infinity, hence is bounded by a constant C_1 ; therefore $|f(t)| \leq C_1(1 + |t|)^{-2}$, that is, (H1) with $\varepsilon = 1$. For (H2): $|\hat{f}(\xi)| = \frac{a}{\pi(a^2 + \xi^2)} \leq \frac{a}{\pi} \cdot \frac{2}{(1 + |\xi|)^2} \cdot \max(1, \frac{1}{a^2})$, because $(1 + |\xi|)^2 \leq 2(1 + \xi^2)$ and $a^2 + \xi^2 \geq \min(1, a^2)(1 + \xi^2)$: this is (H2) with $\varepsilon = 1$.

Step 3 — the "spatial" side. The sum of the samples of f is a geometric series of ratio $q = e^{-2\pi a} \in (0, 1)$:

$$\sum_{n \in \mathbb{Z}} e^{-2\pi a|n|} = 1 + 2 \sum_{n \geq 1} q^n = 1 + \frac{2q}{1 - q} = \frac{1 - q + 2q}{1 - q} = \frac{1 + q}{1 - q} = \frac{e^{\pi a} + e^{-\pi a}}{e^{\pi a} - e^{-\pi a}} = \coth(\pi a),$$

where in the last step numerator and denominator were multiplied by $e^{\pi a}$ (since $q = e^{-2\pi a}$).

Step 4 — Poisson. Theorem 19.12 at $t = 0$ gives $\sum_n f(n) = \sum_n \hat{f}(n)$, that is,

$$\coth(\pi a) = \frac{a}{\pi} \Sigma(a), \quad \text{hence} \quad \boxed{\Sigma(a) = \sum_{n \in \mathbb{Z}} \frac{1}{a^2 + n^2} = \frac{\pi}{a} \coth(\pi a)}.$$

For $a = 1$: $\Sigma(1) = \pi \coth \pi = \pi \cdot 1.0037419 = 3.1533481$.

Independent check 1: direct summation. Summing the terms for $|n| \leq 4,000,000$ gives 3.1533476; the neglected tail is worth $2 \sum_{n > 4 \cdot 10^6} n^{-2} \approx \frac{2}{4 \cdot 10^6} = 5.0 \cdot 10^{-7}$, and indeed the observed discrepancy is $5.0 \cdot 10^{-7}$. ✓ For $a = \frac{1}{2}$ the formula gives 6.8507543 and the direct sum 6.8507538 (same tail discrepancy); for $a = 2$, 1.5708073 against 1.5708068. ✓

Independent check 2: the spatial side. $\sum_{|n| \leq 200} e^{-2\pi|n|} = 1.0037419$, which agrees to seven decimal places with $\coth \pi = 1.0037419$. ✓

Interpretation. The identity says that the energy of a two-sided exponential, sampled at the integers in time, coincides with that sampled at the integers in frequency. This is why the constant π appears in a sum that, at first sight, looks purely arithmetic.

Typical errors. (1) Applying Poisson without checking (H2): (H1) alone is not enough, and there are continuous, integrable functions for which the two series of the formula do not coincide. (2) Taking $f(t) = e^{-a|t|}$ instead of $e^{-2\pi a|t|}$: one gets a correct identity but with $\frac{a}{2\pi}$ in place of a , and comparison with the classical form requires a further rescaling. (3) Forgetting the term $n = 0$ in the two-sided geometric series, which is 1 and not 2.

Extension. The result as $a \rightarrow 0^+$ produces $\zeta(2)$: isolating the term $n = 0$, $\Sigma(a) = \frac{1}{a^2} + 2 \sum_{n \geq 1} \frac{1}{a^2 + n^2}$, while $\frac{\pi}{a} \coth(\pi a) = \frac{1}{a^2} + \frac{\pi^2}{3} + O(a^2)$; equating and letting $a \rightarrow 0^+$ gives $\sum_{n \geq 1} \frac{1}{n^2} = \frac{\pi^2}{6} = 1.6449341$. This is part (c) of Exercise 19.4.

Exercise 19.7: Duration and bandwidth of a modulated Gaussian pulse. *Type:* quantitative verification of the uncertainty principle, with comparison. Let $f(t) = 2^{1/4} e^{2\pi i \xi_0 t} e^{-\pi(t-t_0)^2}$ with $t_0 = 1$ and $\xi_0 = 3$. Compute $\|f\|_2$, the time spread $\Delta_t^2 = \int (t - t_0)^2 |f|^2 dt$ and the frequency spread $\Delta_\xi^2 = \int (\xi - \xi_0)^2 |\hat{f}|^2 d\xi$, and compare the product with the bound of Corollary 19.6. Then repeat the computation for the rectangle Π .

Solution. Strategy. Translation and modulation do not change the moduli of f and $\hat{f}$, but shift their centers: it is convenient to reduce to the centered Gaussian, for which the computation is Lemma 19.5.

Step 1 — the norm. $|f(t)| = 2^{1/4}e^{-\pi(t-t_0)^2}$, hence, with $s = t - t_0$ and Lemma 19.5 with $b = 2$,

$$\|f\|_2^2 = \sqrt{2} \int e^{-2\pi s^2} ds = \sqrt{2} \cdot \frac{1}{\sqrt{2}} = 1.$$

Step 2 — the time spread. With the same substitution and Lemma 19.5 (second integral, $b = 2$),

$$\Delta_t^2 = \sqrt{2} \int s^2 e^{-2\pi s^2} ds = \sqrt{2} \cdot \frac{1}{2\pi \cdot 2^{3/2}} = \frac{1}{4\pi} = 0.0795775.$$

Step 3 — the transform. Set $g(t) = 2^{1/4}e^{-\pi t^2}$; then $f(t) = e^{2\pi i \xi_0 t} g(t - t_0)$. By Theorem 19.3(ii) and (iii),

$$\hat{f}(\xi) = e^{-2\pi i(\xi - \xi_0)t_0} \hat{g}(\xi - \xi_0), \quad \text{hence} \quad |\hat{f}(\xi)| = |\hat{g}(\xi - \xi_0)|.$$

By Theorem 19.6, $\hat{g}(\eta) = 2^{1/4}e^{-\pi\eta^2}$.

Step 4 — the frequency spread. With $\eta = \xi - \xi_0$ and the computation of Step 2,

$$\Delta_\xi^2 = \sqrt{2} \int \eta^2 e^{-2\pi\eta^2} d\eta = \frac{1}{4\pi} = 0.0795775.$$

Step 5 — the product.

$$\Delta_t^2 \Delta_\xi^2 = \frac{1}{4\pi} \cdot \frac{1}{4\pi} = \boxed{\frac{1}{16\pi^2} = 0.0063326},$$

exactly the minimum of Corollary 19.6: the modulated Gaussian pulse is a minimizer, as predicted by the equality case.

Step 6 — comparison with the rectangle. Π already has norm 1 in L^2 ($\int \Pi^2 = 1$) and center $t_0 = 0$ by symmetry, and

$$\Delta_t^2(\Pi) = \int_{-1/2}^{1/2} t^2 dt = \left[\frac{t^3}{3} \right]_{-1/2}^{1/2} = \frac{1}{12} = 0.0833333,$$

slightly more than the Gaussian. But $\Delta_\xi^2(\Pi) = \int \xi^2 \text{sinc}^2 \xi d\xi = \int \frac{\sin^2(\pi\xi)}{\pi^2} d\xi = +\infty$, because the integrand is periodic, nonnegative and not identically zero. The product is therefore $+\infty$: the inequality is verified, but trivially. Note that $\Pi \notin \mathcal{S}$, so Theorem 19.13 does not concern it: the computation shows, however, that the statement is not vacuous and that the finiteness of the two spreads is a real requirement.

Independent check. Simpson quadrature on $[-12, 14]$ with 400,000 subintervals applied to $|f|^2$ and to $(t-1)^2|f|^2$: 1.0000000 and 0.0795775, against 1 and $\frac{1}{4\pi} = 0.0795775$. ✓ The same quadrature on $[-12, 12]$ for the centered Gaussian $2^{1/4}e^{-\pi t^2}$ gives the same two values, confirming that translating and modulating changes nothing. ✓

Interpretation. The product $\Delta_t \Delta_\xi \geq \frac{1}{4\pi}$ says that one cannot have a signal that is simultaneously short and narrow-band. The Gaussian is the only profile that achieves the minimum, which is why it appears wherever the best time–frequency compromise is needed: from the Gabor window to the optimization of radar pulses.

Typical errors. (1) Computing the spreads with respect to 0 instead of the centers t_0 and ξ_0 : one gets larger values and the minimum seems violated the wrong way. (2) Forgetting the normalization $\|f\|_2 = 1$: without it the product scales as $\|f\|_2^4$ and the comparison with

$\frac{1}{16\pi^2}$ is meaningless. (3) Concluding from Step 6 that "the rectangle violates the principle": it satisfies it, trivially.

Extension. Repeating with $f_a(t) = (2a)^{1/4}e^{-\pi at^2}$ one finds $\Delta_t^2 = \frac{1}{4\pi a}$ and $\Delta_\xi^2 = \frac{a}{4\pi}$: the product remains $\frac{1}{16\pi^2}$ for every $a > 0$, while the two factors exchange with each other under $a \rightarrow 1/a$. This is Figure 19.3 read in numbers.

19.17. Self-assessment quiz

- (Definition) A *tempered distribution* is
 - a measurable function with polynomial growth
 - a linear, continuous functional on $\mathcal{S}(\mathbb{R})$
 - a function with a single point of discontinuity
 - a pointwise limit of L^1 functions
- (Hypothesis) In Theorem 19.12 hypothesis (H2), that is, the decay of $\hat{f}$, serves to
 - guarantee that f is continuous
 - make the series $\sum_n \hat{f}(n)e^{2\pi i n t}$ converge absolutely and uniformly, so that its sum is continuous and its coefficients can be computed
 - make f integrable
 - ensure that $\hat{f}$ is real
- (Symbolic computation) The transform of $e^{-2t}u(t)$ equals
 - $\frac{1}{2 + 2\pi i \xi}$
 - $\frac{4}{4 + 4\pi^2 \xi^2}$
 - $\frac{1}{2 + i \xi}$
 - $\frac{2}{2 + 2\pi i \xi}$
- (Numerical computation) $\int_{-\infty}^{+\infty} \frac{\sin^4 x}{x^4} dx$ equals, to seven decimal places,
 - 2.0943951
 - 3.1415927
 - 2.3561945
 - 1.5707963
- (Proof step) In the proof of Theorem 19.5 the minus sign that appears after the substitution comes
 - from reversing the limits of integration
 - from the choice $h = \frac{1}{2\xi}$, for which $e^{-2\pi i \xi h} = e^{-\pi i} = -1$
 - from the fact that f changes sign
 - from the derivative of the exponential
- (Error diagnosis) A student writes $\int \delta(t)\varphi(t) dt = \varphi(0)$ meaning a Lebesgue integral, and concludes that δ is a function that is zero away from the origin with integral 1. The error is
 - the value $\varphi(0)$ should be replaced by $\varphi(1)$
 - a function that is zero almost everywhere has zero integral, and Proposition 19.8 rules out any integral representation with a locally integrable function
 - the integral should be understood over $[0, +\infty)$
 - φ must have compact support
- (Transfer) $\sum_{n \in \mathbb{Z}} \frac{1}{1 + n^2}$ equals, to seven decimal places,
 - 1.6449341
 - 3.1533481
 - 3.1415927
 - 2.0943951
- (Source and metacognition) The uncertainty principle, in the form proved in this chapter, and the Poisson summation formula are found respectively in
 - Stein–Shakarchi, *Fourier Analysis: An Introduction*, Ch. 5, §4 "The Heisenberg uncertainty principle" (p. 158) and §3 "The Poisson summation formula" (p. 153)
 - Stein–Shakarchi, Ch. 1 "The Genesis of Fourier Analysis"
 - Rudin, *Real and Complex Analysis*, Ch. 11
 - NIST DLMF, §1.14(iii) "Laplace Transform"

19.18. Teacher's key

BEST PRACTICE

Quiz — answers, rationale, and diagnosis (items 1–4).

1) **B.** *Rationale:* this is Definition 19.7: linearity plus sequential continuity with respect to the seminorms of $\mathcal{S}$. *Distractors:* A describes a *class* of examples (Proposition 19.6), not the definition, and excludes the delta from it; C has no connection to the notion; D is false, because a pointwise limit of L^1 functions is still a function. *Diagnosed error:* identifying a distribution with a "generalized" function rather than with a functional. *Source:* NIST DLMF §1.16(v) "Tempered Distributions". *Prerequisite:* the Schwartz class (Definition 19.5). *Remediation:* redo Proposition 19.7 and Proposition 19.8 in sequence.

2) **B.** *Rationale:* Step 1 of the proof of Theorem 19.12 uses (H2) *only* for the Weierstrass criterion, which makes the frequency-side series uniformly convergent and hence its sum continuous; without continuity one cannot apply the uniqueness of coefficients of Step 4. *Distractors:* A is false, continuity of f is a separate hypothesis; C is what follows from (H1), not from (H2) (Step 3 of Theorem 19.11); D is meaningless, $\hat{f}$ is real only if f is even. *Diagnosed error:* not distinguishing the role of the two decay hypotheses. *Source:* Stein–Shakarchi, Ch. 5, §3; NIST DLMF §1.8(iv), eq. 1.8.14. *Prerequisite:* the Weierstrass criterion. *Remediation:* construct an f satisfying (H1) but not (H2) and see where the proof breaks down.

3) **A.** *Rationale:* this is row 8 of the table (Theorem 19.15, derivation (d)) with $a = 2$: $\int_0^\infty e^{-2t} e^{-2\pi i \xi t} dt = \frac{1}{2+2\pi i \xi}$. *Distractors:* B is the transform of $e^{-2|t|}$ (row 6), that is, the *two-sided* case; C is the same formula in convention (B), in angular frequency; D has an extra 2 in the numerator, the error of one who confuses row 6 with row 8. *Diagnosed error:* confusing the causal and two-sided exponentials, or forgetting the 2π of convention (A). *Source:* Theorem 19.15, derivation (d); Bracewell, Ch. 6. *Prerequisite:* the primitive of e^{-zt} with $\operatorname{Re} z > 0$. *Remediation:* recompute rows 6 and 8 for $a = 1$ and compare the moduli at $\xi = 0$ (2 versus 1).

4) **A.** *Rationale:* this is Solved Exercise 19.5: $\int \frac{\sin^4 x}{x^4} dx = \pi \int \operatorname{sinc}^4 = \pi \cdot \frac{2}{3} = \frac{2\pi}{3} = 2.0943951$. *Distractors:* B is π , the value of $\int \frac{\sin^2 x}{x^2} dx$; C is $\frac{3\pi}{4} = 2.3561945$, that is, $\int \frac{\sin^3 x}{x^3} dx$ — the wrong exponent; D is $\frac{\pi}{2}$. *Diagnosed error:* getting the power wrong, or forgetting the factor π of the change of variable $x = \pi \xi$. *Source:* Solved Exercise 19.5, Steps 1–5. *Prerequisite:* Proposition 19.3 and Corollary 19.1. *Remediation:* redo the computation for $\int \operatorname{sinc}^2$ and $\int \operatorname{sinc}^3$ and order the three values $1 > \frac{3}{4} > \frac{2}{3}$.

BEST PRACTICE

Quiz — answers, rationale, and diagnosis (items 5–8).

5) **B.** *Rationale:* in Step 1 of the proof of Theorem 19.5 one chooses $h = \frac{1}{2\xi}$ precisely because $e^{-2\pi i \xi h} = e^{-\pi i} = -1$: it is half a period of the oscillation, and translating by half a period flips the sign of the character. *Distractors:* A is the typical error of one who confuses this substitution with the one in Step (iv) of Theorem 19.3, where the sign really does come from the limits; C is false, f is arbitrary; D is unrelated, nothing is differentiated. *Diagnosed error:* not identifying the algebraic origin of a sign. *Source:* Theorem 19.5, Step 1; Rudin, *Real and Complex Analysis*, Ch. 9. *Prerequisite:* $e^{i\pi} = -1$. *Remediation:* redo Step 1 with $h = \frac{1}{4\xi}$ and see what results (a factor $-i$, which does not produce the useful average).

6) **B.** *Rationale:* this is exactly Proposition 19.8: no locally integrable function can realize the pairing $\varphi \mapsto \varphi(0)$; and in any case a function that is zero almost everywhere has zero integral, whatever value is assigned to it at the origin. *Distractors:* A changes the point of evaluation, which is not the error; C restricting the domain fixes nothing; D is false,

the definition uses $\mathcal{S}$, which contains functions without compact support. *Diagnosed error:* treating δ as a function, that is, mistaking a notation for a definition (Remark 19.9). *Source:* Proposition 19.8; NIST DLMF §1.16(iii). *Prerequisite:* absolute continuity of the integral. *Remediation:* reread Step 4 of Proposition 19.8 and reconstruct the choice of η and δ with $\varepsilon = \frac{1}{10}$.

7) B. *Rationale:* this is Solved Exercise 19.6 with $a = 1$: $\sum_n \frac{1}{1+n^2} = \pi \coth \pi = 3.1533481$; the direct sum up to $|n| \leq 4 \cdot 10^6$ gives 3.1533476, with the predicted tail of $5 \cdot 10^{-7}$. *Distractors:* A is $\frac{\pi^2}{6} = \sum_{n \geq 1} n^{-2}$, that is, the *one-sided* sum *without* the a^2 term; C is π , that is, the value one would get by swapping $\coth \pi$ for 1; D is $\frac{2\pi}{3}$. *Diagnosed error:* confusing the two-sided sum with the one-sided one, or forgetting the term $n = 0$. *Source:* Solved Exercise 19.6, Steps 3–4. *Prerequisite:* geometric series and the definition of $\coth$. *Remediation:* compute $\sum_{n \geq 1} \frac{1}{1+n^2} = \frac{\pi \coth \pi - 1}{2} = 1.0766740$ and compare it with the direct sum 1.0766738.

8) A. *Rationale:* the book by Stein and Shakarchi devotes §4 of Chapter 5 (p. 158) to the uncertainty principle and §3 (p. 153) to the Poisson formula, with sub-section 3.1 "Theta and zeta functions" containing the identity of Corollary 19.5. *Distractors:* B is the introductory chapter on the wave and heat equations; C is Rudin's chapter on harmonic functions, not on the transform (which is Chapter 9); D is the DLMF section devoted to the Laplace transform, not the Fourier transform (which is §1.14(i)). *Diagnosed error:* citing "the book" without the chapter, or attributing a result to a nearby section. *Source:* see the "Sources" section. *Prerequisite:* knowing how to read a table of contents by section. *Remediation:* compile a table "result / author / chapter / proved here yes or no" for the twelve main statements of the chapter.

BEST PRACTICE

Assigned Exercise 19.2 — answers.

(a) By the "link with (A)" row of the table (Remark 19.1), $\hat{f}_B(\omega) = \hat{f}(\omega/2\pi)$, hence

$$\hat{f}_B(\omega) = \frac{2a}{a^2 + 4\pi^2 \left(\frac{\omega}{2\pi}\right)^2} = \frac{2a}{a^2 + \omega^2}, \quad \hat{f}_C(\omega) = \frac{1}{\sqrt{2\pi}} \cdot \frac{2a}{a^2 + \omega^2}.$$

The form in (B) is that of Inherited Exercise 19.1: it is the same result.

(b) $\int |f|^2 dt = \int e^{-2a|t|} dt = 2 \int_0^\infty e^{-2at} dt = \frac{1}{a}$. For the second integral, with $u = 2\pi\xi$ ($d\xi = \frac{du}{2\pi}$) and the hint,

$$\int |\hat{f}|^2 d\xi = \int \frac{4a^2 d\xi}{(a^2 + 4\pi^2 \xi^2)^2} = \frac{4a^2}{2\pi} \int \frac{du}{(a^2 + u^2)^2} = \frac{4a^2}{2\pi} \cdot \frac{\pi}{2a^3} = \frac{1}{a}.$$

The two values coincide: Plancherel is verified *without constants*. Numerical check for $a = 1$: both 1.0000000. ✓

(c) In convention (B): $\int |\hat{f}_B|^2 d\omega = \int \frac{4a^2 d\omega}{(a^2 + \omega^2)^2} = 4a^2 \cdot \frac{\pi}{2a^3} = \frac{2\pi}{a}$, and indeed $\frac{1}{2\pi} \cdot \frac{2\pi}{a} = \frac{1}{a} = \int |f|^2$: exactly the factor $\frac{1}{2\pi}$ announced by the "Plancherel" row of the table appears.

(d) Because the transform of the rectangle has as zeros the points where the character completes an integer number of turns. In (A) this happens for $\xi \in \mathbb{Z} \setminus \{0\}$, and $\frac{\sin \pi \xi}{\pi \xi}$ vanishes there; in (B) it happens for $\omega = 2\pi k$, $k \neq 0$, and $\frac{\sin(\omega/2)}{\omega/2}$ vanishes there. These are the same physical points, written in two different variables: normalization puts the zeros at the *integers*, which makes reading the "bandwidth" of a window of duration T immediate (zeros at multiples of $1/T$).

BEST PRACTICE

Assigned Exercise 19.3 — answers.

(a) $(\Pi * \Lambda)(t) = \int_{-1/2}^{1/2} \Lambda(t - \tau) d\tau = \int_{t-1/2}^{t+1/2} \Lambda(s) ds$. Let F be the primitive of Λ that vanishes at $-\infty$ ($F(x) = 0$ for $x \leq -1$, $F(x) = \frac{(1+x)^2}{2}$ for $-1 \leq x \leq 0$, $F(x) = 1 - \frac{(1-x)^2}{2}$ for $0 \leq x \leq 1$, $F(x) = 1$ for $x \geq 1$); then $(\Pi * \Lambda)(t) = F(t + \frac{1}{2}) - F(t - \frac{1}{2})$, that is, by symmetry,

$$(\Pi * \Lambda)(t) = \begin{cases} \frac{3}{4} - t^2, & |t| \leq \frac{1}{2}, \\ \frac{1}{2} \left(\frac{3}{2} - |t| \right)^2, & \frac{1}{2} \leq |t| \leq \frac{3}{2}, \\ 0, & |t| \geq \frac{3}{2}. \end{cases}$$

In particular $(\Pi * \Lambda)(0) = \frac{3}{4}$ and $(\Pi * \Lambda)(\pm \frac{3}{2}) = 0$; the two expressions match at $|t| = \frac{1}{2}$, where both equal $\frac{1}{2}$. Numerical check (Simpson, 200,000 subintervals): $t = 0 \rightarrow 0.7500000$; $t = 0.25 \rightarrow 0.6875000 = \frac{3}{4} - \frac{1}{16}$; $t = 0.5 \rightarrow 0.5000000$; $t = 0.7 \rightarrow 0.3200000 = \frac{1}{2}(0.8)^2$; $t = 1 \rightarrow 0.1250000 = \frac{1}{2}(0.5)^2$; $t = 1.5 \rightarrow 0.0000000$. ✓

(b) $\Pi * \Lambda = \Pi * \Pi * \Pi$ is continuous (an integral of a uniformly continuous function over an interval that depends continuously on t) and has transform sinc^3 (Theorem 19.4(iv)), integrable because $|\text{sinc}| \leq 1$ and $\text{sinc}^2 \in L^1$. Theorem 19.9 at $x = 0$ gives $\int \text{sinc}^3 \xi d\xi = (\Pi * \Lambda)(0) = \frac{3}{4}$. With $x = \pi\xi$, $\int \frac{\sin^3 x}{x^3} dx = \pi \cdot \frac{3}{4} = \frac{3\pi}{4} = 2.3561945$; quadrature on $[-3000, 3000]$ with 6,000,000 subintervals: 2.3561945. ✓

(c) $R_\Lambda(0) = \int \Lambda^2 = 2 \int_0^1 (1-s)^2 ds = \frac{2}{3}$, and $\widehat{R_\Lambda} = |\hat{\Lambda}|^2 = \text{sinc}^4$; Theorem 19.9 at $x = 0$ gives $\int \text{sinc}^4 = \frac{2}{3} = 0.6666667$, confirmed numerically. ✓

(d) Because $\text{sinc} = \hat{\Pi}$ is not integrable (Proposition 19.4): Theorem 19.9 requires $\hat{f} \in L^1$ and here the hypothesis fails. The principal value exists and equals 1, that is, $\Pi(0)$, as suggested by Remark 19.7; equivalently $\int_{-\infty}^{+\infty} \frac{\sin x}{x} dx = \pi$ (the Dirichlet integral, improper and not absolutely convergent, which this chapter does *not* prove). Numerical check of the principal value: $\int_{-R}^R \text{sinc}$ equals 0.9959475 for $R = 50$, 0.9995947 for $R = 500$, 0.9999595 for $R = 5000$: it converges to 1 like $1 - \frac{c}{R}$ with $c \approx 0.20$. ✓

BEST PRACTICE

Assigned Exercise 19.4 — answers.

(a) This is Step 2 of Solved Exercise 19.6: take $\varepsilon = 1$ in both hypotheses, with $C_1 = \max_t (1 + |t|)^2 e^{-2\pi a|t|}$ for (H1) and $C_2 = \frac{2a}{\pi} \max(1, \frac{1}{a^2})$ for (H2). Both maxima exist because the functions are continuous and vanish at infinity.

(b) $\sum_{n \in \mathbb{Z}} \frac{1}{a^2 + n^2} = \frac{\pi}{a} \coth(\pi a)$. Values: $a = \frac{1}{2} \rightarrow 6.8507543$ (formula) against 6.8507538 (direct sum up to $|n| \leq 4 \cdot 10^6$, predicted tail $5 \cdot 10^{-7}$); $a = 2 \rightarrow 1.5708073$ against 1.5708068. ✓

(c) Isolating the term $n = 0$: $\frac{1}{a^2} + 2 \sum_{n \geq 1} \frac{1}{a^2 + n^2} = \frac{\pi}{a} \coth(\pi a) = \frac{\pi}{a} \left(\frac{1}{\pi a} + \frac{\pi a}{3} + O(a^3) \right) = \frac{1}{a^2} + \frac{\pi^2}{3} + O(a^2)$. Cancelling $\frac{1}{a^2}$ and letting $a \rightarrow 0^+$ (legitimate: the series on the left converges uniformly for $a \in [0, 1]$ by comparison with $\sum n^{-2}$), one obtains $2 \sum_{n \geq 1} \frac{1}{n^2} = \frac{\pi^2}{3}$, that is, $\sum_{n \geq 1} \frac{1}{n^2} = \frac{\pi^2}{6} = 1.6449341$. ✓

(d) For $\varphi(t) = e^{-\pi t^2}$ Theorem 19.6 gives $\hat{\varphi} = \varphi$, hence $\langle \mathbb{I}, \varphi \rangle = \langle \mathbb{I}, \hat{\varphi} \rangle = \sum_n e^{-\pi n^2} = \vartheta(1) = 1.0864348$: the equality is verified, but *vacuously*, because the Gaussian is a fixed point of $\mathcal{F}$ and the two sides are literally the same sum. The theorem requires the equality for *every* $\varphi \in \mathcal{S}$, and the proof (Theorem 19.14) necessarily goes through the Poisson formula. A nontrivial test is obtained with $\varphi(t) = e^{-\pi a t^2}$ for $a \neq 1$: then $\langle \mathbb{I}, \varphi \rangle = \vartheta(a)$ and

$\langle \mathbb{I}, \hat{\varphi} \rangle = a^{-1/2} \vartheta(1/a)$, which coincide by Corollary 19.5 but not term by term — for $a = 2$, 1.0037349 on both sides. ✓

19.19. Formulary of the chapter

Definition and convention.

$$\hat{f}(\xi) = \int f(t) e^{-2\pi i \xi t} dt, \quad \mathcal{F}^{-1} h(x) = \int h(\xi) e^{2\pi i x \xi} d\xi, \quad \|\hat{f}\|_{\infty} \leq \|f\|_1.$$

Passage to angular frequency: $\hat{f}_B(\omega) = \hat{f}(\frac{\omega}{2\pi})$, $\hat{f}_C = \frac{1}{\sqrt{2\pi}} \hat{f}_B$. Normalized sinc function: $\text{sinc } x = \frac{\sin \pi x}{\pi x}$.

The eight rules.

$$\begin{aligned} \widehat{f(\cdot - t_0)} &= e^{-2\pi i \xi t_0} \hat{f}; & \widehat{e^{2\pi i \xi_0 \cdot} f(\xi)} &= \hat{f}(\xi - \xi_0); & \widehat{f(a \cdot)}(\xi) &= \frac{1}{|a|} \hat{f}\left(\frac{\xi}{a}\right); \\ \widehat{f(-\cdot)}(\xi) &= \hat{f}(-\xi); & \widehat{\hat{f}}(\xi) &= \overline{\hat{f}(-\xi)}; & \widehat{f'}(\xi) &= 2\pi i \xi \hat{f}(\xi); & \widehat{tf(t)}(\xi) &= \frac{i}{2\pi} \hat{f}'(\xi); \\ \widehat{f * g} &= \hat{f} \hat{g}; & R_f &= f * \tilde{f} \quad (\tilde{f}(t) = \overline{f(-t)}), & \widehat{R_f} &= |\hat{f}|^2. \end{aligned}$$

f real $\Rightarrow \hat{f}(-\xi) = \overline{\hat{f}(\xi)}$; f real and even $\Rightarrow \hat{f}$ real and even; f real and odd $\Rightarrow \hat{f}$ purely imaginary and odd.

Inversion, Plancherel, Riemann–Lebesgue.

$$f \in \mathcal{S} \Rightarrow f(x) = \int \hat{f}(\xi) e^{2\pi i x \xi} d\xi, \quad \mathcal{F}^2 = R, \quad \mathcal{F}^4 = \text{id};$$

$$f, \hat{f} \in L^1 \Rightarrow f = \mathcal{F}^{-1} \hat{f} \text{ a.e.}; \quad \int f \bar{g} = \int \hat{f} \bar{\hat{g}}, \quad \|\hat{f}\|_2 = \|f\|_2; \quad f \in L^1 \Rightarrow \hat{f}(\xi) \xrightarrow{|\xi| \rightarrow \infty} 0.$$

Multiplication formula: $\int \hat{f} g = \int f \hat{g}$. Gaussian kernel: $K_{\delta}(u) = \frac{1}{\delta} e^{-\pi u^2 / \delta^2}$, $\int K_{\delta} = 1$, $f * K_{\delta} \rightarrow f$ in L^1 .

Periodization, Poisson, uncertainty.

$$(Pf)(t) = \sum_{n \in \mathbb{Z}} f(t + n), \quad c_n(Pf) = \hat{f}(n); \quad \sum_{n \in \mathbb{Z}} f(t + n) = \sum_{n \in \mathbb{Z}} \hat{f}(n) e^{2\pi i n t}.$$

$$\vartheta(a) = \sum_{n \in \mathbb{Z}} e^{-\pi a n^2} = \frac{1}{\sqrt{a}} \vartheta\left(\frac{1}{a}\right); \quad \sum_{n \in \mathbb{Z}} \frac{1}{a^2 + n^2} = \frac{\pi}{a} \coth(\pi a).$$

$$\|f\|_2 = 1 \Rightarrow \left(\int (t - t_0)^2 |f|^2 \right) \left(\int (\xi - \xi_0)^2 |\hat{f}|^2 \right) \geq \frac{1}{16\pi^2},$$

with equality if and only if $f(t) = A e^{2\pi i \xi_0 t} e^{-\pi a (t - t_0)^2}$, $|A|^2 = \sqrt{2a}$.

Essential table, and the numerical values of the chapter.

$$\widehat{\Pi} = \text{sinc}, \quad \widehat{\Lambda} = \text{sinc}^2, \quad \widehat{e^{-\pi t^2}} = e^{-\pi \xi^2}, \quad \widehat{e^{-\pi a t^2}} = a^{-1/2} e^{-\pi \xi^2 / a}, \quad \widehat{t e^{-\pi t^2}} = -i \xi e^{-\pi \xi^2};$$

$$\begin{aligned}
\widehat{e^{-a|t|}} &= \frac{2a}{a^2 + 4\pi^2\xi^2}, & \frac{1}{\pi} \widehat{\frac{a}{a^2 + t^2}} &= e^{-2\pi a|\xi|}, & \widehat{e^{-at}u(t)} &= \frac{1}{a + 2\pi i\xi}; \\
\hat{\delta} &= 1, & \hat{1} &= \delta, & \hat{\mathbb{I}} &= \mathbb{I}. \\
\int e^{-\pi t^2} dt &= 1, & \int t^2 e^{-\pi b t^2} dt &= \frac{1}{2\pi b^{3/2}}, & \int \operatorname{sinc}^2 &= 1, & \int \operatorname{sinc}^3 &= \frac{3}{4}, & \int \operatorname{sinc}^4 &= \frac{2}{3}; \\
\int \frac{\sin^3 x}{x^3} dx &= \frac{3\pi}{4} = 2.3561945, & \int \frac{\sin^4 x}{x^4} dx &= \frac{2\pi}{3} = 2.0943951, \\
e^{-\pi} &= 0.0432139, & \vartheta(1) &= 1.0864348, & \pi \coth \pi &= 3.1533481, & \frac{1}{16\pi^2} &= 0.0063326, & \frac{1}{4\pi} &= 0.0795775.
\end{aligned}$$

Sources and bibliography

Chapter 5 "The Fourier Transform on $\mathbb{R}$ " (from p. 129): §1 "Elementary theory of the Fourier transform", with §1.3 "The Schwartz space" (p. 134), §1.4 "The Fourier transform on $\mathcal{S}$ " (p. 136), §1.5 "The Fourier inversion" and §1.6 "The Plancherel formula" — is the source of Definition 19.5, of Theorem 19.7, of Theorem 19.8 and of Theorem 19.10; §3 "The Poisson summation formula" (p. 153), with §3.1 "Theta and zeta functions", the source of Theorem 19.12 and of Corollary 19.5; §4 "The Heisenberg uncertainty principle" (p. 158), the source of Theorem 19.13. Bibliographic data verified on the publisher's record (Princeton University Press, ISBN 9780691113845) and the structure of Chapter 5 with pagination verified on the full-text index of the Internet Archive/Open Library copy — verified on 6 September 2026.
- [2] W. Rudin, *Real and Complex Analysis*, 3rd edition, McGraw-Hill, New York, 1987 (ISBN 0-07-054234-1, LCCN 86-000007, xiv+416 pages). Chapter 9 "Fourier Transforms", with the sections "Formal properties", "The inversion theorem", "The Plancherel theorem" and "The Banach algebra L^1 ": this is the alternative source for Theorem 19.9 and for the extension of Plancherel to L^2 stated in Remark 19.8, and for the measure-theory prerequisites listed in the opening *infobox* (dominated convergence, Fubini–Tonelli, density of C_c in L^1 , the Riesz theorem). The page numbers of those four sections — 192, 195, 200 and following — come from the index of the 2nd edition (New York 1974, ISBN 0-07-054233-3, LCCN 73-015743, xii+452 pages), the only one for which the full text is indexed; in the 3rd edition the titles are the same and the pagination differs. Bibliographic data and section titles verified on the Open Library records OL2707518M (3rd ed.) and OL5422092M (2nd ed.) and on Open Library's full-text search — verified on 6 September 2026.
- [3] R. N. Bracewell, *The Fourier Transform and Its Applications*, 3rd edition, McGraw-Hill Series in Electrical and Computer Engineering, McGraw-Hill, Boston, 2000 (ISBN 0-07-303938-1, 616 pages). This is the engineering reference source for convention (A) of the table in Remark 19.1, for the table of Theorem 19.15 and for the notation $\mathbb{I}$ of the Dirac comb (Definition 19.10); Chapter 3 "Convolution", Chapter 5 "The Impulse Symbol" — with the "sifting property" cited in Remark 19.9 — and Chapter 6 "The Basic Theorems" correspond respectively to Section 19.4, to Section 19.12 and to Section 19.3 of this chapter; Chapter 10 "Sampling and Series" is the source of the panorama on sampling (Remark 19.10), which is not proved here. Bibliographic data of the 3rd edition verified on the Open Library record for ISBN 0073039381; the chapter titles are verified on the full-text index of the 2nd edition (New York 1978, ISBN 0-07-007013-X, LCCN 77-

013376, xvi+444 pages, Open Library record OL4545611M), the only one indexed — verified on 6 September 2026.

- [4] NIST *Digital Library of Mathematical Functions*, <https://dlmf.nist.gov/>, version 1.2.7 of 15 June 2026 (release consulted). §1.14 "Integral Transforms", subsection §1.14(i) "Fourier Transform": defines $\mathcal{F}f(x) = \frac{1}{2\pi} \int f(t)e^{ixt}dt$ and reports the two Parseval formulas; this is the convention *different* from ours cited in Remark 19.1. §1.8 "Fourier Series", subsection §1.8(iv) "Poisson's Summation Formula", equation 1.8.14: states $\sum_n f(x+n) = \sum_n e^{2\pi inx} \int f(t)e^{-2\pi int}dt$ — in our convention (A) — under the hypothesis that f is twice continuously differentiable with f and $|f''|$ integrable on $(-\infty, \infty)$; these are hypotheses *different* from those of Theorem 19.12, which requires only continuity and decay $O((1+|t|)^{-1-\varepsilon})$ for f and $\hat{f}$: neither implies the other. §1.16 "Distributions", subsections §1.16(iii) "Dirac Delta Distribution", §1.16(v) "Tempered Distributions" and §1.16(vii) "Fourier Transforms of Tempered Distributions", equation 1.16.35 ($\langle \mathcal{F}(u), \phi \rangle = \langle u, \mathcal{F}(\phi) \rangle$): this is the source of Definition 19.7 and of Definition 19.9 — verified on 6 September 2026.
- [5] For results of the treatise recalled with \ref: the Fourier series on the circle, Parseval's identity and the uniqueness of the coefficients are Theorem 17.1 and Corollary 17.2 of Chapter 17, where they are proved; the Dirichlet–Jordan theorem cited in Remark 19.7 is Theorem 17.4 of the same chapter. The material inherited from Volume II (Chapter 4, §9) is reproduced in full in Section 19.2 and in Section 19.14.
- [6] Numerical checks: all values of the chapter were computed twice, in closed form and with executed Python scripts (composite Simpson quadrature with $2 \cdot 10^5$ – $4 \cdot 10^7$ subintervals, truncated sums with the tail estimated explicitly), and the two results agree to the seventh decimal place except where the text states and justifies the residual discrepancy (the integral of sinc^2 and the sums $\frac{1}{a^2+n^2}$, where the truncated tail is computed and compared with the observed discrepancy).

The Laplace transform

The Fourier transform of Chapter 19 requires the signal to be integrable over the whole line: a hypothesis that a growing exponential does not satisfy, and that not even the unit step satisfies. The Laplace transform removes the obstacle by multiplying the signal by a damping factor $e^{-\sigma t}$ before transforming it, and pays the price of having to declare, each time, *for which* σ the computation makes sense. That price is the true content of the chapter: the set of admissible values is not just any set, it is always a right half-plane (Theorem 20.2), on which the transform is automatically holomorphic (Theorem 20.3), and whose boundary — the imaginary axis — is exactly the locus where the Laplace transform becomes a Fourier transform again (Theorem 20.19).

The chapter proceeds as follows. Section 20.1 reproduces *in full* the material that the executive plan moved here from Volume II (Chapter 4, §10, and Appendix A, §2): the definition, the table of pairs, the properties, the transfer function, BIBO stability, a worked example, exercises and quiz. That text leaves some hypotheses implicit (“for $\operatorname{Re}(s)$ sufficiently large”, “under suitable regularity hypotheses”): the rest of the chapter serves to make them explicit and to prove every statement.

Section 20.2 proves that the region of convergence is a half-plane (Theorem 20.2), introduces the two abscissas σ_c and σ_a and exhibits an example in which they differ (Proposition 20.1). Section 20.3 proves the holomorphy of the transform by differentiation under the integral sign, with the hypothesis that justifies it (Theorem 20.3) and the formula for all derivatives (Corollary 20.2). Section 20.4 proves the computation rules: linearity (Theorem 20.4), translation in time and in frequency (Theorems 20.5 and 20.6), time scaling (Theorem 20.7), differentiation and integration in time (Theorems 20.8 and 20.9), multiplication by t (Corollary 20.5) and convolution (Theorem 20.10). Section 20.5 computes the elementary transforms one by one and collects them into a table in which *every row carries its own region of convergence* together with a pointer to where it is proved (Theorem 20.11). Section 20.6 proves the initial value theorem (Theorem 20.12) and the final value theorem (Theorem 20.13), each with explicit hypotheses and with a counterexample showing what happens if they fail (Examples 20.3 and 20.4). Section 20.7 proves the uniqueness of the inverse transform (Theorem 20.14), inversion by partial fractions with simple and multiple poles (Theorems 20.15 and 20.16) and inversion by residues in the rational case (Theorem 20.17), which rests entirely on Chapter 15. Section 20.8 closes the circle with the restriction to the imaginary axis.

INFO

Level and prerequisites. Level **C** (undergraduate), with two passages at level **D** (the proof of the half-plane of convergence for simple convergence, and the proof of Lerch’s uniqueness theorem).

Internal prerequisites. The Fourier transform, convolution, the Dirac delta (Chapter 19, Definition 19.1, Theorem 19.4, Definition 19.8); holomorphic functions, Liouville’s theorem, removable singularities, Laurent series and residues (Chapter 15, Theorem 15.8, Theorem 15.13, Theorem 15.4, Proposition 15.2); the trigonometric approximation theorem of Weierstrass (Chapter 17, Corollary 17.3); Euler’s Gamma function (Chapter 11); the complex exponential and Euler’s formulas (Volume II, Chapter 3).

External prerequisites, assumed and not reproved:

- Lebesgue integration on $[0, \infty)$: the dominated convergence theorem, Tonelli's theorem and Fubini's theorem for double integrals over a measurable subset of $[0, \infty)^2$;
- absolutely continuous functions on a compact interval and their integration-by-parts formula: if g is absolutely continuous on $[0, T]$ and h is of class C^1 on $[0, T]$, then $\int_0^T g' h \, dt = [gh]_0^T - \int_0^T gh' \, dt$;
- Dirichlet's criterion for improper integrals: if $\Phi(X) = \int_1^X \varphi$ is bounded and ψ is of class C^1 with $\psi(u) \rightarrow 0$ and $\int_1^\infty |\psi'| < \infty$, then $\int_1^\infty \varphi \psi$ converges;
- the Weierstrass approximation theorem in *polynomial* form: every continuous function on $[0, 1]$ is the uniform limit of polynomials (the trigonometric form is proved in Chapter 17);
- the fundamental lemma of the calculus of variations in L^1 : if $h \in L^1(0, 1)$ and $\int_0^1 h \varphi \, dx = 0$ for every φ continuous on $[0, 1]$, then $h = 0$ almost everywhere.

Everything else is proved here.

What is learned. How to state the region of convergence of every transform and recognize that it is a half-plane; how to differentiate under the integral sign knowing which hypothesis authorizes it; how to derive every row of the table of transforms from a few already-proved rules, instead of memorizing it; how to use the initial and final value theorems knowing when they do *not* apply; how to invert a rational function by partial fractions with simple and multiple poles, and to recognize the same formula as a sum of residues; how to read the Fourier transform as the restriction of the Laplace transform to the imaginary axis, and to know when that restriction makes sense.

Warning. Conventions of the chapter.

- **Causal signals.** Unless stated otherwise, f is a function $f : [0, \infty) \rightarrow \mathbb{C}$ that is *locally integrable*, i.e. Lebesgue integrable on every compact interval $[0, T]$. Identifying f with its extension by zero for $t < 0$ gives a function on all of $\mathbb{R}$: this is *causality*.
- **Unilateral transform.** $\mathcal{L}\{f\}(s) = F(s) = \int_0^\infty f(t)e^{-st} \, dt$, with $s = \sigma + i\omega$, $\sigma = \operatorname{Re}(s)$, $\omega = \operatorname{Im}(s)$. The notation $\int_0^\infty$ always means $\lim_{T \rightarrow \infty} \int_0^T$, and the integral over $[0, T]$ is a Lebesgue integral.
- **Two kinds of convergence.** The integral *converges* at s if that limit exists and is finite; it *converges absolutely* at s if $\int_0^\infty |f(t)|e^{-\sigma t} \, dt < \infty$. The two notions do not coincide (Proposition 20.1), and every statement declares which of the two it uses.
- $u(t)$ is the **Heaviside unit step**: $u(t) = 1$ for $t \geq 0$ and $u(t) = 0$ for $t < 0$. The value at 0 is irrelevant for the integrals.
- $|e^{-st}| = e^{-\sigma t}$: this is the identity that governs the entire chapter, and follows from $|e^z| = e^{\operatorname{Re}(z)}$ (Volume II, Chapter 3).
- The letters $p, p_1, \dots, p_r$ denote poles in the s -plane; Γ is Euler's Gamma function (Chapter 11).
- Numerical values are rounded to the seventh decimal digit and recomputed twice by independent methods: a closed formula and an executed Python script.

20.1. The Laplace transform

This section reproduces, without any cuts, the text of Volume II (Chapter 4, Section 10) and the table of Appendix A, Section 2, which the executive plan moved here. The hypotheses left implicit are made explicit and proved in the sections that follow: a precise pointer to each is given in the attention box at the end of the section.

The Laplace transform further generalizes the Fourier transform, allowing treatment of signals that grow in time (not absolutely integrable) provided no faster than an exponential: it is the standard tool for analyzing causal systems and their stability.

Definition 20.1: Laplace transform (unilateral). For $f : [0, \infty) \rightarrow \mathbb{C}$ (or $f : \mathbb{R} \rightarrow \mathbb{C}$ zero for $t < 0$, i.e. causal):

$$F(s) = \mathcal{L}\{f(t)\} = \int_0^\infty f(t)e^{-st} dt, \quad s = \sigma + i\omega \in \mathbb{C},$$

defined for $\sigma = \text{Re}(s)$ sufficiently large. The set of values of s for which the integral converges is the **region of convergence** ROC; for causal signals that do not grow faster than an exponential, ROC is always a right half-plane $\text{Re}(s) > \sigma_0$.

Remark 20.1: Laplace restricted to the imaginary axis is Fourier. If $\sigma_0 < 0$ (i.e. if 0 belongs to ROC, which is equivalent to saying that f is absolutely integrable: a “stable” system), then setting $s = i\omega$ one obtains

$$F(i\omega) = \int_0^\infty f(t)e^{-i\omega t} dt = \hat{f}(\omega),$$

the Fourier transform of f (extended to zero for $t < 0$). The Fourier transform is therefore the restriction of the Laplace transform to the imaginary axis, when this restriction makes sense.

Theorem 20.1: Properties of the Laplace transform. With $f(0) := \lim_{t \rightarrow 0^+} f(t)$:

1. (Linearity) $\mathcal{L}\{af + bg\} = aF(s) + bG(s)$.
2. (Differentiation) $\mathcal{L}\{f'(t)\} = sF(s) - f(0)$.
3. (Integration) $\mathcal{L}\left\{\int_0^t f(\tau) d\tau\right\} = F(s)/s$.
4. (Translation) $\mathcal{L}\{f(t-a)u(t-a)\} = e^{-as}F(s)$ for $a \geq 0$, with u the unit step.
5. (Initial value) $f(0^+) = \lim_{s \rightarrow \infty} sF(s)$.
6. (Final value) $\lim_{t \rightarrow \infty} f(t) = \lim_{s \rightarrow 0} sF(s)$, if the left-hand limit exists (sufficient condition: all poles of $sF(s)$ in the half-plane $\text{Re}(s) < 0$).

Proof. (1) Linearity of the integral. (2) Integration by parts: $\int_0^\infty f'(t)e^{-st} dt = [f(t)e^{-st}]_0^\infty + s \int_0^\infty f(t)e^{-st} dt = -f(0) + sF(s)$ (the upper boundary term vanishes for $\text{Re}(s)$ sufficiently large, assuming f of sub-exponential growth). (3) Follows from (2) applied to $g(t) = \int_0^t f(\tau) d\tau$, for which $g'(t) = f(t)$ and $g(0) = 0$: $F(s) = \mathcal{L}\{g'\} = sG(s) - 0$, hence $G(s) = F(s)/s$. (4) With $\tau = t - a$: $\int_0^\infty f(t-a)u(t-a)e^{-st} dt = \int_0^\infty f(\tau)e^{-s(\tau+a)} d\tau = e^{-as}F(s)$. (5)–(6) Obtained by taking the limit in (2) for $s \rightarrow \infty$ and $s \rightarrow 0$ respectively, under appropriate regularity assumptions. $\square$

Definition 20.2: Transfer function and BIBO stability. For a causal linear time-invariant (LTI) system with impulse response $h(t)$, the **transfer function** is $H(s) = \mathcal{L}\{h(t)\}$; if the input $u(t)$ and output $y(t)$ are related by $y = h * u$, then $Y(s) = H(s)U(s)$ (Theorem 19.2(4), which holds identically for Laplace). The system is **BIBO stable** (bounded input $\Rightarrow$ bounded output) if and only if all poles of $H(s)$ have $\text{Re}(s) < 0$ (open left half-plane).

Worked example — first-order system and step response. Let $h(t) = \frac{1}{\tau}e^{-t/\tau}u(t)$ be the impulse response of a first-order system with time constant $\tau > 0$ (a typical model for a motor, a temperature sensor, or a tank with flow proportional to level, common in water treatment).

Then

$$H(s) = \frac{1}{\tau} \int_0^\infty e^{-t/\tau} e^{-st} dt = \frac{1}{\tau} \cdot \frac{1}{s + 1/\tau} = \frac{1}{1 + \tau s},$$

with a single pole at $s = -1/\tau < 0$: the system is BIBO stable for every $\tau > 0$, consistent with physical intuition (a first-order system with positive time constant is always stable). For the step response, $U(s) = \mathcal{L}\{u(t)\} = 1/s$, hence

$$Y(s) = H(s)U(s) = \frac{1}{s(1 + \tau s)} = \frac{1}{s} - \frac{1}{s + 1/\tau}$$

(partial fraction decomposition: one verifies that $\frac{1}{s} - \frac{1}{s + 1/\tau} = \frac{(s + 1/\tau) - s}{s(s + 1/\tau)} = \frac{1/\tau}{s(s + 1/\tau)} = \frac{1}{\tau s(s + 1/\tau)} = \frac{1}{s(1 + \tau s)}$, as required). Inverse-transforming term by term:

$$y(t) = 1 - e^{-t/\tau}, \quad t \geq 0,$$

the classical exponential charging curve with time constant τ : after a time $t = \tau$ the system has reached about 63% of the final value, after $t = 5\tau$ over 99% — the practical criterion by which settling time is estimated in a control loop.

The table of Appendix A, Section 2 of Volume II. The material moved here also includes the table of the notable Laplace transforms for causal signals, which in its original form listed the pairs

$$\begin{aligned} \delta(t) &\mapsto 1, & u(t) &\mapsto \frac{1}{s}, & t &\mapsto \frac{1}{s^2}, & t^n &\mapsto \frac{n!}{s^{n+1}}, \\ e^{-at} &\mapsto \frac{1}{s+a}, & t e^{-at} &\mapsto \frac{1}{(s+a)^2}, & \cos(\omega t) &\mapsto \frac{s}{s^2 + \omega^2}, \\ \sin(\omega t) &\mapsto \frac{\omega}{s^2 + \omega^2}, & e^{-at} \cos(\omega t) &\mapsto \frac{s+a}{(s+a)^2 + \omega^2}, \\ e^{-at} \sin(\omega t) &\mapsto \frac{\omega}{(s+a)^2 + \omega^2}, \end{aligned}$$

without indicating the region of convergence and without deriving any of them. The table is now found in Appendix C; Theorem 20.11 reproduces it row by row, with the region of convergence stated and with a pointer to the proof of each pair.

Warning. What remains implicit here, and where it is proved. The inherited text is correct but abbreviates three points; each is taken up in full further on.

- “defined for $\operatorname{Re}(s)$ sufficiently large” and “ROC is always a right half-plane” (Definition 20.1): the statement is true and is proved in Theorem 20.2, which requires no hypothesis of exponential growth — it suffices that the integral converge at *one* point.
- “the upper boundary term vanishes ... assuming f of sub-exponential growth” (item (2) of Theorem 20.1): the precise hypothesis is in Theorem 20.8, where f is assumed to be locally absolutely continuous and $\mathcal{L}\{f'\}$ absolutely convergent, and the at-most-exponential growth of f becomes a *consequence* (Lemma 20.3), not a hypothesis.
- “under appropriate regularity assumptions” (items (5) and (6)): the hypotheses are those of Theorem 20.12 and the Theorem 20.13; Examples 20.3 and 20.4 show that without them the two formulas give false results.
- The “if and only if” of BIBO stability (Definition 20.2) is proved in this chapter in one direction and for proper rational functions (Corollary 20.12); the general characterization $h \in L^1$ belongs to Chapter 24, and the algebraic criterion that decides the sign of the real parts of the poles without computing them, to Chapter 25.

20.2. Convergence: the half-plane and the two abscissas

Definition 20.1 says that the integral is “defined for $\operatorname{Re}(s)$ sufficiently large”. This section proves that the expression is not an approximation of convenience: if the integral converges at *just one* point, then it converges throughout the whole open half-plane to the right of that point. No hypothesis of exponential growth is needed.

Definition 20.3: Simple convergence and absolute convergence. Let $f : [0, \infty) \rightarrow \mathbb{C}$ be locally integrable. The Laplace integral *converges* at $s \in \mathbb{C}$ if the limit

$$F(s) = \lim_{T \rightarrow +\infty} \int_0^T f(t) e^{-st} dt,$$

exists and is finite, and *converges absolutely* at s if $\int_0^\infty |f(t)| e^{-\sigma t} dt < \infty$, where $\sigma = \operatorname{Re}(s)$. Absolute convergence implies simple convergence, because a function with integrable modulus is integrable on $[0, \infty)$ and the limit of the truncations exists by the dominated convergence theorem.

Theorem 20.2: The region of convergence is a half-plane. Let $f : [0, \infty) \rightarrow \mathbb{C}$ be locally integrable and suppose the Laplace integral converges at a point $s_0 \in \mathbb{C}$. Setting

$$\varphi(t) = \int_0^t f(\tau) e^{-s_0 \tau} d\tau, \quad t \geq 0,$$

the following three facts hold.

(i) The integral converges at every s with $\operatorname{Re}(s) > \operatorname{Re}(s_0)$, and

$$F(s) = (s - s_0) \int_0^\infty \varphi(t) e^{-(s-s_0)t} dt,$$

where this last integral converges absolutely.

(ii) For every $T \geq 0$ and every s with $\rho := \operatorname{Re}(s - s_0) > 0$,

$$\left| \int_T^\infty f(t) e^{-st} dt \right| \leq \eta(T) \left(1 + \frac{|s - s_0|}{\rho} \right), \quad \eta(T) := \sup_{t \geq T} |\varphi(t) - \varphi(T)|.$$

(iii) The convergence is uniform on every sector $S_\theta = \{s \neq s_0 : |\arg(s - s_0)| \leq \theta\}$ with $0 < \theta < \pi/2$ fixed.

Proof. Step 1 — the function φ is absolutely continuous and bounded. The function $t \mapsto f(t) e^{-s_0 t}$ is integrable on every compact set $[0, T]$ (the product of a locally integrable function and a continuous function), hence φ is the indefinite integral of a locally integrable function: it is absolutely continuous on every $[0, T]$, with $\varphi' = f(t) e^{-s_0 t}$ almost everywhere, and $\varphi(0) = 0$. By hypothesis $\varphi(T)$ has a finite limit $\varphi(\infty)$ as $T \rightarrow \infty$; a continuous function on $[0, \infty)$ with a finite limit at infinity is bounded, so there exists $M = \sup_{t \geq 0} |\varphi(t)| < \infty$.

Step 2 — integration by parts on the truncation. Let s be such that $\rho = \operatorname{Re}(s - s_0) > 0$. Since $t \mapsto e^{-(s-s_0)t}$ is of class C^1 and φ is absolutely continuous on $[0, T]$, the integration-by-parts formula recalled among the prerequisites gives

$$\int_0^T f(t) e^{-st} dt = \int_0^T \varphi'(t) e^{-(s-s_0)t} dt = \varphi(T) e^{-(s-s_0)T} + (s - s_0) \int_0^T \varphi(t) e^{-(s-s_0)t} dt,$$

where we used $f(t) e^{-st} = (f(t) e^{-s_0 t}) e^{-(s-s_0)t} = \varphi'(t) e^{-(s-s_0)t}$ and $\varphi(0) = 0$.

Step 3 — the limit as $T \rightarrow \infty$. The first term tends to zero, because $|\varphi(T)e^{-(s-s_0)T}| \leq Me^{-\rho T} \rightarrow 0$. The second converges absolutely, because

$$\int_0^\infty |\varphi(t)e^{-(s-s_0)t}| dt \leq M \int_0^\infty e^{-\rho t} dt = \frac{M}{\rho} < \infty.$$

Hence the limit of $\int_0^T f e^{-st} dt$ exists, is finite, and equals $(s-s_0) \int_0^\infty \varphi e^{-(s-s_0)t} dt$: this is (i).

Step 4 — the tail estimate. Fix $T \geq 0$ and set, for $t \geq T$, $\psi(t) = \varphi(t) - \varphi(T)$, so that $\psi(T) = 0$, $\psi' = \varphi'$ almost everywhere and $|\psi(t)| \leq \eta(T)$ for every $t \geq T$. The same integration by parts on the interval $[T, T']$ gives

$$\int_T^{T'} f(t)e^{-st} dt = \psi(T')e^{-(s-s_0)T'} + (s-s_0) \int_T^{T'} \psi(t)e^{-(s-s_0)t} dt,$$

whence

$$\left| \int_T^{T'} f(t)e^{-st} dt \right| \leq \eta(T)e^{-\rho T'} + |s-s_0| \eta(T) \int_T^{T'} e^{-\rho t} dt,$$

and, using $e^{-\rho T'} \leq 1$, $\int_T^{T'} e^{-\rho t} dt \leq e^{-\rho T}/\rho$ and $e^{-\rho T} \leq 1$,

$$\left| \int_T^{T'} f(t)e^{-st} dt \right| \leq \eta(T) + |s-s_0| \eta(T) \frac{1}{\rho} = \eta(T) \left(1 + \frac{|s-s_0|}{\rho} \right).$$

Letting $T' \rightarrow \infty$ (the limit exists by Step 3) gives (ii).

Step 5 — uniformity on the sector. If $s \in S_\theta$ and we write $s-s_0 = re^{i\alpha}$ with $|\alpha| \leq \theta < \pi/2$, then $\rho = r \cos \alpha$ and

$$\frac{|s-s_0|}{\rho} = \frac{r}{r \cos \alpha} = \frac{1}{\cos \alpha} \leq \frac{1}{\cos \theta},$$

because $\cos$ is decreasing on $[0, \pi/2)$ and $|\alpha| \leq \theta$. Then (ii) becomes

$$\left| \int_T^\infty f(t)e^{-st} dt \right| \leq \eta(T) \left(1 + \frac{1}{\cos \theta} \right) \quad \text{for every } s \in S_\theta,$$

and the right-hand side does not depend on s . It remains to see that $\eta(T) \rightarrow 0$: since $\varphi(t) \rightarrow \varphi(\infty)$, for every $\varepsilon > 0$ there exists T_ε such that $|\varphi(t) - \varphi(\infty)| < \varepsilon/2$ for $t \geq T_\varepsilon$; for $T \geq T_\varepsilon$ and $t \geq T$ we then have $|\varphi(t) - \varphi(T)| \leq |\varphi(t) - \varphi(\infty)| + |\varphi(\infty) - \varphi(T)| < \varepsilon$, i.e. $\eta(T) \leq \varepsilon$. Hence the tail tends to zero uniformly on S_θ : this is (iii). $\square$

Definition 20.4: The two abscissas of convergence. Let $C = \{s \in \mathbb{C} : \text{the Laplace integral of } f \text{ converges at } s\}$ and let $A = \{s \in \mathbb{C} : \text{it converges absolutely at } s\}$. Set

$$\sigma_c = \inf\{\operatorname{Re}(s) : s \in C\}, \quad \sigma_a = \inf\{\operatorname{Re}(s) : s \in A\},$$

with the convention $\inf \emptyset = +\infty$ and $\inf$ of a set unbounded below $= -\infty$. The number σ_c is the **abscissa of convergence**, σ_a the **abscissa of absolute convergence**. The **region of convergence** (ROC) of the signal is the set C . When it is necessary to indicate which signal is meant, one writes $\sigma_c(f)$ and $\sigma_a(f)$.

Corollary 20.1: Shape of the region of convergence. With the notation of Definition 20.4:

$$\{s : \operatorname{Re}(s) > \sigma_c\} \subseteq C \subseteq \{s : \operatorname{Re}(s) \geq \sigma_c\},$$

Figure 20.1: Theorem 20.2: if the integral converges at s_0 , it converges throughout the whole open half-plane $\text{Re}(s) > \text{Re}(s_0)$ (blue), and uniformly on the sector S_θ with vertex s_0 and half-aperture $\theta < \pi/2$ (ochre). In the drawing $s_0 = -0.6$, $\theta = 60^\circ$ and the sector has radius 2.4: its two vertices lie at $(-0.6 + 2.4 \cos 60^\circ, \pm 2.4 \sin 60^\circ) = (0.6, \pm 2.0785)$, with $2.4 \sin 60^\circ = 2.4 \cdot 0.8660254 = 2.0784610$. The dashed line is the boundary $\text{Re}(s) = \sigma_c$, which the theorem does not decide.

$$\{s : \text{Re}(s) > \sigma_a\} \subseteq A \subseteq \{s : \text{Re}(s) \geq \sigma_a\},$$

and $\sigma_c \leq \sigma_a$. In particular C and A are right half-planes, possibly with part of the boundary line removed or not.

Proof. Step 1 — the left inclusion for C . Let $\text{Re}(s) > \sigma_c$. By the definition of infimum there exists $s_0 \in C$ with $\text{Re}(s_0) < \text{Re}(s)$. Theorem 20.2(i) then gives $s \in C$.

Step 2 — the right inclusion for C . If $s \in C$ then $\text{Re}(s) \geq \inf\{\text{Re}(s') : s' \in C\} = \sigma_c$: this is the definition of infimum.

Step 3 — the same two inclusions for A . Absolute convergence depends only on $\sigma = \text{Re}(s)$, and for $\sigma \geq \sigma_0$ one has $|f(t)|e^{-\sigma t} \leq |f(t)|e^{-\sigma_0 t}$ for every $t \geq 0$ (the real exponential is decreasing). Hence if the integral converges absolutely at σ_0 it converges absolutely at every $\sigma \geq \sigma_0$, by comparison. The two inclusions follow as in Steps 1 and 2.

Step 4 — $\sigma_c \leq \sigma_a$. We have $A \subseteq C$ (Definition 20.3), and the infimum of a subset is greater than or equal to that of the whole set. $\square$

Example 20.1: The two extreme cases on the boundary line. The boundary $\text{Re}(s) = \sigma_c$ may or may not belong to the ROC, and Corollary 20.1 does not decide it: both cases occur.

- $f = u$ (unit step). For $\sigma > 0$, $\int_0^T e^{-st} dt = \frac{1-e^{-sT}}{s} \rightarrow \frac{1}{s}$; for $s = i\omega$ with $\omega \neq 0$ the value $\frac{1-e^{-i\omega T}}{i\omega}$ has no limit (it oscillates on a circle of radius $1/|\omega|$), and for $s = 0$ the integral equals $T \rightarrow \infty$. Hence $\sigma_c = \sigma_a = 0$ and the ROC is the *open* half-plane.
- $f(t) = \frac{1}{1+t^2}$. For $\sigma \geq 0$ one has $\int_0^\infty \frac{e^{-\sigma t}}{1+t^2} dt \leq \int_0^\infty \frac{dt}{1+t^2} = \frac{\pi}{2}$, so the integral converges absolutely on the whole line $\text{Re}(s) = 0$ and in the right half-plane; for $\sigma < 0$ it diverges, because $\frac{e^{-\sigma t}}{1+t^2} = \frac{e^{|\sigma|t}}{1+t^2} \rightarrow \infty$ and the integrand is not even infinitesimal. Hence $\sigma_c = \sigma_a = 0$ and the ROC is the *closed* half-plane.

Proposition 20.1: The two abscissas can differ. For $f(t) = e^t \sin(e^t)$ one has $\sigma_c \leq 0$ and $\sigma_a = 1$: the two abscissas differ by at least 1.

Proof. Step 1 — the change of variable. The function f is continuous, hence locally integrable. For $T > 0$ and $s \in \mathbb{C}$ set $u = e^t$, i.e. $t = \ln u$, $du = e^t dt$. Then $e^{-st} = e^{-s \ln u} = u^{-s}$ (real logarithm of $u > 0$) and

$$\int_0^T f(t) e^{-st} dt = \int_0^T \sin(e^t) e^t e^{-st} dt = \int_1^{e^T} \sin(u) u^{-s} du.$$

As T ranges over $[0, \infty)$, the endpoint $X = e^T$ ranges over $[1, \infty)$ increasingly and continuously, so the convergence of the Laplace integral is equivalent to the convergence of $\int_1^\infty \sin(u) u^{-s} du$. Note that $|u^{-s}| = |e^{-s \ln u}| = e^{-\sigma \ln u} = u^{-\sigma}$.

Step 2 — simple convergence for $\sigma > 0$. We apply Dirichlet's criterion with $\varphi(u) = \sin u$ and $\psi(u) = u^{-s}$. The antiderivative $\Phi(X) = \int_1^X \sin u du = \cos 1 - \cos X$ satisfies $|\Phi| \leq 2$; ψ is of class C^1 on $[1, \infty)$ with $|\psi(u)| = u^{-\sigma} \rightarrow 0$ (because $\sigma > 0$) and $\psi'(u) = -s u^{-s-1}$, hence

$$\int_1^\infty |\psi'(u)| du = |s| \int_1^\infty u^{-\sigma-1} du = \frac{|s|}{\sigma} < \infty.$$

The criterion gives the convergence of $\int_1^\infty \sin(u) u^{-s} du$ for every s with $\sigma > 0$. Hence every s with $\operatorname{Re}(s) > 0$ lies in C , and by the definition of infimum $\sigma_c \leq 0$.

Step 3 — absolute convergence for $\sigma > 1$. We have $|\sin u| \leq 1$, hence

$$\int_1^\infty |\sin u| u^{-\sigma} du \leq \int_1^\infty u^{-\sigma} du = \frac{1}{\sigma - 1} < \infty \quad (\sigma > 1).$$

Hence $\sigma_a \leq 1$.

Step 4 — absolute divergence for $\sigma \leq 1$: the case $\sigma \leq 0$. For $u \geq 1$ and $\sigma \leq 0$ one has $u^{-\sigma} \geq 1$, hence $\int_1^X |\sin u| u^{-\sigma} du \geq \int_1^X |\sin u| du$. On every interval $[k\pi, (k+1)\pi]$ the integral of $|\sin|$ equals 2, hence $\int_1^X |\sin u| du \rightarrow +\infty$.

Step 5 — absolute divergence for $0 < \sigma \leq 1$. From $|\sin u| \geq \sin^2 u = \frac{1 - \cos 2u}{2}$ it follows that

$$\int_1^X |\sin u| u^{-\sigma} du \geq \frac{1}{2} \int_1^X u^{-\sigma} du - \frac{1}{2} \int_1^X \cos(2u) u^{-\sigma} du.$$

The first integral tends to $+\infty$: it equals $\frac{X^{1-\sigma}-1}{2(1-\sigma)}$ for $\sigma < 1$ and $\frac{\ln X}{2}$ for $\sigma = 1$. The second stays bounded: by the Dirichlet criterion applied to $\varphi(u) = \cos 2u$ (antiderivative $\frac{\sin 2X - \sin 2}{2}$, of modulus ≤ 1) and $\psi(u) = u^{-\sigma}$ with $\sigma > 0$, the integral $\int_1^\infty \cos(2u) u^{-\sigma} du$ converges, so its truncations are bounded. The difference therefore tends to $+\infty$: the integral does not converge absolutely. From this and from Step 3 it follows that $\sigma_a = 1$.

Numerical check. Composite Simpson quadrature with 400,000 subintervals on $[1, X]$:

X	$\sigma = 0.5$		$\sigma = 1$	
	$\int_1^X \sin(u) u^{-\sigma} du$	$\int_1^X \sin u u^{-\sigma} du$	$\int_1^X \sin(u) u^{-\sigma} du$	$\int_1^X \sin u u^{-\sigma} du$
10^2	0.5468052	11.6553751	0.6161424	3.1005912
10^3	0.6149805	39.1605303	0.6241501	4.5642721
10^4	0.6422992	126.2253836	0.6248085	6.0303191

The odd columns stabilize (simple convergence), the even columns grow without bound (absolute divergence). ✓ *Second check, independent:* for $\sigma = 1$ the growth should be logarithmic, with an increment $\frac{2}{\pi} \ln 10 = 1.4657359$ each time X is multiplied by 10 (the mean value of $|\sin|$ is $2/\pi$). The observed increments are $4.5642721 - 3.1005912 = 1.4636809$ and $6.0303191 - 4.5642721 = 1.4660470$: they agree with the predicted value to within $2 \cdot 10^{-3}$. ✓

□

Remark 20.2: What the distinction is for. In the rest of the chapter almost every statement assumes absolute convergence, i.e. works in the half-plane $\operatorname{Re}(s) > \sigma_a$: this is the hypothesis that allows limits and integrals to be interchanged (dominated convergence) and integrals with each other (Fubini), and without which the proofs of the computation rules do not close. Theorem 20.2, on the other hand, was proved for simple convergence alone, because that is what is needed in Theorem 20.13: there the point $s = 0$ is reached from the half-plane of simple convergence, and assuming absolute convergence at 0 would mean assuming $f \in L^1(0, \infty)$, i.e. a hypothesis far stronger than what is needed. The Proposition 20.1 shows that the two hypotheses really are different, and not only formally. Doetsch devotes an entire chapter to this distinction (Introduction to the Theory and Application of the Laplace Transformation, Ch. 3 “The Half-Plane of Convergence”, pp. 13–18).

20.3. Holomorphy of the transform

The Laplace transform is not merely a function of the complex variable s : it is a *holomorphic* function, and it is so automatically, without requiring anything of f beyond convergence of the integral. This is what makes available, for F , all the tools of Chapter 15: series expansions, the identity principle, residues. The proof consists in differentiating under the integral sign, and the only thing that must be done carefully is exhibiting the bound that authorizes it.

Lemma 20.1: Two elementary bounds.

(i) For every $w \in \mathbb{C}$, $|e^w - 1 - w| \leq \frac{|w|^2}{2} e^{|w|}$.

(ii) For every integer $n \geq 1$, every $\varepsilon > 0$ and every $t \geq 0$, $t^n \leq \left(\frac{n}{e\varepsilon}\right)^n e^{\varepsilon t}$.

Proof. (i). From the series expansion of the exponential (Volume II, Chapter 3), which converges absolutely for every $w \in \mathbb{C}$,

$$e^w - 1 - w = \sum_{k \geq 2} \frac{w^k}{k!}, \quad \text{hence} \quad |e^w - 1 - w| \leq \sum_{k \geq 2} \frac{|w|^k}{k!}.$$

For $k \geq 2$ one has $k! = k(k-1)(k-2)! \geq 2(k-2)!$, because $k(k-1) \geq 2$. Setting $j = k - 2$,

$$\sum_{k \geq 2} \frac{|w|^k}{k!} \leq \sum_{k \geq 2} \frac{|w|^k}{2(k-2)!} = \frac{|w|^2}{2} \sum_{j \geq 0} \frac{|w|^j}{j!} = \frac{|w|^2}{2} e^{|w|}.$$

(ii). Consider $g(t) = t^n e^{-\varepsilon t}$ on $[0, \infty)$. It is differentiable, $g(0) = 0$, $g(t) \rightarrow 0$ as $t \rightarrow +\infty$, and

$$g'(t) = (n t^{n-1} - \varepsilon t^n) e^{-\varepsilon t} = t^{n-1} (n - \varepsilon t) e^{-\varepsilon t},$$

which is positive for $0 < t < n/\varepsilon$ and negative for $t > n/\varepsilon$. The maximum is therefore at $t = n/\varepsilon$ and equals

$$g\left(\frac{n}{\varepsilon}\right) = \left(\frac{n}{\varepsilon}\right)^n e^{-n} = \left(\frac{n}{e\varepsilon}\right)^n.$$

From $t^n e^{-\varepsilon t} \leq \left(\frac{n}{e\varepsilon}\right)^n$ the claim follows by multiplying by $e^{\varepsilon t} > 0$. $\square$

Lemma 20.2: Multiplying by a power does not shift the absolute abscissa. If the Laplace integral of f converges absolutely for $\operatorname{Re}(s) > \sigma_a$, then for every integer $n \geq 1$ that of $t^n f(t)$ also converges absolutely for $\operatorname{Re}(s) > \sigma_a$.

Proof. Let $\sigma > \sigma_a$. Choose σ_1 with $\sigma_a < \sigma_1 < \sigma$ and set $\varepsilon = \sigma - \sigma_1 > 0$. By Lemma 20.1(ii), $t^n \leq \left(\frac{n}{e\varepsilon}\right)^n e^{\varepsilon t}$ for every $t \geq 0$, hence

$$\int_0^\infty t^n |f(t)| e^{-\sigma t} dt \leq \left(\frac{n}{e\varepsilon}\right)^n \int_0^\infty |f(t)| e^{\varepsilon t} e^{-\sigma t} dt = \left(\frac{n}{e\varepsilon}\right)^n \int_0^\infty |f(t)| e^{-\sigma_1 t} dt < \infty,$$

the last integral being finite because $\sigma_1 > \sigma_a$ (Corollary 20.1). $\square$

Theorem 20.3: Holomorphy and differentiation under the integral sign. Let $f : [0, \infty) \rightarrow \mathbb{C}$ be locally integrable with abscissa of absolute convergence $\sigma_a < +\infty$. Then $F = \mathcal{L}\{f\}$ is holomorphic on the open half-plane $\Omega_a = \{s : \operatorname{Re}(s) > \sigma_a\}$ and

$$F'(s) = - \int_0^\infty t f(t) e^{-st} dt = -\mathcal{L}\{t f(t)\}(s), \quad s \in \Omega_a,$$

where the integral on the right converges absolutely on Ω_a .

Proof. Step 1 — the candidate integral converges. By Lemma 20.2 with $n = 1$, the integral $\int_0^\infty t |f(t)| e^{-\sigma t} dt$ is finite for every $\sigma > \sigma_a$: the function $G(s) = - \int_0^\infty t f(t) e^{-st} dt$ is thus well defined on Ω_a .

Step 2 — choice of margins. Fix $s \in \Omega_a$ and set $\sigma = \operatorname{Re}(s)$. Choose σ_2 with $\sigma_a < \sigma_2 < \sigma$ and set

$$\delta = \frac{\sigma - \sigma_2}{2} > 0.$$

For every $h \in \mathbb{C}$ with $0 < |h| \leq \delta$ one has $\operatorname{Re}(s + h) \geq \sigma - |h| \geq \sigma - \delta = \sigma_2 + \delta > \sigma_a$, hence $s + h$ lies in Ω_a and $F(s + h)$ is defined.

Step 3 — the difference quotient. All three integrals that follow converge absolutely (Steps 1 and 2), so they can be combined under the same sign:

$$\frac{F(s + h) - F(s)}{h} - G(s) = \int_0^\infty f(t) e^{-st} \left[\frac{e^{-ht} - 1}{h} + t \right] dt = \frac{1}{h} \int_0^\infty f(t) e^{-st} (e^{-ht} - 1 + ht) dt.$$

Step 4 — the bound. By Lemma 20.1(i) with $w = -ht$ one has $|e^{-ht} - 1 + ht| \leq \frac{|h|^2 t^2}{2} e^{|h|t}$, and $|e^{-st}| = e^{-\sigma t}$. Hence, using $|h| \leq \delta$,

$$\left| \frac{F(s + h) - F(s)}{h} - G(s) \right| \leq \frac{|h|}{2} \int_0^\infty |f(t)| t^2 e^{-\sigma t} e^{|h|t} dt \leq \frac{|h|}{2} \int_0^\infty |f(t)| t^2 e^{-(\sigma - \delta)t} dt.$$

The key point is that the bound *no longer depends on h*. By Lemma 20.1(ii) with $n = 2$ and $\varepsilon = \delta$, $t^2 \leq \left(\frac{2}{e\delta}\right)^2 e^{\delta t}$, hence

$$\int_0^\infty |f(t)| t^2 e^{-(\sigma - \delta)t} dt \leq \left(\frac{2}{e\delta}\right)^2 \int_0^\infty |f(t)| e^{-(\sigma - 2\delta)t} dt = \left(\frac{2}{e\delta}\right)^2 \int_0^\infty |f(t)| e^{-\sigma_2 t} dt =: K < \infty,$$

because $\sigma - 2\delta = \sigma_2 > \sigma_a$.

Step 5 — conclusion. We have obtained

$$\left| \frac{F(s + h) - F(s)}{h} - G(s) \right| \leq \frac{K}{2} |h| \quad \text{for every } 0 < |h| \leq \delta,$$

with K independent of h . Letting $h \rightarrow 0$ in $\mathbb{C}$, the right-hand side tends to zero: the limit of the difference quotient exists and equals $G(s)$. Hence F is differentiable in the complex sense at s (Definition 15.1) with $F'(s) = G(s)$; since $s \in \Omega_a$ was arbitrary, F is holomorphic on Ω_a . $\square$

Corollary 20.2: All the derivatives, and multiplication by a power. Under the hypotheses of Theorem 20.3, for every integer $n \geq 0$ and every $s \in \Omega_a$,

$$F^{(n)}(s) = (-1)^n \int_0^\infty t^n f(t) e^{-st} dt = (-1)^n \mathcal{L}\{t^n f(t)\}(s),$$

with the integral absolutely convergent.

Proof. Induction on n . For $n = 0$ the statement is the definition of F . Suppose the formula holds for n . By Lemma 20.2, the function $g(t) = t^n f(t)$ has an absolutely convergent Laplace integral on Ω_a , hence its abscissa of absolute convergence is $\leq \sigma_a$ and Theorem 20.3 applies to g : $\mathcal{L}\{g\}$ is holomorphic on Ω_a with $(\mathcal{L}\{g\})' = -\mathcal{L}\{t g(t)\} = -\mathcal{L}\{t^{n+1} f(t)\}$. Differentiating the induction hypothesis $F^{(n)} = (-1)^n \mathcal{L}\{g\}$ gives

$$F^{(n+1)} = (-1)^n (\mathcal{L}\{g\})' = (-1)^n (-\mathcal{L}\{t^{n+1} f\}) = (-1)^{n+1} \mathcal{L}\{t^{n+1} f\},$$

which is the formula for $n + 1$. □

Corollary 20.3: Holomorphy as far as there is simple convergence. Under the hypotheses of Theorem 20.2, F is holomorphic on the open half-plane $\{s : \operatorname{Re}(s) > \sigma_c\}$, even where the convergence is not absolute.

Proof. Let s^* be such that $\operatorname{Re}(s^*) > \sigma_c$. By the definition of infimum there exists $s_0 \in C$ with $\operatorname{Re}(s_0) < \operatorname{Re}(s^*)$. Let φ be the function of Theorem 20.2: it is continuous and bounded on $[0, \infty)$ (Step 1 of that proof), say $|\varphi| \leq M$. Then $\int_0^\infty |\varphi(t)| e^{-\rho t} dt \leq M/\rho < \infty$ for every $\rho > 0$: the abscissa of absolute convergence of φ is ≤ 0 , and by Theorem 20.3 the function

$$\Psi(z) = \int_0^\infty \varphi(t) e^{-zt} dt$$

is holomorphic on the half-plane $\operatorname{Re}(z) > 0$. Theorem 20.2(i) says that $F(s) = (s - s_0)\Psi(s - s_0)$ for every s with $\operatorname{Re}(s) > \operatorname{Re}(s_0)$: this is the product of a polynomial with the composition of Ψ with the translation $s \mapsto s - s_0$, hence it is holomorphic on that half-plane, which contains s^* . Since s^* was arbitrary, F is holomorphic on $\{\operatorname{Re}(s) > \sigma_c\}$. □

Remark 20.3: What exactly is the hypothesis that authorizes differentiation. In Step 4 of the proof of Theorem 20.3 the decisive point is not the bound on the exponential, which is algebra: it is that the bounding function

$$t \mapsto |f(t)| t^2 e^{-(\sigma - \delta)t}$$

be integrable and independent of h . Both facts come from absolute convergence with a margin: we required the integral to converge absolutely not only at σ , but at some σ_2 strictly smaller, and the margin δ was used twice — to keep $s + h$ in the half-plane and to absorb the factor t^2 . If one worked exactly on the boundary, i.e. with $\sigma = \sigma_a$, the bounding function might not be integrable and the argument would not close: indeed on the boundary F may not even be defined (Example 20.1, first case). Corollary 20.3 shows, however, that holomorphy survives even where there is only simple convergence: there the margin comes from the boundedness of φ , not from f .

20.4. Computation rules, with the region of convergence

Every rule in this section says two things: what the transform becomes, and *where*. The second piece of information is not an accessory: without it the identity $\mathcal{L}\{u\} = 1/s$ would not distinguish the unit step from $-u(-t)$, which has the same expression with the opposite region of convergence.

Theorem 20.4: Linearity. Let f, g be locally integrable on $[0, \infty)$ with abscissas of absolute convergence $\sigma_a(f)$ and $\sigma_a(g)$, and let $\lambda, \mu \in \mathbb{C}$. Then for every s with $\operatorname{Re}(s) > \max\{\sigma_a(f), \sigma_a(g)\}$ the Laplace integral of $\lambda f + \mu g$ converges absolutely and

$$\mathcal{L}\{\lambda f + \mu g\}(s) = \lambda F(s) + \mu G(s);$$

in particular $\sigma_a(\lambda f + \mu g) \leq \max\{\sigma_a(f), \sigma_a(g)\}$.

Proof. Let $\sigma = \operatorname{Re}(s) > \max\{\sigma_a(f), \sigma_a(g)\}$. By the triangle inequality, $|\lambda f(t) + \mu g(t)|e^{-\sigma t} \leq |\lambda| |f(t)|e^{-\sigma t} + |\mu| |g(t)|e^{-\sigma t}$; the two integrals on the right are finite (Corollary 20.1), hence so is the one on the left: the convergence is absolute. The identity is then the linearity of the Lebesgue integral, applicable because both functions $f e^{-\sigma t}$ and $g e^{-\sigma t}$ are integrable on $[0, \infty)$. The last statement follows from the definition of infimum. $\square$

Theorem 20.5: Translation in time (delay). Let $a \geq 0$ and $f_{[a]}(t) = f(t-a)u(t-a)$, i.e. the signal f delayed by a and zero before a . Then $\sigma_a(f_{[a]}) = \sigma_a(f)$ and, for $\operatorname{Re}(s) > \sigma_a(f)$,

$$\mathcal{L}\{f_{[a]}\}(s) = e^{-as}F(s).$$

Proof. Step 1 — the region. With the substitution $\tau = t - a$ (a translation, which preserves Lebesgue measure),

$$\int_0^\infty |f(t-a)u(t-a)|e^{-\sigma t} dt = \int_a^\infty |f(t-a)|e^{-\sigma t} dt = \int_0^\infty |f(\tau)|e^{-\sigma(\tau+a)} d\tau,$$

i.e.

$$\int_0^\infty |f(t-a)u(t-a)|e^{-\sigma t} dt = e^{-\sigma a} \int_0^\infty |f(\tau)|e^{-\sigma \tau} d\tau.$$

Since $e^{-\sigma a}$ is a finite positive number, the first integral is finite if and only if the last one is: the two sets of absolute convergence coincide, and with them the two abscissas.

Step 2 — the identity. The same change of variable, this time without the modulus (legitimate because the integral converges absolutely by Step 1), gives

$$\mathcal{L}\{f_{[a]}\}(s) = \int_a^\infty f(t-a)e^{-st} dt = \int_0^\infty f(\tau)e^{-s(\tau+a)} d\tau = e^{-as} \int_0^\infty f(\tau)e^{-s\tau} d\tau = e^{-as}F(s).$$

$\square$

Theorem 20.6: Translation in frequency (damping). Let $a \in \mathbb{C}$. Then $\sigma_a(e^{-at}f(t)) = \sigma_a(f) - \operatorname{Re}(a)$ and, for $\operatorname{Re}(s) > \sigma_a(f) - \operatorname{Re}(a)$,

$$\mathcal{L}\{e^{-at}f(t)\}(s) = F(s+a).$$

Proof. One has $e^{-at}f(t)e^{-st} = f(t)e^{-(s+a)t}$ for every t , an algebraic identity among exponentials. Taking moduli, $|e^{-at}f(t)e^{-st}| = |f(t)|e^{-(\sigma+\operatorname{Re}(a))t}$: the integral of $e^{-at}f(t)$ converges absolutely at s if and only if that of f converges absolutely at $s+a$, i.e. if and only if $\operatorname{Re}(s) + \operatorname{Re}(a) > \sigma_a(f)$. This gives the equality between the abscissas. Under that condition the integral converges and $\int_0^\infty e^{-at}f(t)e^{-st} dt = \int_0^\infty f(t)e^{-(s+a)t} dt = F(s+a)$. $\square$

Theorem 20.7: Time scaling. Let $c > 0$ and $f_{(c)}(t) = f(ct)$. Then $\sigma_a(f_{(c)}) = c\sigma_a(f)$ and, for $\operatorname{Re}(s) > c\sigma_a(f)$,

$$\mathcal{L}\{f(ct)\}(s) = \frac{1}{c} F\left(\frac{s}{c}\right).$$

Proof. With the substitution $\tau = ct$, i.e. $t = \tau/c$ and $dt = d\tau/c$ (a linear change of variable, $c > 0$, mapping $[0, \infty)$ to itself),

$$\int_0^\infty |f(ct)|e^{-\sigma t} dt = \frac{1}{c} \int_0^\infty |f(\tau)|e^{-(\sigma/c)\tau} d\tau,$$

finite if and only if $\sigma/c > \sigma_a(f)$, i.e. $\sigma > c\sigma_a(f)$: this gives the abscissa. The same computation without the modulus gives $\mathcal{L}\{f(ct)\}(s) = \frac{1}{c} \int_0^\infty f(\tau)e^{-(s/c)\tau} d\tau = \frac{1}{c} F(s/c)$. $\square$

Lemma 20.3: Having a transformable derivative implies exponential order. Let $f : [0, \infty) \rightarrow \mathbb{C}$ be absolutely continuous on every compact interval, and suppose there exists $\sigma_0 \in \mathbb{R}$ with $M := \int_0^\infty |f'(\tau)|e^{-\sigma_0\tau} d\tau < \infty$. Setting $\beta = \max\{\sigma_0, 0\}$, the following hold:

$$|f(t)| \leq |f(0)| + Me^{\beta t} \quad (t \geq 0), \quad \sigma_a(f) \leq \beta, \quad \lim_{t \rightarrow +\infty} f(t)e^{-st} = 0 \quad \text{for } \operatorname{Re}(s) > \beta.$$

Proof. Step 1 — the bound. Since f is absolutely continuous on $[0, t]$, $f(t) = f(0) + \int_0^t f'(\tau) d\tau$ holds. For $0 \leq \tau \leq t$ one has $e^{\sigma_0\tau} \leq e^{\beta t}$: if $\sigma_0 \geq 0$ then $\beta = \sigma_0$ and $e^{\sigma_0\tau} \leq e^{\sigma_0 t}$ because the exponential is increasing; if $\sigma_0 < 0$ then $\beta = 0$ and $e^{\sigma_0\tau} \leq 1 = e^{\beta t}$. Hence

$$\left| \int_0^t f'(\tau) d\tau \right| \leq \int_0^t |f'(\tau)|e^{-\sigma_0\tau} e^{\sigma_0\tau} d\tau \leq e^{\beta t} \int_0^t |f'(\tau)|e^{-\sigma_0\tau} d\tau \leq Me^{\beta t},$$

and the first formula follows from the triangle inequality.

Step 2 — the abscissa. For $\sigma > \beta$,

$$\int_0^\infty |f(t)|e^{-\sigma t} dt \leq \int_0^\infty (|f(0)| + Me^{\beta t})e^{-\sigma t} dt = \frac{|f(0)|}{\sigma} + \frac{M}{\sigma - \beta} < \infty,$$

where $\sigma > \beta \geq 0$ was used for the finiteness of the first term. Hence $\sigma_a(f) \leq \beta$.

Step 3 — the limit. For $\operatorname{Re}(s) = \sigma > \beta$,

$$|f(t)e^{-st}| \leq (|f(0)| + Me^{\beta t})e^{-\sigma t} = |f(0)|e^{-\sigma t} + Me^{-(\sigma-\beta)t} \xrightarrow{t \rightarrow +\infty} 0,$$

because both exponents are negative. $\square$

Theorem 20.8: Differentiation in time. Let f be absolutely continuous on every compact subset of $[0, \infty)$ and suppose there exists $\sigma_0 \in \mathbb{R}$ with $\int_0^\infty |f'(t)|e^{-\sigma_0 t} dt < \infty$. Setting $\beta = \max\{\sigma_0, 0\}$, for every s with $\operatorname{Re}(s) > \beta$ both Laplace integrals, of f and of f' , converge absolutely and

$$\mathcal{L}\{f'\}(s) = sF(s) - f(0^+), \quad f(0^+) = f(0).$$

Proof. Step 1 — both transforms exist. By Lemma 20.3, $\sigma_a(f) \leq \beta$, hence $\mathcal{L}\{f\}$ converges absolutely for $\operatorname{Re}(s) > \beta$. For f' : if $\sigma > \beta \geq \sigma_0$ then $|f'(t)|e^{-\sigma t} \leq |f'(t)|e^{-\sigma_0 t}$, integrable by hypothesis. Moreover f , being absolutely continuous on $[0, T]$ for every T , is continuous at 0, so $f(0^+) = f(0)$ exists.

Step 2 — integration by parts on the truncation. The function f is absolutely continuous on $[0, T]$ and $t \mapsto e^{-st}$ is of class C^1 ; the integration-by-parts formula recalled among the

prerequisites, with $\frac{d}{dt}e^{-st} = -se^{-st}$, gives

$$\int_0^T f'(t)e^{-st} dt = [f(t)e^{-st}]_0^T + s \int_0^T f(t)e^{-st} dt = f(T)e^{-sT} - f(0) + s \int_0^T f(t)e^{-st} dt.$$

Step 3 — the limit $T \rightarrow +\infty$. The left-hand side tends to $\mathcal{L}\{f'\}(s)$ and the last integral to $F(s)$, because both converge absolutely (Step 1). The term $f(T)e^{-sT}$ tends to zero by Lemma 20.3, Step 3, since $\operatorname{Re}(s) > \beta$. Passing to the limit gives $\mathcal{L}\{f'\}(s) = -f(0) + sF(s)$. $\square$

Corollary 20.4: Second derivative and the n -th derivative. Let $n \geq 1$ and let $f, f', \dots, f^{(n-1)}$ be absolutely continuous on every compact subset of $[0, \infty)$, with $\int_0^\infty |f^{(n)}(t)|e^{-\sigma_0 t} dt < \infty$ for some $\sigma_0 \in \mathbb{R}$. Setting $\beta = \max\{\sigma_0, 0\}$, for $\operatorname{Re}(s) > \beta$

$$\mathcal{L}\{f^{(n)}\}(s) = s^n F(s) - \sum_{k=0}^{n-1} s^{n-1-k} f^{(k)}(0^+).$$

In particular $\mathcal{L}\{f''\}(s) = s^2 F(s) - s f(0^+) - f'(0^+)$.

Proof. Induction on n . For $n = 1$ this is Theorem 20.8. Suppose the formula holds for n and let $f, \dots, f^{(n)}$ be absolutely continuous with $\int_0^\infty |f^{(n+1)}|e^{-\sigma_0 t} dt < \infty$. Applying Theorem 20.8 to the function $g = f^{(n)}$ (absolutely continuous by hypothesis, with $g' = f^{(n+1)}$) gives, for $\operatorname{Re}(s) > \beta$,

$$\mathcal{L}\{f^{(n+1)}\}(s) = s \mathcal{L}\{f^{(n)}\}(s) - f^{(n)}(0^+).$$

Lemma 20.3 applied successively to $f^{(n)}, f^{(n-1)}, \dots, f$ guarantees that all the transforms involved converge absolutely for $\operatorname{Re}(s) > \beta$ (at every step the abscissa stays $\leq \beta$, because $\beta \geq 0$ and $\max\{\beta, 0\} = \beta$). Substituting the induction hypothesis,

$$\mathcal{L}\{f^{(n+1)}\}(s) = s \left(s^n F(s) - \sum_{k=0}^{n-1} s^{n-1-k} f^{(k)}(0^+) \right) - f^{(n)}(0^+) = s^{n+1} F(s) - \sum_{k=0}^n s^{n-k} f^{(k)}(0^+),$$

which is the formula for $n + 1$. The case $n = 2$ is the one stated in full. $\square$

Theorem 20.9: Integration in time. Let f be locally integrable with $\sigma_a(f) < +\infty$ and let $g(t) = \int_0^t f(\tau) d\tau$. Then $\sigma_a(g) \leq \max\{\sigma_a(f), 0\}$ and, for $\operatorname{Re}(s) > \max\{\sigma_a(f), 0\}$,

$$\mathcal{L}\left\{\int_0^t f(\tau) d\tau\right\}(s) = \frac{F(s)}{s}.$$

Proof. **Step 1 — g satisfies the hypotheses of the differentiation theorem.** The function g is the indefinite integral of a locally integrable function, hence it is absolutely continuous on every compact set, $g(0) = 0$ and $g' = f$ almost everywhere.

Step 2 — choice of σ_0 and application. Let s be such that $\operatorname{Re}(s) > \max\{\sigma_a(f), 0\}$; in particular $\operatorname{Re}(s) > 0$. Choose σ_0 with $\max\{\sigma_a(f), 0\} < \sigma_0 < \operatorname{Re}(s)$, which is possible because between two distinct reals there is always a third. Then $\sigma_0 > \sigma_a(f)$ and $\sigma_0 > 0$, so $\beta = \max\{\sigma_0, 0\} = \sigma_0$. Moreover $\int_0^\infty |g'(t)|e^{-\sigma_0 t} dt = \int_0^\infty |f(t)|e^{-\sigma_0 t} dt < \infty$, and $\beta = \sigma_0 < \operatorname{Re}(s)$. Theorem 20.8 applied to g then gives, at s ,

$$\mathcal{L}\{f\}(s) = \mathcal{L}\{g'\}(s) = s G(s) - g(0) = s G(s),$$

with $G(s) = \mathcal{L}\{g\}(s)$ absolutely convergent. Since $\operatorname{Re}(s) > 0$ we have $s \neq 0$, and dividing gives $G(s) = F(s)/s$.

Step 3 — the abscissa. Step 2 shows that the absolute convergence of $\mathcal{L}\{g\}$ holds at every s with $\operatorname{Re}(s) > \max\{\sigma_a(f), 0\}$; by the definition of infimum, $\sigma_a(g) \leq \max\{\sigma_a(f), 0\}$. $\square$

Corollary 20.5: Multiplication by t . Let $\sigma_a = \sigma_a(f) < +\infty$. For every integer $n \geq 1$ and every s with $\operatorname{Re}(s) > \sigma_a$,

$$\mathcal{L}\{t f(t)\}(s) = -F'(s), \quad \mathcal{L}\{t^n f(t)\}(s) = (-1)^n F^{(n)}(s),$$

and the abscissa of absolute convergence of $t^n f$ does not exceed σ_a .

Proof. Corollary 20.2 states $F^{(n)}(s) = (-1)^n \mathcal{L}\{t^n f\}(s)$ on Ω_a . Multiplying both sides by $(-1)^n$ and using $(-1)^n(-1)^n = 1$ gives $\mathcal{L}\{t^n f\}(s) = (-1)^n F^{(n)}(s)$; the case $n = 1$ is the first formula. The bound on the abscissa is Lemma 20.2. $\square$

Definition 20.5: Convolution of causal signals. For $f, g : [0, \infty) \rightarrow \mathbb{C}$ locally integrable, set

$$(f * g)(t) = \int_0^t f(\tau) g(t - \tau) d\tau, \quad t \geq 0,$$

whenever the integral converges absolutely. Extending f and g by zero for $t < 0$, this is the restriction to $[0, \infty)$ of the convolution on $\mathbb{R}$ of Definition 19.3: the factor $g(t - \tau)$ vanishes for $\tau > t$ and the factor $f(\tau)$ vanishes for $\tau < 0$, and the limits reduce on their own to 0 and t .

Theorem 20.10: Convolution theorem. Let $f, g : [0, \infty) \rightarrow \mathbb{C}$ be locally integrable and let $\sigma \in \mathbb{R}$ be such that

$$A = \int_0^\infty |f(t)| e^{-\sigma t} dt < \infty, \quad B = \int_0^\infty |g(t)| e^{-\sigma t} dt < \infty.$$

Then:

- (i) for almost every $t \geq 0$ the integral defining $(f * g)(t)$ converges absolutely, and $f * g$ is measurable;
- (ii) $\int_0^\infty |(f * g)(t)| e^{-\sigma t} dt \leq AB < \infty$, in particular $\sigma_a(f * g) \leq \sigma$;
- (iii) for every s with $\operatorname{Re}(s) \geq \sigma$, $\mathcal{L}\{f * g\}(s) = F(s)G(s)$.

Proof. Step 1 — the change of variable that separates the two functions. Consider the linear map $\Phi(\tau, v) = (\tau, \tau + v)$ from $Q = [0, \infty)^2$ onto the sector $W = \{(\tau, t) : 0 \leq \tau \leq t\}$. It is bijective, with inverse $(\tau, t) \mapsto (\tau, t - \tau)$, and has Jacobian determinant

$$\det \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix} = 1,$$

hence it preserves Lebesgue measure on $\mathbb{R}^2$. The function $(\tau, t) \mapsto f(\tau)g(t - \tau)e^{-\sigma t}$ is measurable on W , being the composition of the measurable function $(x, y) \mapsto f(x)g(y)e^{-\sigma(x+y)}$ with Φ^{-1} .

Step 2 — Tonelli. The integrand, once moduli are taken, is nonnegative, so Tonelli's theorem allows integration in whichever order one prefers:

$$\int_0^\infty \left(\int_0^t |f(\tau)| |g(t - \tau)| d\tau \right) e^{-\sigma t} dt = \iint_W |f(\tau)| |g(t - \tau)| e^{-\sigma t} d\tau dt.$$

Transporting the integral to Q via Φ (which preserves measure) and using $e^{-\sigma t} = e^{-\sigma\tau} e^{-\sigma v}$ with $t = \tau + v$,

$$\iint_W |f(\tau)| |g(t - \tau)| e^{-\sigma t} d\tau dt = \iint_Q |f(\tau)| e^{-\sigma\tau} |g(v)| e^{-\sigma v} d\tau dv = A \cdot B < \infty.$$

Step 3 — (i) and (ii). Since the double integral of the moduli is finite, by Tonelli's theorem the function $t \mapsto \int_0^t |f(\tau)| |g(t-\tau)| d\tau$ is measurable and finite for almost every t : this is (i). Moreover, by the inequality between the modulus of the integral and the integral of the modulus,

$$\int_0^\infty |(f * g)(t)| e^{-\sigma t} dt \leq \int_0^\infty \left(\int_0^t |f(\tau)| |g(t-\tau)| d\tau \right) e^{-\sigma t} dt = AB,$$

which is (ii); the statement about the abscissa follows because for $\sigma' \geq \sigma$ one has $e^{-\sigma' t} \leq e^{-\sigma t}$.

Step 4 — (iii): Fubini. Let $\operatorname{Re}(s) \geq \sigma$. Then $|f(\tau)g(t-\tau)e^{-st}| = |f(\tau)| |g(t-\tau)| e^{-\operatorname{Re}(s)t} \leq |f(\tau)| |g(t-\tau)| e^{-\sigma t}$, whose double integral is finite by Step 2: Fubini's theorem applies and allows the order of integration to be exchanged and the integral to be transported via Φ . Hence

$$\mathcal{L}\{f * g\}(s) = \iint_W f(\tau)g(t-\tau)e^{-st} d\tau dt = \iint_Q f(\tau)e^{-s\tau} g(v)e^{-sv} d\tau dv,$$

and this last double integral, by Fubini's theorem applied to the product of two functions of separated variables, equals

$$\left(\int_0^\infty f(\tau)e^{-s\tau} d\tau \right) \left(\int_0^\infty g(v)e^{-sv} dv \right) = F(s)G(s).$$

□

***Remark 20.4: The product in the s -domain is what makes Laplace useful.** Theorem 20.10 is the technical reason why the analysis of linear systems is done in s and not in t : the response of a causal system to a causal input is the convolution $y = h * u$ (Definition 20.2), i.e. an integral for every instant, and it becomes the product $Y(s) = H(s)U(s)$, i.e. a multiplication. The same identity in the Fourier domain is Theorem 19.4; the difference is that here one does not require $f, g \in L^1(\mathbb{R})$, but only that some σ exist that damps both: the step and the growing exponential qualify, and in Fourier they do not.*

20.5. The elementary transforms, computed one by one

No row of the table should be memorized: every row is obtained from one of the rules of Section 20.4 applied to one of the only two transforms that must be computed by hand, that of the step and that of the exponential. Here the computation is carried out for all of them, declaring the region of convergence each time.

Proposition 20.2: The unit step. For $f = u$ one has $\sigma_c = \sigma_a = 0$, the ROC is the open half-plane $\operatorname{Re}(s) > 0$, and

$$\mathcal{L}\{u\}(s) = \frac{1}{s}, \quad \operatorname{Re}(s) > 0.$$

Proof. For $\operatorname{Re}(s) = \sigma > 0$ the function $t \mapsto e^{-st}$ has antiderivative $-e^{-st}/s$ (the derivative of e^{-st} is $-se^{-st}$, and $s \neq 0$), hence

$$\int_0^T e^{-st} dt = \frac{1 - e^{-sT}}{s}.$$

Since $|e^{-sT}| = e^{-\sigma T} \rightarrow 0$ for $\sigma > 0$, the limit as $T \rightarrow \infty$ equals $1/s$. Convergence is absolute: $\int_0^\infty e^{-\sigma t} dt = 1/\sigma < \infty$. For $\sigma < 0$ the integrand $e^{-\sigma t} = e^{|\sigma|t}$ is not even infinitesimal and the integral diverges; for $\sigma = 0$ Example 20.1 shows that the limit does not exist. Hence $\sigma_c = \sigma_a = 0$ and the line $\operatorname{Re}(s) = 0$ is excluded. □

Proposition 20.3: The complex exponential. Let $a \in \mathbb{C}$ and $f(t) = e^{at}$. Then $\sigma_c = \sigma_a = \operatorname{Re}(a)$, the ROC is the open half-plane $\operatorname{Re}(s) > \operatorname{Re}(a)$, and

$$\mathcal{L}\{e^{at}\}(s) = \frac{1}{s-a}, \quad \operatorname{Re}(s) > \operatorname{Re}(a).$$

Proof. Apply Theorem 20.6 with $f = u$ and with $-a$ in place of a : the function $e^{at}u(t)$ has transform $U(s-a) = \frac{1}{s-a}$, with abscissa $\sigma_a(u) + \operatorname{Re}(a) = \operatorname{Re}(a)$ by Proposition 20.2. A direct computation confirms this: for $\operatorname{Re}(s-a) > 0$,

$$\int_0^T e^{at} e^{-st} dt = \int_0^T e^{-(s-a)t} dt = \frac{1 - e^{-(s-a)T}}{s-a} \xrightarrow{T \rightarrow \infty} \frac{1}{s-a}.$$

The exclusion of the line $\operatorname{Re}(s) = \operatorname{Re}(a)$ follows from the same property for the step, carried over by the frequency shift, which is a bijection between the two regions of convergence. $\square$

Corollary 20.6: The integer powers. For every integer $n \geq 0$, the function t^n has $\sigma_a = 0$ and

$$\mathcal{L}\{t^n\}(s) = \frac{n!}{s^{n+1}}, \quad \operatorname{Re}(s) > 0.$$

Proof. Step 1 — the n -th derivative of $1/s$. It is proved by induction that $\frac{d^n}{ds^n} s^{-1} = (-1)^n n! s^{-n-1}$ for $s \neq 0$. For $n = 0$ this is $s^{-1} = s^{-1}$. If it holds for n , then differentiating,

$$\frac{d^{n+1}}{ds^{n+1}} s^{-1} = \frac{d}{ds} [(-1)^n n! s^{-n-1}] = (-1)^n n! (-n-1) s^{-n-2} = (-1)^{n+1} (n+1)! s^{-n-2}.$$

Step 2 — applying the multiplication rule. Corollary 20.5 with $f = u$ (which has $\sigma_a = 0$ by Proposition 20.2) and $U(s) = 1/s$ gives, for $\operatorname{Re}(s) > 0$,

$$\mathcal{L}\{t^n\}(s) = \mathcal{L}\{t^n u(t)\}(s) = (-1)^n U^{(n)}(s) = (-1)^n (-1)^n n! s^{-n-1} = \frac{n!}{s^{n+1}}.$$

The claim $\sigma_a(t^n) \leq 0$ is Lemma 20.2; and $\sigma_a \geq 0$ because for $\sigma \leq 0$ the integrand $t^n e^{-\sigma t}$ is not infinitesimal (for $n \geq 1$ it tends to $+\infty$; for $n = 0$ Proposition 20.2 applies). Hence $\sigma_a = 0$. $\square$

Corollary 20.7: Damped powers. For every integer $n \geq 0$ and every $a \in \mathbb{C}$,

$$\mathcal{L}\{t^n e^{at}\}(s) = \frac{n!}{(s-a)^{n+1}}, \quad \operatorname{Re}(s) > \operatorname{Re}(a),$$

with $\sigma_a = \operatorname{Re}(a)$. In particular $\mathcal{L}\{t e^{-at}\}(s) = \frac{1}{(s+a)^2}$ for $\operatorname{Re}(s) > -\operatorname{Re}(a)$.

Proof. Apply Theorem 20.6 to the function $f(t) = t^n$, whose transform is $n!/s^{n+1}$ with $\sigma_a = 0$ (Corollary 20.6), exchanging a with $-a$: this gives

$$\mathcal{L}\{e^{at} t^n\}(s) = F(s-a) = \frac{n!}{(s-a)^{n+1}},$$

valid for $\operatorname{Re}(s) - \operatorname{Re}(a) > 0$, with abscissa $0 + \operatorname{Re}(a) = \operatorname{Re}(a)$. The particular case is $n = 1$ with a changed in sign. $\square$

Proposition 20.4: Sine and cosine. Let $\omega \in \mathbb{R}$, $\omega \neq 0$. The functions $\cos(\omega t)$ and $\sin(\omega t)$ have $\sigma_c = \sigma_a = 0$ and, for $\operatorname{Re}(s) > 0$,

$$\mathcal{L}\{\cos(\omega t)\}(s) = \frac{s}{s^2 + \omega^2}, \quad \mathcal{L}\{\sin(\omega t)\}(s) = \frac{\omega}{s^2 + \omega^2}.$$

Proof. Step 1 — Euler's formulas. For every real t , $\cos(\omega t) = \frac{e^{i\omega t} + e^{-i\omega t}}{2}$ and $\sin(\omega t) = \frac{e^{i\omega t} - e^{-i\omega t}}{2i}$ (Volume II, Chapter 3).

Step 2 — linearity. The two functions $e^{\pm i\omega t}$ have $\operatorname{Re}(\pm i\omega) = 0$, hence abscissa 0 and transforms $\frac{1}{s \mp i\omega}$ for $\operatorname{Re}(s) > 0$ (Proposition 20.3). Theorem 20.4 then gives, for $\operatorname{Re}(s) > \max\{0, 0\} = 0$,

$$\mathcal{L}\{\cos(\omega t)\}(s) = \frac{1}{2} \left(\frac{1}{s - i\omega} + \frac{1}{s + i\omega} \right) = \frac{1}{2} \cdot \frac{(s + i\omega) + (s - i\omega)}{(s - i\omega)(s + i\omega)} = \frac{1}{2} \cdot \frac{2s}{s^2 + \omega^2} = \frac{s}{s^2 + \omega^2},$$

having used $(s - i\omega)(s + i\omega) = s^2 - (i\omega)^2 = s^2 + \omega^2$. Likewise

$$\mathcal{L}\{\sin(\omega t)\}(s) = \frac{1}{2i} \left(\frac{1}{s - i\omega} - \frac{1}{s + i\omega} \right) = \frac{1}{2i} \cdot \frac{2i\omega}{s^2 + \omega^2} = \frac{\omega}{s^2 + \omega^2}.$$

Step 3 — the abscissa is exactly 0. From $|\cos(\omega t)| \leq 1$ it follows that $\sigma_a \leq 0$ (comparison with the step). If $\sigma_a < 0$ held the integral would converge absolutely at $s = 0$, i.e. $\int_0^\infty |\cos(\omega t)| dt < \infty$; but on every period $[k\pi/|\omega|, (k+1)\pi/|\omega|]$ that integral equals $2/|\omega|$, and the sum of infinitely many terms equal to $2/|\omega| > 0$ diverges. Hence $\sigma_a = 0$; and $\sigma_c = 0$ because at $s = 0$ the integral $\int_0^T \cos(\omega t) dt = \frac{\sin(\omega T)}{\omega}$ has no limit. The same argument holds for the sine.

Numerical check. Simpson quadrature with 400,000 subintervals on $[0, 60]$: $\mathcal{L}\{\cos 2t\}(0.5) = 0.1176471$, against $\frac{0.5}{0.25+4} = \frac{0.5}{4.25} = 0.1176471$; and $\mathcal{L}\{\sin 3t\}(1) = 0.3000000$, against $\frac{3}{1+9} = 0.3$. $\checkmark$ $\square$

Corollary 20.8: Damped sine and cosine. Let $a \in \mathbb{C}$ and $\omega \in \mathbb{R} \setminus \{0\}$. Then, for $\operatorname{Re}(s) > -\operatorname{Re}(a)$,

$$\mathcal{L}\{e^{-at} \cos(\omega t)\}(s) = \frac{s + a}{(s + a)^2 + \omega^2}, \quad \mathcal{L}\{e^{-at} \sin(\omega t)\}(s) = \frac{\omega}{(s + a)^2 + \omega^2},$$

with absolute abscissa of convergence $-\operatorname{Re}(a)$. The poles of these two functions are $s = -a \pm i\omega$.

Proof. This is Theorem 20.6 applied to the two functions of Proposition 20.4, which have $\sigma_a = 0$: the transform is evaluated at $s + a$ and the abscissa becomes $0 - \operatorname{Re}(a)$. Substituting $s \mapsto s + a$ in the two formulas gives the stated expressions. The poles are found by setting the denominator to zero: $(s + a)^2 = -\omega^2$, i.e. $s + a = \pm i\omega$, i.e. $s = -a \pm i\omega$.

Numerical check. With $a = 2$, $\omega = 3$, $s = 1$: the formula gives $\frac{1+2}{(1+2)^2+9} = \frac{3}{18} = 0.1666667$ for the sine and $\frac{3}{18} = 0.1666667$ also for the cosine (because $s + a = 3 = \omega$). Numerical quadrature gives 0.1666667 in both cases. $\checkmark$ $\square$

Proposition 20.5: Delayed step and rectangular pulse. Let $a > 0$.

(i) $\mathcal{L}\{u(t - a)\}(s) = \frac{e^{-as}}{s}$ for $\operatorname{Re}(s) > 0$, with $\sigma_c = \sigma_a = 0$.

(ii) For the window $\pi_a = u(t) - u(t - a)$ (value 1 on $[0, a]$, 0 afterward) the region of

convergence is all of $\mathbb{C}$ and

$$\mathcal{L}\{\pi_a\}(s) = \frac{1 - e^{-as}}{s} \quad (s \neq 0), \quad \mathcal{L}\{\pi_a\}(0) = a.$$

The function $s \mapsto \mathcal{L}\{\pi_a\}(s)$ is entire.

Proof. (i). This is Theorem 20.5 with $f = u$: one has $u(t - a) = u(t - a)u(t - a)$, hence $\mathcal{L}\{u(t - a)\} = e^{-as}\mathcal{L}\{u\} = e^{-as}/s$, and the abscissa does not change, remaining that of the step (Proposition 20.2).

(ii) — **the region.** π_a vanishes outside $[0, a]$, hence for every $\sigma \in \mathbb{R}$

$$\int_0^\infty |\pi_a(t)|e^{-\sigma t} dt = \int_0^a e^{-\sigma t} dt < \infty,$$

because the integrand is continuous on a compact set. Convergence is absolute for every $s \in \mathbb{C}$: $\sigma_a = -\infty$ and the ROC is the whole plane.

(ii) — **the value.** For $s \neq 0$, from the computation in Proposition 20.2 restricted to $[0, a]$: $\int_0^a e^{-st} dt = \frac{1 - e^{-as}}{s}$. For $s = 0$ the integral equals $\int_0^a dt = a$. The two expressions match up: from the expansion $e^{-as} = \sum_{k \geq 0} \frac{(-as)^k}{k!}$ it follows that

$$\frac{1 - e^{-as}}{s} = \frac{1}{s} \left(as - \frac{a^2 s^2}{2} + \frac{a^3 s^3}{6} - \dots \right) = a - \frac{a^2 s}{2} + \frac{a^3 s^2}{6} - \dots,$$

a power series convergent for every $s \in \mathbb{C}$: hence $s = 0$ is a removable singularity (Definition 15.6), the continuation equals a at 0, and the function is entire. $\square$

Definition 20.6: Laplace transform of a measure, and the delayed impulse. Let μ be a finite Borel measure on $[0, \infty)$. Its **Laplace transform** is

$$\mathcal{L}\{\mu\}(s) = \int_{[0, \infty)} e^{-st} d\mu(t).$$

For $a \geq 0$, δ_a denotes the **Dirac measure** concentrated at a , that is, $\delta_a(E) = 1$ if $a \in E$ and $\delta_a(E) = 0$ otherwise; one writes $\delta = \delta_0$. A locally integrable function f is identified with the measure $f(t) dt$, and in this case the definition reduces to the usual Laplace integral.

Proposition 20.6: Delayed impulse. For every $a \geq 0$ one has $\mathcal{L}\{\delta_a\}(s) = e^{-as}$ for every $s \in \mathbb{C}$: the region of convergence is the whole plane. In particular $\mathcal{L}\{\delta\} \equiv 1$. Moreover, for every locally integrable f ,

$$(\delta_a * f)(t) = f(t - a)u(t - a),$$

consistently with Theorem 20.5 and with Theorem 20.10.

Proof. Step 1 — the value of the transform. The integral of a continuous function g with respect to the Dirac measure δ_a equals $g(a)$: indeed δ_a is the probability measure assigning mass 1 to the single point a , and for every simple function $\sum c_k \mathbf{1}_{E_k}$ the integral is $\sum_k c_k \delta_a(E_k) = c_{k_0}$ where E_{k_0} is the unique set of the partition containing a ; passing to the limit over simple functions gives $\int g d\delta_a = g(a)$. With $g(t) = e^{-st}$, continuous for every fixed s , this gives $\mathcal{L}\{\delta_a\}(s) = e^{-as}$, defined for every $s \in \mathbb{C}$. For $a = 0$ the value is $e^0 = 1$.

Step 2 — the convolution. The convolution of a measure μ with a function is $(\mu * f)(t) = \int_{[0, t]} f(t - \tau) d\mu(\tau)$; with $\mu = \delta_a$ Step 1 gives $f(t - a)$ if $a \leq t$, and 0 if $a > t$ (because then $a \notin [0, t]$ and the mass is not caught): that is, exactly $f(t - a)u(t - a)$. Transforming,

$\mathcal{L}\{\delta_a * f\} = e^{-as}F(s) = \mathcal{L}\{\delta_a\} \cdot F$, in agreement with Theorem 20.5. $\square$

Warning. 0^- or 0^+ : why the delta forces a choice. The integral $\int_0^\infty$ of Definition 20.1 does not say whether the point 0 is included. For a locally integrable function the question is empty, because a point has zero measure. For a measure it is not: δ has all its mass at 0, and

$$\int_{[0,\infty)} e^{-st} d\delta(t) = 1, \quad \int_{(0,\infty)} e^{-st} d\delta(t) = 0.$$

Definition 20.6 integrates over $[0, \infty)$, i.e. it adopts the convention called “ 0^- ” in signal theory texts, and it is the one that makes the row $\delta \mapsto 1$ of the table true and makes Corollary 20.4 consistent when f has a jump at the origin. The Dirac delta as a *tempered distribution* is Definition 19.8 of Chapter 19: the Definition 20.6 used here is more modest (a measure, not a distribution) but sufficient for every row of the table, and it does not require distribution theory.

Example 20.2: Non-integer powers and the Gamma function. Let $\alpha > -1$ be real and $f(t) = t^\alpha$. The integral converges absolutely for $\sigma > 0$: near 0 because $\int_0^1 t^\alpha dt = \frac{1}{\alpha+1} < \infty$, and at infinity because $t^\alpha e^{-\sigma t}$ decays exponentially. For $s > 0$ real substitute $x = st$, $dx = s dt$:

$$\int_0^\infty t^\alpha e^{-st} dt = \int_0^\infty \left(\frac{x}{s}\right)^\alpha e^{-x} \frac{dx}{s} = \frac{1}{s^{\alpha+1}} \int_0^\infty x^\alpha e^{-x} dx = \frac{\Gamma(\alpha+1)}{s^{\alpha+1}},$$

with Γ Euler’s Gamma function (Chapter 11). The formula extends to the whole half-plane $\operatorname{Re}(s) > 0$ with the principal determination of $s^{\alpha+1} = e^{(\alpha+1)\operatorname{Log} s}$: both sides are holomorphic on $\operatorname{Re}(s) > 0$ (the first by Theorem 20.3, the second because the principal logarithm is holomorphic outside the negative real half-axis) and coincide on the half-line $(0, \infty)$, which has accumulation points in the domain: the identity principle (Theorem 15.10) forces equality everywhere. For $\alpha = n$ integer one recovers $\Gamma(n+1) = n!$ and Corollary 20.6. *Numerical check.* For $\alpha = \frac{1}{2}$ and $s = 1$ the formula gives $\Gamma(3/2) = \frac{\sqrt{\pi}}{2} = 0.8862269$; Simpson quadrature on $[0, 200]$ with 2,000,000 subintervals gives 0.8862268, with discrepancy $8 \cdot 10^{-8}$ due to the singularity of the derivative of the integrand at 0. $\checkmark$

Theorem 20.11: Table of Laplace transforms, with the region of convergence.

Every row of Table 20.1 and of Table 20.2 is an identity valid exactly in the region of convergence indicated in the third column, and the fourth column refers to the result that proves it. In particular no row is assumed: all of them follow from Proposition 20.2 and from Proposition 20.3 through the rules of Section 20.4.

Proof. The rows of Table 20.1 are, in order, Proposition 20.6 (two rows: $a = 0$ and $a > 0$), Proposition 20.2, Proposition 20.5(i) and (ii), Corollary 20.6 (two rows: $n = 1$ and general n), Example 20.2, Proposition 20.3, Corollary 20.7, Proposition 20.4 (two rows) and Corollary 20.8 (two rows). What remains to be justified are the last two rows, the hyperbolic ones. For $b \in \mathbb{C}$ one has $\cosh(bt) = \frac{e^{bt} + e^{-bt}}{2}$ and $\sinh(bt) = \frac{e^{bt} - e^{-bt}}{2}$; the two exponentials have abscissas $\operatorname{Re}(b)$ and $-\operatorname{Re}(b)$, hence by Theorem 20.4 the combination converges absolutely for $\operatorname{Re}(s) > \max\{\operatorname{Re}(b), -\operatorname{Re}(b)\} = |\operatorname{Re}(b)|$, and there

$$\mathcal{L}\{\cosh(bt)\}(s) = \frac{1}{2} \left(\frac{1}{s-b} + \frac{1}{s+b} \right) = \frac{s}{s^2 - b^2},$$

$$\mathcal{L}\{\sinh(bt)\}(s) = \frac{1}{2} \left(\frac{1}{s-b} - \frac{1}{s+b} \right) = \frac{b}{s^2 - b^2},$$

having used $(s-b)(s+b) = s^2 - b^2$. *Numerical check:* for $b = 1$ and $s = 2$ the formula gives $\frac{2}{4-1} = 0.6666667$, and quadrature on $[0, 60]$ gives 0.6666667. ✓
The rows of Table 20.2 are, in order, Theorems 20.4, 20.5, 20.6 and 20.7, Theorem 20.8 with Corollary 20.4, Theorem 20.9, Corollary 20.5 and Theorem 20.10: each was proved with its own region of convergence, reported here unchanged. $\square$

Table 20.1: Elementary pairs. The third column is the region of convergence: without it the second column does not identify the signal. Here $a \geq 0$, $n \geq 0$ integer, $\alpha > -1$ real, $\omega \in \mathbb{R} \setminus \{0\}$, $b, c \in \mathbb{C}$.

20.6. Initial value and final value

The two formulas

$$f(0^+) = \lim_{s \rightarrow \infty} sF(s), \quad \lim_{t \rightarrow \infty} f(t) = \lim_{s \rightarrow 0} sF(s)$$

are the tool with which, in a control loop, one reads the initial value and the steady-state error without inverting the transform. They are also the two formulas most often used wrongly: both are true only under precise hypotheses, and both, if the hypotheses fail, return a number — a

Figure 20.2: Pole map and region of convergence of $e^{-t} \cos(2t) u(t)$, whose transform is $\frac{s+1}{(s+1)^2+4}$ (Corollary 20.8 with $c = 1$, $\omega = 2$). The two poles are $s = -1 \pm 2i$ (ochre crosses), the ROC is the open half-plane $\operatorname{Re}(s) > -1$ (blue), and the imaginary axis (green) belongs to it: by Theorem 20.19 the signal then also has a Fourier transform, obtained by setting $s = i\omega$. Coordinates verified: setting $(s+1)^2 + 4$ to zero gives $s+1 = \pm 2i$.

wrong one — instead of signaling an error. This section proves the hypotheses and shows the two ways of getting it wrong.

Proposition 20.7: A transform vanishes at infinity. If f is locally integrable with $\sigma_a = \sigma_a(f) < +\infty$, then

$$\lim_{\sigma \rightarrow +\infty} F(\sigma) = 0$$

(limit along the reals). Consequently a function of s that does not tend to 0 as $\sigma \rightarrow +\infty$ is not the Laplace transform of any locally integrable function with finite abscissa.

Proof. Fix $\sigma_1 > \sigma_a$, so that $\int_0^\infty |f(t)|e^{-\sigma_1 t} dt < \infty$. Let (σ_n) be any real sequence with $\sigma_n \rightarrow +\infty$; discarding finitely many terms if necessary one may assume $\sigma_n \geq \sigma_1$ for every n . For $t > 0$ one has $|f(t)|e^{-\sigma_n t} \rightarrow 0$, and for every n

$$|f(t)e^{-\sigma_n t}| \leq |f(t)|e^{-\sigma_1 t},$$

a function integrable on $[0, \infty)$ and independent of n . The dominated convergence theorem gives $F(\sigma_n) = \int_0^\infty f(t)e^{-\sigma_n t} dt \rightarrow 0$. Since the sequence was arbitrary, $F(\sigma) \rightarrow 0$ as $\sigma \rightarrow +\infty$. The last statement is the contrapositive. $\square$

Theorem 20.12: Initial value theorem. Let $f : [0, \infty) \rightarrow \mathbb{C}$ be absolutely continuous on every compact set and suppose there exists $\sigma_0 \in \mathbb{R}$ with $\int_0^\infty |f'(t)|e^{-\sigma_0 t} dt < \infty$. Then

$$\lim_{\operatorname{Re}(s) \rightarrow +\infty} sF(s) = f(0^+),$$

in the precise sense: for every $\varepsilon > 0$ there exists $\Sigma \in \mathbb{R}$ such that $|sF(s) - f(0^+)| < \varepsilon$ for every $s \in \mathbb{C}$ with $\operatorname{Re}(s) > \Sigma$. In particular the limit holds along the real axis.

Proof. Step 1 — rewriting. Let $\beta = \max\{\sigma_0, 0\}$. Theorem 20.8 gives, for every s with $\operatorname{Re}(s) > \beta$,

$$sF(s) - f(0^+) = \mathcal{L}\{f'\}(s).$$

It thus suffices to show that $\mathcal{L}\{f'\}(s) \rightarrow 0$ as $\operatorname{Re}(s) \rightarrow +\infty$.

Step 2 — the estimate depends only on the real part. For $\sigma = \operatorname{Re}(s)$,

$$|\mathcal{L}\{f'\}(s)| = \left| \int_0^\infty f'(t)e^{-st} dt \right| \leq \int_0^\infty |f'(t)| e^{-\sigma t} dt =: I(\sigma),$$

because $|e^{-st}| = e^{-\sigma t}$. The bound $I(\sigma)$ does not depend on $\operatorname{Im}(s)$: this is why the limit can be taken over the whole half-plane and not only along the real axis.

Step 3 — $I(\sigma) \rightarrow 0$. Fix $\sigma_1 > \beta$. For $\sigma \geq \sigma_1$ one has $|f'(t)|e^{-\sigma t} \leq |f'(t)|e^{-\sigma_1 t}$, integrable and independent of σ , and for every $t > 0$ one has $|f'(t)|e^{-\sigma t} \rightarrow 0$ as $\sigma \rightarrow +\infty$. As in the proof of Proposition 20.7, the dominated convergence theorem applied along an arbitrary sequence $\sigma_n \rightarrow +\infty$ gives $I(\sigma_n) \rightarrow 0$, hence $I(\sigma) \rightarrow 0$.

Step 4 — conclusion. Given $\varepsilon > 0$, choose $\Sigma \geq \sigma_1$ with $I(\sigma) < \varepsilon$ for $\sigma > \Sigma$ (Step 3). For every s with $\operatorname{Re}(s) > \Sigma$, Steps 1 and 2 give $|sF(s) - f(0^+)| \leq I(\operatorname{Re}(s)) < \varepsilon$. $\square$

Example 20.3: What happens when the initial-value hypothesis fails. (a) An impulse at the origin. Consider the measure $\mu = \delta + e^{-t} dt$, the sum of the Dirac measure at 0 and a function. Its transform (Definition 20.6, Proposition 20.6 and Proposition 20.3) is

$$\Phi(s) = 1 + \frac{1}{s+1} = \frac{s+2}{s+1}, \quad \operatorname{Re}(s) > -1.$$

The “function” part of μ is $g(t) = e^{-t}$, with $g(0^+) = 1$. But

$$s\Phi(s) = s + \frac{s}{s+1} \quad \text{equals} \quad 10.9090909, \quad 100.9900990, \quad 1000.9990010$$

for $s = 10$, $s = 100$, $s = 1000$: it diverges, instead of tending to 1. $\checkmark$ (Independent check: $s + \frac{s}{s+1} \geq s \rightarrow +\infty$.) The hypothesis that fails is the most radical possible: Φ is not the transform of any function. Indeed $\Phi(\sigma) \rightarrow 1 \neq 0$ as $\sigma \rightarrow +\infty$, and Proposition 20.7 then excludes Φ from being the transform of a locally integrable function with finite abscissa. The initial value theorem requires f to be absolutely continuous: an impulse at the origin is not, and the formula fails spectacularly.

(b) An integrable singularity at the origin. Let $f(t) = t^{-1/2}$ for $t > 0$. It is locally integrable and, by Example 20.2 with $\alpha = -\frac{1}{2}$,

$$F(s) = \frac{\Gamma(1/2)}{s^{1/2}} = \sqrt{\frac{\pi}{s}}, \quad \operatorname{Re}(s) > 0,$$

where $\Gamma(1/2) = \sqrt{\pi}$. Then $sF(s) = \sqrt{\pi s} \rightarrow +\infty$: the formula does not return a finite number. Here there is no contradiction but no information either, because f is not absolutely continuous on $[0, T]$ (it is not even bounded near 0) and $f(0^+) = +\infty$ is not a number. This is a case where the formula “tells the truth” only because both sides diverge: it is not a check on the theorem, it is a coincidence.

Theorem 20.13: Final value theorem. Let $f : [0, \infty) \rightarrow \mathbb{C}$ be locally integrable and suppose there exists finite

$$L = \lim_{t \rightarrow +\infty} f(t).$$

Then $\sigma_a(f) \leq 0$ (hence F is defined for $\operatorname{Re}(s) > 0$) and

$$\lim_{s \rightarrow 0^+} sF(s) = L,$$

where the limit is taken along the positive reals.

Proof. Step 1 — the abscissa. Since $f(t) \rightarrow L$, there exists T_1 with $|f(t) - L| \leq 1$, and hence $|f(t)| \leq |L| + 1$, for $t \geq T_1$. For $\sigma > 0$,

$$\int_0^\infty |f(t)|e^{-\sigma t} dt \leq \int_0^{T_1} |f(t)| dt + (|L| + 1) \int_{T_1}^\infty e^{-\sigma t} dt = \int_0^{T_1} |f| dt + (|L| + 1) \frac{e^{-\sigma T_1}}{\sigma} < \infty,$$

the first term being finite because f is integrable on every compact set. Hence $\sigma_a(f) \leq 0$.

Step 2 — the decomposition. Let $\varepsilon > 0$ and choose $T_0 \geq 0$ such that $|f(t) - L| < \varepsilon$ for every $t \geq T_0$. For real $s > 0$ split

$$sF(s) = \underbrace{s \int_0^{T_0} f(t)e^{-st} dt}_{A(s)} + \underbrace{s \int_{T_0}^\infty (f(t) - L)e^{-st} dt}_{B(s)} + \underbrace{sL \int_{T_0}^\infty e^{-st} dt}_{C(s)},$$

a legitimate decomposition because all three integrals converge absolutely for $s > 0$ (Step 1) and the sum of the three integrands is $sf(t)e^{-st}$ on each of the two intervals.

Step 3 — the three pieces. The third is computed exactly: $\int_{T_0}^\infty e^{-st} dt = \frac{e^{-sT_0}}{s}$, hence $C(s) = Le^{-sT_0} \rightarrow L$ as $s \rightarrow 0^+$ (continuity of the exponential). The second is bounded:

$$|B(s)| \leq s \int_{T_0}^\infty |f(t) - L|e^{-st} dt \leq s\varepsilon \int_{T_0}^\infty e^{-st} dt = \varepsilon e^{-sT_0} \leq \varepsilon.$$

The first is bounded by $|A(s)| \leq s \int_0^{T_0} |f(t)| dt$ (because $e^{-st} \leq 1$ for $t \geq 0$, $s > 0$), a quantity that tends to 0 as $s \rightarrow 0^+$, since $\int_0^{T_0} |f|$ is a fixed finite number.

Step 4 — conclusion. From $|sF(s) - L| \leq |A(s)| + |B(s)| + |C(s) - L|$ it follows that

$$\limsup_{s \rightarrow 0^+} |sF(s) - L| \leq 0 + \varepsilon + 0 = \varepsilon.$$

Since $\varepsilon > 0$ was arbitrary, the lim sup is zero, i.e. $sF(s) \rightarrow L$. □

Remark 20.5: The hypothesis is on the signal, not on the transform. Theorem 20.13 assumes that the limit of f exists: this is a hypothesis on the time domain, which is not read directly off the s -domain. The operational condition found in control texts — “all poles of $sF(s)$ in the half-plane $\operatorname{Re}(s) < 0$ ” — is a sufficient condition valid for rational F , and is proved further on as Corollary 20.11, after the partial fraction decomposition. Doetsch proves the version with $s \rightarrow 0$ inside a Stolz sector $|\arg s| \leq \theta < \pi/2$ and places it among the Abelian theorems (Introduction to the Theory and Application of the Laplace Transformation, Ch. 33 “Asymptotic Behaviour of the Image Function near Infinity,” pp. 221–230, and Ch. 34, pp. 231–233): the proof given here, with the limit along the reals, is sufficient for every use made of it in this chapter.

Example 20.4: What happens when the final-value hypothesis fails. (a) Poles on the imaginary axis. Let $f(t) = \sin t$, with $F(s) = \frac{1}{s^2 + 1}$ for $\operatorname{Re}(s) > 0$ (Proposition 20.4).

Then

$$sF(s) = \frac{s}{s^2 + 1} \quad \text{equals} \quad 0.0990099, \quad 0.00999990, \quad 0.0010000$$

for $s = 0.1, 0.01, 0.001$: it tends to 0. But $\lim_{t \rightarrow \infty} \sin t$ *does not exist*: the formula returns the number 0, which is not the final value of anything. ✓ (Independent check: $|s/(s^2 + 1)| \leq s \rightarrow 0$.) The hypothesis violated is the existence of the limit; in the s -plane the symptom is that the poles of $sF(s)$, namely $\pm i$, lie *on* the imaginary axis and not to its left.

(b) A pole in the right half-plane. Let $f(t) = e^t$, with $F(s) = \frac{1}{s-1}$ for $\operatorname{Re}(s) > 1$ (Proposition 20.3). The expression $sF(s) = \frac{s}{s-1}$ makes sense as a rational function even at $s = 0$, where it equals 0; and it equals -0.1111111 , -0.0101010 , -0.0010010 for $s = 0.1, 0.01, 0.001$, tending to 0. But $f(t) = e^t \rightarrow +\infty$. ✓ The error here is even more blatant: the point $s = 0$ *does not belong to the region of convergence* $\operatorname{Re}(s) > 1$, and evaluating $sF(s)$ near 0 means using the analytic continuation of F outside the ROC. This is why the ROC must be declared in every row of the table.

(c) A double pole at the origin: both sides diverge. Let $F(s) = \frac{s+3}{s^2(s+1)}$, whose inverse transform is $f(t) = 3t - 2 + 2e^{-t}$ (Worked Exercise 20.6). Then $sF(s) = \frac{s+3}{s(s+1)}$ equals 28.1818182, 298.0198020, 2998.0019980 for $s = 0.1, 0.01, 0.001$, while $f(10) = 28.0000908$, $f(100) = 298.0000000$, $f(1000) = 2998.0000000$: the two sequences diverge *together*, and with almost the same value, because $f(t) \approx 3t$ and $sF(s) \approx 3/s$. ✓ This is not a confirmation of the theorem: the theorem does not apply, because the limit of f does not exist finite. It is only how, in this case, the divergence shows up on both sides.

20.7. Inversion: uniqueness, partial fractions, residues

Inverting the transform means going back from F to f . Even before finding a formula one must know that the answer is unique, otherwise “the” inverse transform does not exist as an object: this is Theorem 20.14. Then, for rational F — which are practically all those met in linear systems with constant coefficients — the answer is written explicitly, in two ways that turn out to be the same way: the partial fraction decomposition and the sum of residues.

Theorem 20.14: Uniqueness of the inverse transform (Lerch). Let $f, g : [0, \infty) \rightarrow \mathbb{C}$ be locally integrable with finite absolute abscissas of convergence, and let $s_0 \in \mathbb{R}$ with $s_0 > \max\{\sigma_a(f), \sigma_a(g)\}$. If

$$F(s_0 + n) = G(s_0 + n) \quad \text{for every integer } n \geq 0,$$

then $f = g$ almost everywhere on $[0, \infty)$.

Proof. Let $h = f - g$; by Theorem 20.4 one has $\sigma_a(h) \leq \max\{\sigma_a(f), \sigma_a(g)\} < s_0$ and $H(s_0 + n) = 0$ for every $n \geq 0$. It must be shown that $h = 0$ almost everywhere.

Step 1 — the change of variable $x = e^{-t}$. The map $t \mapsto x = e^{-t}$ is a C^∞ diffeomorphism from $(0, \infty)$ onto $(0, 1)$, decreasing, with inverse $x \mapsto t = -\ln x$ and $dt = -dx/x$. Set

$$\eta(x) = h(-\ln x) x^{s_0-1}, \quad x \in (0, 1).$$

With this substitution, for every $n \geq 0$,

$$H(s_0 + n) = \int_0^\infty h(t) e^{-(s_0+n)t} dt = \int_0^1 h(-\ln x) x^{s_0+n} \frac{dx}{x} = \int_0^1 \eta(x) x^n dx,$$

having used $e^{-(s_0+n)t} = (e^{-t})^{s_0+n} = x^{s_0+n}$ and the fact that the endpoints $t = 0, \infty$ correspond to $x = 1, 0$, which compensates the sign of $-dx/x$. The same substitution applied to the moduli gives

$$\int_0^1 |\eta(x)| dx = \int_0^\infty |h(t)| e^{-s_0 t} dt < \infty,$$

because $s_0 > \sigma_a(h)$: hence $\eta \in L^1(0, 1)$.

Step 2 — all moments vanish. By hypothesis $\int_0^1 \eta(x) x^n dx = 0$ for every $n \geq 0$. By linearity of the integral, for every polynomial $p(x) = \sum_{n=0}^N c_n x^n$ one has $\int_0^1 \eta(x) p(x) dx = \sum_{n=0}^N c_n \int_0^1 \eta x^n dx = 0$.

Step 3 — from polynomials to continuous functions. Let φ be continuous on $[0, 1]$ and let $\varepsilon > 0$. By the Weierstrass approximation theorem in its polynomial form (recalled among the prerequisites; the corresponding trigonometric form is Corollary 17.3) there exists a polynomial p with $\sup_{[0,1]} |\varphi - p| < \varepsilon$. Then, by Step 2,

$$\left| \int_0^1 \eta \varphi dx \right| = \left| \int_0^1 \eta (\varphi - p) dx \right| \leq \varepsilon \int_0^1 |\eta| dx = \varepsilon \|\eta\|_1.$$

Since $\varepsilon > 0$ is arbitrary and $\|\eta\|_1$ is finite, $\int_0^1 \eta \varphi dx = 0$ for every continuous φ .

Step 4 — conclusion. The fundamental lemma of the calculus of variations in L^1 (among the prerequisites) then gives $\eta = 0$ almost everywhere on $(0, 1)$. Since $x^{s_0-1} \neq 0$ for $x \in (0, 1)$, it follows that $h(-\ln x) = 0$ for almost every $x \in (0, 1)$. The map $x \mapsto -\ln x$ is a diffeomorphism with nowhere-vanishing derivative, hence it sends sets of measure zero to sets of measure zero and conversely (change-of-variables formula): $h = 0$ almost everywhere on $(0, \infty)$, i.e. $f = g$ almost everywhere. $\square$

Corollary 20.9: Two signals with the same transform coincide. If $F(s) = G(s)$ for every s in a half-plane $\operatorname{Re}(s) > \sigma^*$ contained in the regions of absolute convergence of f and g , then $f = g$ almost everywhere. In particular the notation $f = \mathcal{L}^{-1}\{F\}$ determines f up to sets of measure zero, and it determines exactly the unique continuous inverse transform, if one exists.

Proof. Choose a real $s_0 > \max\{\sigma^*, \sigma_a(f), \sigma_a(g)\}$: then $s_0 + n > \sigma^*$ for every integer $n \geq 0$, hence $F(s_0 + n) = G(s_0 + n)$, and Theorem 20.14 gives $f = g$ almost everywhere. If moreover f and g are both continuous and coincide almost everywhere, they coincide everywhere: the set $\{t : f(t) \neq g(t)\}$ is open in $[0, \infty)$ (by continuity of $f - g$) and every nonempty open subset of $[0, \infty)$ has positive measure, hence that set is empty. $\square$

Theorem 20.15: Partial fractions: simple poles. Let $R = N/D$ be a rational function with $\deg N < \deg D = r$ and with D having r distinct roots $p_1, \dots, p_r$. Then

$$R(s) = \sum_{k=1}^r \frac{A_k}{s - p_k}, \quad A_k = \frac{N(p_k)}{D'(p_k)} = \lim_{s \rightarrow p_k} (s - p_k) R(s),$$

for every $s \notin \{p_1, \dots, p_r\}$.

Proof. Step 1 — the value of A_k . Since p_k is a simple root of D , one has $D(p_k) = 0$ and $D'(p_k) \neq 0$. Hence

$$\lim_{s \rightarrow p_k} (s - p_k) R(s) = \lim_{s \rightarrow p_k} \frac{(s - p_k) N(s)}{D(s) - D(p_k)} = N(p_k) \cdot \lim_{s \rightarrow p_k} \frac{s - p_k}{D(s) - D(p_k)} = \frac{N(p_k)}{D'(p_k)},$$

by the definition of derivative and because $D'(p_k) \neq 0$. The two expressions for A_k coincide.

Step 2 — the difference is holomorphic on all of $\mathbb{C}$. Set

$$S(s) = R(s) - \sum_{k=1}^r \frac{A_k}{s - p_k},$$

a rational function, holomorphic on $\mathbb{C} \setminus \{p_1, \dots, p_r\}$. Fix k . As $s \rightarrow p_k$,

$$(s - p_k)S(s) = (s - p_k)R(s) - A_k - \sum_{j \neq k} \frac{A_j(s - p_k)}{s - p_j} \rightarrow A_k - A_k - 0 = 0,$$

since for $j \neq k$ the denominator $p_k - p_j$ does not vanish. In particular $(s - p_k)S(s)$ is bounded near p_k , hence $S(s) = \frac{(s - p_k)S(s)}{s - p_k}$ has at most a simple pole at p_k ; but the numerator tends to 0, so S itself is bounded in a punctured neighborhood of p_k . By Riemann's theorem on removable singularities (Theorem 15.13) the singularity is removable: S extends to a function holomorphic at p_k . Doing this for every k , S extends to an entire function.

Step 3 — S tends to zero at infinity. Writing $N(s) = \sum_{i=0}^m n_i s^i$ with $m < r$ and $D(s) = \sum_{i=0}^r d_i s^i$ with $d_r \neq 0$, for $s \neq 0$ one has

$$R(s) = \frac{s^m(n_m + n_{m-1}s^{-1} + \dots)}{s^r(d_r + d_{r-1}s^{-1} + \dots)} = s^{m-r} \cdot \frac{n_m + O(|s|^{-1})}{d_r + O(|s|^{-1})} \xrightarrow{|s| \rightarrow \infty} 0,$$

because $m - r \leq -1$ and the second factor tends to n_m/d_r , finite. Also every $A_k/(s - p_k) \rightarrow 0$. Hence $S(s) \rightarrow 0$ as $|s| \rightarrow \infty$.

Step 4 — Liouville. From Step 3 there exists $\rho > 0$ with $|S(s)| \leq 1$ for $|s| \geq \rho$; on the closed disk $|s| \leq \rho$, S is continuous (being entire) and hence bounded, the disk being compact. So S is entire and bounded on $\mathbb{C}$: by Liouville's theorem (Theorem 15.8) it is constant, and the constant is its limit at infinity, i.e. 0. Hence $S \equiv 0$, which is the claim. $\square$

Theorem 20.16: Partial fractions: multiple poles. Let $R = N/D$ be rational with $\deg N < \deg D$ and $D(s) = d \prod_{k=1}^r (s - p_k)^{m_k}$, with $p_1, \dots, p_r$ distinct, $m_k \geq 1$ and $d \neq 0$. Then

$$R(s) = \sum_{k=1}^r \sum_{j=1}^{m_k} \frac{A_{k,j}}{(s - p_k)^j}, \quad A_{k,j} = \frac{1}{(m_k - j)!} \lim_{s \rightarrow p_k} \frac{d^{m_k-j}}{ds^{m_k-j}} [(s - p_k)^{m_k} R(s)].$$

For $m_k = 1$ this recovers $A_{k,1} = \lim_{s \rightarrow p_k} (s - p_k)R(s)$ of Theorem 20.15.

Proof. **Step 1 — the principal part at p_k .** The function $g_k(s) = (s - p_k)^{m_k} R(s)$ coincides, away from the poles, with $\frac{N(s)}{d \prod_{i \neq k} (s - p_i)^{m_i}}$, which is holomorphic in a neighborhood of p_k (the denominator does not vanish there). Let $g_k(s) = \sum_{i \geq 0} \frac{g_k^{(i)}(p_k)}{i!} (s - p_k)^i$ be its Taylor expansion (Theorem 15.6), convergent in a disk around p_k . Dividing by $(s - p_k)^{m_k}$ gives the Laurent expansion of R at p_k (Theorem 15.4):

$$R(s) = \sum_{i \geq 0} \frac{g_k^{(i)}(p_k)}{i!} (s - p_k)^{i - m_k}.$$

The coefficient of $(s - p_k)^{-j}$, with $1 \leq j \leq m_k$, is obtained for $i = m_k - j$ and equals $\frac{g_k^{(m_k-j)}(p_k)}{(m_k-j)!}$, that is, exactly $A_{k,j}$ as defined in the statement. The *principal part* of R at p_k is thus $\Pi_k(s) = \sum_{j=1}^{m_k} \frac{A_{k,j}}{(s - p_k)^j}$.

Step 2 — the difference is entire. Set $S = R - \sum_{k=1}^r \Pi_k$, holomorphic on $\mathbb{C} \setminus \{p_1, \dots, p_r\}$. Fix k : in a punctured neighborhood of p_k , by Step 1, $R - \Pi_k$ is the sum of only the regular part

of the Laurent series, i.e. a convergent power series, hence it extends continuously to p_k ; and the other Π_i , $i \neq k$, are holomorphic at p_k . Hence S is bounded in a punctured neighborhood of p_k and, by Theorem 15.13, extends holomorphically. Doing this for every k , S is entire.

Step 3 — Liouville. As in Step 3 of the proof of Theorem 20.15, $R(s) \rightarrow 0$ as $|s| \rightarrow \infty$ because $\deg N < \deg D$, and every $A_{k,j}(s - p_k)^{-j} \rightarrow 0$; hence $S(s) \rightarrow 0$ at infinity, S is entire and bounded, and Theorem 15.8 gives $S \equiv 0$.

Step 4 — the case $m_k = 1$. For $m_k = 1$ the only admissible index is $j = 1$, the derivative of order $m_k - j = 0$ is the identity and $0! = 1$: the formula reduces to $A_{k,1} = \lim_{s \rightarrow p_k} (s - p_k)R(s)$. $\square$

Corollary 20.10: Inverse transform of a proper rational function. With the notation of Theorem 20.16, the unique (up to sets of measure zero) causal function whose Laplace transform is R is

$$f(t) = \sum_{k=1}^r \sum_{j=1}^{m_k} A_{k,j} \frac{t^{j-1}}{(j-1)!} e^{p_k t}, \quad t \geq 0,$$

and its region of convergence is the half-plane $\operatorname{Re}(s) > \max_k \operatorname{Re}(p_k)$.

Proof. By Corollary 20.7 with $n = j - 1$ and $c = p_k$,

$$\mathcal{L}\left\{\frac{t^{j-1}}{(j-1)!} e^{p_k t}\right\}(s) = \frac{1}{(j-1)!} \cdot \frac{(j-1)!}{(s - p_k)^j} = \frac{1}{(s - p_k)^j}, \quad \operatorname{Re}(s) > \operatorname{Re}(p_k).$$

Applying Theorem 20.4 to the finite combination with coefficients $A_{k,j}$ gives, for $\operatorname{Re}(s) > \max_k \operatorname{Re}(p_k)$, $\mathcal{L}\{f\}(s) = \sum_{k,j} \frac{A_{k,j}}{(s - p_k)^j} = R(s)$ by Theorem 20.16. Uniqueness is Corollary 20.9. That the abscissa is exactly $\max_k \operatorname{Re}(p_k)$ and not less follows from the fact that R has a pole at each p_k , while by Theorem 20.3 the transform is holomorphic to the right of the abscissa: no pole can lie in the region of convergence. $\square$

Theorem 20.17: Inversion by residues, rational case. Let R be proper rational with poles $p_1, \dots, p_r$ and let $f = \mathcal{L}^{-1}\{R\}$. Then, for every $t \geq 0$,

$$f(t) = \sum_{k=1}^r \operatorname{Res}_{s=p_k} [R(s) e^{st}],$$

where the residue is, as in Chapter 15, the coefficient a_{-1} of the Laurent expansion (Theorem 15.4) that appears in the residue theorem (Theorem 15.5).

Proof. **Step 1 — the expansion of the exponential factor.** Fix k and $t \geq 0$. For every s ,

$$e^{st} = e^{p_k t} e^{(s-p_k)t} = e^{p_k t} \sum_{i \geq 0} \frac{t^i}{i!} (s - p_k)^i,$$

a power series in $(s - p_k)$ convergent on all of $\mathbb{C}$.

Step 2 — the product and the coefficient a_{-1} . By Step 1 of the proof of Theorem 20.16, in a punctured neighborhood of p_k one has $R(s) = \Pi_k(s) + \Theta_k(s)$ with $\Pi_k(s) = \sum_{j=1}^{m_k} A_{k,j}(s - p_k)^{-j}$ and Θ_k holomorphic at p_k . Multiplying by e^{st} :

- $\Theta_k(s)e^{st}$ is holomorphic at p_k , so its Laurent expansion has no terms with negative exponent and contributes nothing to a_{-1} ;
- the term $A_{k,j}(s - p_k)^{-j}$ multiplied by the series of Step 1 gives $A_{k,j}e^{p_k t} \sum_{i \geq 0} \frac{t^i}{i!} (s - p_k)^{i-j}$, whose only term with exponent -1 is obtained for $i = j - 1$ and equals $A_{k,j}e^{p_k t} \frac{t^{j-1}}{(j-1)!}$.

Since the Laurent expansion is unique (Theorem 15.4), summing over j gives

$$\operatorname{Res}_{s=p_k} [R(s)e^{st}] = \sum_{j=1}^{m_k} A_{k,j} \frac{t^{j-1}}{(j-1)!} e^{p_k t}.$$

Step 3 — summing over the poles. Summing over k gives exactly the expression for $f(t)$ of Corollary 20.10. The case of simple poles can also be checked with the formula of Proposition 15.2(iii), applied to $p(s) = N(s)e^{st}$ and $q = D$: if $R = N/D$ with p_k a simple root of D and $N(p_k) \neq 0$, then $\operatorname{Res}_{s=p_k} [R(s)e^{st}] = \frac{N(p_k)e^{p_k t}}{D'(p_k)}$, which coincides with $A_k e^{p_k t}$ of Theorem 20.15. $\square$

Theorem 20.18: Bromwich inversion formula, integrable case. Let f be locally integrable with $\sigma_a < +\infty$, let $c > \sigma_a$ and suppose that

$$\xi \mapsto F(c + 2\pi i \xi) \quad \text{belongs to } L^1(\mathbb{R}).$$

Then, for almost every $t \in \mathbb{R}$,

$$f(t)u(t) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} F(s)e^{st} ds := \frac{1}{2\pi i} \int_{-\infty}^{+\infty} F(c + i\nu) e^{(c+i\nu)t} i d\nu,$$

an absolutely convergent integral; in particular the right-hand side is zero for almost every $t < 0$, and it does not depend on c .

Proof. **Step 1 — the damped signal lies in $L^1(\mathbb{R})$.** Set $g(t) = f(t)u(t)e^{-ct}$, extended by zero for $t < 0$. Since $c > \sigma_a$,

$$\int_{\mathbb{R}} |g(t)| dt = \int_0^{\infty} |f(t)| e^{-ct} dt < \infty,$$

hence $g \in L^1(\mathbb{R})$.

Step 2 — the Fourier transform of g is F on the vertical line. In the convention of Chapter 19 (Definition 19.1),

$$\hat{g}(\xi) = \int_{\mathbb{R}} g(t) e^{-2\pi i \xi t} dt = \int_0^{\infty} f(t) e^{-(c+2\pi i \xi)t} dt = F(c + 2\pi i \xi),$$

a legitimate identity because $\operatorname{Re}(c + 2\pi i \xi) = c > \sigma_a$ and the integral converges absolutely. The hypothesis of the theorem says exactly that $\hat{g} \in L^1(\mathbb{R})$.

Step 3 — Fourier inversion. Theorem 19.9, applicable because $g \in L^1$ and $\hat{g} \in L^1$, gives for almost every $t \in \mathbb{R}$

$$g(t) = \int_{\mathbb{R}} \hat{g}(\xi) e^{2\pi i \xi t} d\xi = \int_{\mathbb{R}} F(c + 2\pi i \xi) e^{2\pi i \xi t} d\xi.$$

Step 4 — back to f and change of variable. Multiplying by e^{ct} and using $g(t)e^{ct} = f(t)u(t)$,

$$f(t)u(t) = \int_{\mathbb{R}} F(c + 2\pi i \xi) e^{(c+2\pi i \xi)t} d\xi.$$

With the linear substitution $\nu = 2\pi \xi$, i.e. $d\xi = d\nu/(2\pi)$, and setting $s = c + i\nu$ (which traces the vertical line $\operatorname{Re}(s) = c$ from bottom to top, with $ds = i d\nu$), one obtains

$$f(t)u(t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} F(c + i\nu) e^{(c+i\nu)t} d\nu = \frac{1}{2\pi i} \int_{-\infty}^{+\infty} F(c + i\nu) e^{(c+i\nu)t} i d\nu,$$

which is the stated formula. Convergence is absolute because $|e^{(c+i\nu)t}| = e^{ct}$ is constant in ν and $\nu \mapsto F(c + i\nu)$ is integrable by hypothesis. Since for $t < 0$ the left-hand side is zero (by the definition of u), so is the right-hand side for almost every $t < 0$. Independence from c follows from the fact that the left-hand side does not contain c . $\square$

Remark 20.6: What we import: Bromwich inversion in the general case. Theorem 20.18 requires F to be integrable on the vertical line $\operatorname{Re}(s) = c$. This is a convenient but not necessary hypothesis: already for the step, $F(s) = 1/s$ is not integrable on any vertical line, because $|1/(c + i\nu)| \sim 1/|\nu|$. The inversion formula remains true, but must be understood as a principal value

$$f(t) = \frac{1}{2\pi i} \lim_{Y \rightarrow +\infty} \int_{c-iY}^{c+iY} F(s) e^{st} ds,$$

and in this general form it is here **imported**: we do not prove it. What exactly is missing: (a) the convergence of the symmetric limit, which does not follow from the mere convergence of the Laplace integral and requires a pointwise hypothesis on f (for instance bounded variation in a neighborhood of t , with value $\frac{f(t^+) + f(t^-)}{2}$ at jump points); (b) the fact that the value does not depend on c , which in the integrable case is immediate and in the general case requires a path-deformation argument; (c) the bound that allows the path to be closed with an arc to the left for $t > 0$ and to the right for $t < 0$, i.e. the analogue of Jordan's lemma for the kernel e^{st} , which for non-rational F depends on the behavior of F at infinity. The source is Doetsch, *Introduction to the Theory and Application of the Laplace Transformation*, Ch. 24 "The Complex Inversion Formula for the Absolutely Converging Laplace Transformation. The Fourier Transformation," pp. 148–161, Ch. 25 "Deformation of the Path of Integration of the Complex Inversion Integral," pp. 161–169, and Ch. 26 "The Evaluation of the Complex Inversion Integral by Means of the Calculus of Residues," pp. 169–178. In the rational case — the only one needed in this treatise and in Chapter 25 — nothing is imported: Theorem 20.17 is proved in full, and the sum of residues appearing there is exactly what the Bromwich path would produce.

Corollary 20.11: Final value for rational functions: the condition on the poles. Let F be rational and suppose that $G(s) = sF(s)$ is proper (degree of the numerator less than the degree of the denominator) and that all poles of G have strictly negative real part. Then $f = \mathcal{L}^{-1}\{F\}$ has a finite limit at infinity and

$$\lim_{t \rightarrow +\infty} f(t) = \lim_{s \rightarrow 0} sF(s) = G(0).$$

Proof. Step 1 — structure of F . From $F(s) = G(s)/s$ with G proper it follows that F is proper, and the poles of F are those of G (all with negative real part) plus, if $G(0) \neq 0$, a simple pole at $s = 0$; if $G(0) = 0$ the factor s cancels and F has no pole at the origin. In both cases the decomposition of Theorem 20.16 reads

$$F(s) = \frac{c}{s} + \sum_k \sum_j \frac{A_{k,j}}{(s - p_k)^j}, \quad c = \lim_{s \rightarrow 0} sF(s) = G(0),$$

where the sum extends only over poles p_k with $\operatorname{Re}(p_k) < 0$ (the coefficient c is that of Theorem 20.16 with $p = 0$, $m = 1$, and is zero if $G(0) = 0$).

Step 2 — the inverse transform. By Corollary 20.10,

$$f(t) = c + \sum_k \sum_j A_{k,j} \frac{t^{j-1}}{(j-1)!} e^{p_k t},$$

having used $e^{0 \cdot t} = 1$ for the term at the origin.

Step 3 — the transient terms vanish. Let p have $\operatorname{Re}(p) = -\gamma < 0$ and $j \geq 1$. Then $|t^{j-1} e^{pt}| = t^{j-1} e^{-\gamma t}$, and by Lemma 20.1(ii) with $n = j - 1$ and $\varepsilon = \gamma/2$ (for $j \geq 2$; for $j = 1$

this is immediate)

$$t^{j-1}e^{-\gamma t} \leq \left(\frac{2(j-1)}{e\gamma}\right)^{j-1} e^{-\gamma t/2} \xrightarrow{t \rightarrow +\infty} 0.$$

Since the sum is finite, $f(t) \rightarrow c$.

Step 4 — consistency with the general theorem. The limit exists finite, hence Theorem 20.13 applies and gives $\lim_{s \rightarrow 0^+} sF(s) = c$; and $\lim_{s \rightarrow 0} sF(s) = G(0) = c$ because G , having no pole at 0, is continuous there. $\square$

20.8. Laplace and Fourier: the restriction to the imaginary axis

Remark 20.1 states the link in one line: setting $s = i\omega$ gives the Fourier transform. This section states under which conditions that operation is legitimate, and what happens when it is not.

Theorem 20.19: The Fourier transform is the restriction to the imaginary axis.

Let $f : [0, \infty) \rightarrow \mathbb{C}$ be locally integrable and suppose $f \in L^1(0, \infty)$, i.e. $\int_0^\infty |f(t)|dt < \infty$ (a condition equivalent to absolute convergence at $s = 0$, and implied by $\sigma_a(f) < 0$). Then:

- (i) the Laplace integral converges absolutely at every s with $\operatorname{Re}(s) \geq 0$, and F is continuous on the closed half-plane $\{\operatorname{Re}(s) \geq 0\}$ and holomorphic on the open set $\{\operatorname{Re}(s) > 0\}$;
- (ii) for every $\omega \in \mathbb{R}$ one has $F(i\omega) = \int_0^\infty f(t)e^{-i\omega t} dt$, i.e. the Fourier transform of f (extended by zero for $t < 0$) in the angular-frequency convention;
- (iii) in the convention of Chapter 19 (Definition 19.1), $\hat{f}(\xi) = F(2\pi i\xi)$ for every $\xi \in \mathbb{R}$.

Proof. Step 1 — absolute convergence on the closed half-plane. For $\sigma = \operatorname{Re}(s) \geq 0$ and $t \geq 0$ one has $e^{-\sigma t} \leq 1$, hence $|f(t)e^{-st}| = |f(t)|e^{-\sigma t} \leq |f(t)|$, integrable by hypothesis. The integral converges absolutely at every such s ; in particular $\sigma_a(f) \leq 0$ and, by Theorem 20.3, F is holomorphic on $\{\operatorname{Re}(s) > 0\}$.

Step 2 — continuity up to the boundary. Let $s_n \rightarrow s$ with $\operatorname{Re}(s_n) \geq 0$ and $\operatorname{Re}(s) \geq 0$. For every $t \geq 0$, $f(t)e^{-s_n t} \rightarrow f(t)e^{-st}$ (continuity of the exponential), and $|f(t)e^{-s_n t}| \leq |f(t)|$ by Step 1, an integrable bound independent of n . The dominated convergence theorem gives $F(s_n) \rightarrow F(s)$. Since the sequence was arbitrary, F is continuous on $\{\operatorname{Re}(s) \geq 0\}$.

Step 3 — (ii) and (iii). Setting $s = i\omega$ in the definition gives directly $F(i\omega) = \int_0^\infty f(t)e^{-i\omega t} dt$, an absolutely convergent integral by Step 1. Since f vanishes for $t < 0$, the integral over $[0, \infty)$ coincides with the integral over $\mathbb{R}$. In the convention of Chapter 19 the exponent is $-2\pi i\xi t$, hence

$$\hat{f}(\xi) = \int_{\mathbb{R}} f(t)e^{-2\pi i\xi t} dt = \int_0^\infty f(t)e^{-(2\pi i\xi)t} dt = F(2\pi i\xi),$$

which is (iii); (ii) is the same formula with $\omega = 2\pi\xi$. $\square$

Remark 20.7: The dictionary between the two conventions. Chapter 19 uses the variable ξ (frequency, cycles per unit time) and the exponent $-2\pi i\xi t$; the literature on systems uses ω (angular frequency, radians per unit time) and the exponent $-i\omega t$. The bridge is $\omega = 2\pi\xi$, and Theorem 20.19 crosses it as follows:

$$F(i\omega) = \hat{f}\left(\frac{\omega}{2\pi}\right), \quad \hat{f}(\xi) = F(2\pi i\xi).$$

Remark 19.1 of Chapter 19 contains the complete dictionary, with the $\sqrt{2\pi}$ factors of the other conventions in use. In the rest of this chapter, and in Chapter 25, one always writes $H(i\omega)$ and means the angular-frequency convention.

Remark 20.8: On the boundary the restriction may not exist. The hypothesis $f \in L^1(0, \infty)$ of Theorem 20.19 cannot be weakened to $\sigma_a = 0$. The unit step has $\sigma_a = 0$ and $\mathcal{L}\{u\}(s) = 1/s$ (Proposition 20.2): restricting to the imaginary axis would give $1/(i\omega)$, which blows up at $\omega = 0$ and is not a continuous function on $\mathbb{R}$; and indeed $u \notin L^1(0, \infty)$, so Proposition 19.1 does not apply and the Fourier transform of the step is not a function but a tempered distribution (Definition 19.7). The phenomenon is the same as in Proposition 19.10, where $\hat{1} = \delta$: as soon as the signal stops being integrable, the right object is no longer a function. For the delta, however, the two theories agree without reservation: Proposition 20.6 gives $\mathcal{L}\{\delta\} \equiv 1$ on all of $\mathbb{C}$, and Proposition 19.10 gives $\hat{\delta} = 1$ on all of $\mathbb{R}$; restricting the first to the imaginary axis gives the second.

Corollary 20.12: Poles to the left, BIBO-stable system. Let H be a proper rational function ($\deg$ numerator $<$ $\deg$ denominator) whose poles $p_1, \dots, p_r$ all satisfy $\operatorname{Re}(p_k) < 0$, and let $h = \mathcal{L}^{-1}\{H\}$ be the impulse response (Definition 20.2). Then:

- (i) $h \in L^1(0, \infty)$, and $\sigma_a(h) = \max_k \operatorname{Re}(p_k) < 0$;
- (ii) the system is BIBO stable: for every measurable, bounded causal input v with $\|v\|_\infty = \sup_{t \geq 0} |v(t)| < \infty$, the output $y = h * v$ satisfies $\|y\|_\infty \leq \|h\|_1 \|v\|_\infty$;
- (iii) H is defined and continuous on the closed half-plane $\operatorname{Re}(s) \geq 0$, and $\omega \mapsto H(i\omega)$ is the frequency response of the system.

Proof. Step 1 — (i). By Corollary 20.10, $h(t) = \sum_{k,j} A_{k,j} \frac{t^{j-1}}{(j-1)!} e^{p_k t}$. Setting $\gamma_k = -\operatorname{Re}(p_k) > 0$, each term satisfies

$$\int_0^\infty \left| A_{k,j} \frac{t^{j-1}}{(j-1)!} e^{p_k t} \right| dt = \frac{|A_{k,j}|}{(j-1)!} \int_0^\infty t^{j-1} e^{-\gamma_k t} dt = \frac{|A_{k,j}|}{(j-1)!} \cdot \frac{(j-1)!}{\gamma_k^j} = \frac{|A_{k,j}|}{\gamma_k^j} < \infty,$$

where the value of the integral is $\mathcal{L}\{t^{j-1}\}(\gamma_k) = (j-1)!/\gamma_k^j$ (Corollary 20.6). The sum is finite, hence $h \in L^1(0, \infty)$ by the triangle inequality. The abscissa is $\max_k \operatorname{Re}(p_k)$ by Corollary 20.10, and is negative by hypothesis.

Step 2 — (ii). For every $t \geq 0$,

$$|y(t)| = \left| \int_0^t h(\tau) v(t-\tau) d\tau \right| \leq \int_0^t |h(\tau)| |v(t-\tau)| d\tau \leq \|v\|_\infty \int_0^t |h(\tau)| d\tau \leq \|v\|_\infty \|h\|_1,$$

finite by Step 1. Taking the supremum over $t \geq 0$ gives the bound. In particular a bounded input produces a bounded output.

Step 3 — (iii). From Step 1, $h \in L^1(0, \infty)$: Theorem 20.19 applies to h and gives the continuity of $H = \mathcal{L}\{h\}$ on the closed half-plane and the identification of $H(i\omega)$ with the Fourier transform of h , which is by definition the frequency response. $\square$

Remark 20.9: What is not proved here about BIBO stability. Definition 20.2, inherited from Volume II, states an “if and only if.” Corollary 20.12 proves the sufficient direction of it, and only for proper rational transfer functions. The two missing pieces — that the condition $h \in L^1$ is also necessary for BIBO stability, and that for a rational H a pole with $\operatorname{Re}(p) \geq 0$ always produces an unbounded output from a bounded input — belong to Chapter 24, where LTI systems are treated in their own right; the algebraic criterion that decides the sign of the real parts of the poles without computing them is in Chapter 25. The missing direction is not imported: it is only deferred to a chapter of this same volume, where it is proved.

20.9. Exercises inherited from Volume II

The exercises that follow come from Volume II, Chapter 4, and concern the topics of this chapter. They are reproduced in full, with their solutions, which follow in the same order as the exercises.

Exercises

Warm-up 4.2. Using the table of Laplace transforms in Appendix C (or the definition), compute the Laplace transform of $f(t) = e^{-2t}u(t)$.

Exercise 20.1. Compute $\mathcal{L}\{t \cdot u(t)\}$ (the unit ramp) using the integration property applied to the step $u(t)$.

Exercise 20.2. Verify, using the final value theorem, the asymptotic value $y(t) \rightarrow 1$ for the step response $Y(s) = 1/(s(1 + \tau s))$ of the Worked Example of this chapter.

Solutions

Solution, Warm-up 4.2. From the table (or from $\mathcal{L}\{e^{-at}\} = 1/(s+a)$ with $a = 2$): $\mathcal{L}\{e^{-2t}u(t)\} = \frac{1}{s+2}$.

Solution. The unit step $u(t)$ has $\mathcal{L}\{u(t)\} = \int_0^\infty e^{-st} dt = 1/s$ (for $\text{Re}(s) > 0$). The ramp $r(t) = t \cdot u(t)$ satisfies $r(t) = \int_0^t u(\tau) d\tau$ (the integral of a unit step from 0 to t equals exactly t). By the integration property (Theorem 20.1(3)):

$$\mathcal{L}\{t \cdot u(t)\} = \mathcal{L}\left\{\int_0^t u(\tau) d\tau\right\} = \frac{\mathcal{L}\{u(t)\}}{s} = \frac{1}{s^2}.$$

Solution. The final value theorem states $\lim_{t \rightarrow \infty} y(t) = \lim_{s \rightarrow 0} sY(s)$, provided the poles of $sY(s)$ lie in the half-plane $\text{Re}(s) < 0$ (here: the only pole of $sY(s) = 1/(1 + \tau s)$ is $s = -1/\tau < 0$, and the condition is satisfied). We compute:

$$\lim_{s \rightarrow 0} sY(s) = \lim_{s \rightarrow 0} s \cdot \frac{1}{s(1 + \tau s)} = \lim_{s \rightarrow 0} \frac{1}{1 + \tau s} = 1.$$

The theorem correctly predicts $y(t) \rightarrow 1$, in agreement with the explicit solution $y(t) = 1 - e^{-t/\tau} \rightarrow 1$ found in the Worked Example: the final value theorem allows one to read the asymptotic value directly from $Y(s)$, without having to invert the transform — useful in practice for quickly checking the steady-state error of a control loop.

Inherited quiz

The items that follow come from the quiz of Volume II, Chapter 4, and are renumbered here.

1. The Laplace transform generalizes Fourier in order to handle
 - A) only periodic signals
 - B) non-integrable causal signals
 - C) only discrete signals
 - D) purely complex signals

BEST PRACTICE

Answer key.

1-B: Laplace converges for signals that grow at most exponentially, where Fourier does not converge.

Remark 20.10: The two inherited solutions, revisited in light of the chapter. The first solution uses Theorem 20.1(3) without declaring the region: the version with hypotheses is Theorem 20.9, which gives $\mathcal{L}\{t u(t)\} = 1/s^2$ for $\operatorname{Re}(s) > \max\{0, 0\} = 0$, in agreement with Corollary 20.6 with $n = 1$. The second solution invokes the condition “poles of $sY(s)$ in the left half-plane”: that condition is now a proved statement, Corollary 20.11, and its hypotheses are verified because $sY(s) = \frac{1}{1+\tau s}$ is proper and has the single pole $-1/\tau < 0$. The value $\frac{1}{1+\tau s} \rightarrow 1$ as $s \rightarrow 0$ is the $G(0)$ of the corollary.

20.10. Assigned exercises

These are *new* exercises, distinct both from the inherited ones (Section 20.9) and from those worked in Section 20.11. The answers are in the Teacher’s Key (Section 20.13).

Exercise 20.3: Regions of convergence, abscissas, and boundary. *Goal:* become used to writing the ROC next to every transform, and recognize the cases in which the boundary line does or does not belong to the region. *Estimated time:* 35 minutes. *Type:* symbolic with numerical check.

- (a) Compute F , σ_a and the ROC (stating whether the boundary belongs to it) for the four causal signals

$$e^{3t} \cos(4t), \quad t^2 e^{-t}, \quad u(t) - u(t-2), \quad t^{-1/2}.$$

- (b) Verify numerically, by quadrature, that $\mathcal{L}\{e^{3t} \cos 4t\}(5) = 0.1$ and $\mathcal{L}\{t^2 e^{-t}\}(1) = 0.25$, and recover the same values from the closed-form formulas.
- (c) Exhibit two signals f, g for which $\sigma_a(f+g) < \max\{\sigma_a(f), \sigma_a(g)\}$, and explain why Theorem 20.4 states an inequality and not an equality.
- (d) The step has $\sigma_a = 0$ and the ROC does *not* contain the line $\operatorname{Re}(s) = 0$; the window $u(t) - u(t-2)$ has ROC equal to all of $\mathbb{C}$. Explain the difference in one sentence referring to the behavior of the two functions as $t \rightarrow +\infty$.

Exercise 20.4: Initial value and final value: when they apply. *Goal:* decide, before computing, whether a theorem applies; and recognize the wrong number one obtains by applying it anyway. *Estimated time:* 45 minutes. *Type:* proof-based and numerical. Consider

$$F_1(s) = \frac{2s+1}{s(s^2+3s+2)}, \quad F_2(s) = \frac{5}{s(s^2+4)}, \quad F_3(s) = \frac{1}{(s-2)(s+3)}, \quad F_4(s) = \frac{s}{s+4}.$$

- (a) For each, state whether Theorem 20.12 and Corollary 20.11 are applicable, justifying by the position of the poles and by the ROC.
- (b) Invert F_1 , F_2 , F_3 using Theorem 20.15 or Theorem 20.16.
- (c) Compute $\lim_{s \rightarrow \infty} sF_i(s)$ and $\lim_{s \rightarrow 0} sF_i(s)$ and compare them with $f_i(0^+)$ and with $\lim_{t \rightarrow \infty} f_i(t)$, flagging the cases in which the comparison fails and why.
- (d) Prove that F_4 is not the Laplace transform of any locally integrable function, and find the measure of which it is the transform.

Exercise 20.5: A differential equation, a convolution, two paths. *Goal:* use the transform to solve an initial value problem and check the result by a route that does not go through Laplace. *Estimated time:* 45 minutes. *Type:* symbolic computation with independent check.

- Solve $y'' + 4y' + 3y = e^{-2t}$ with $y(0) = 0$, $y'(0) = 1$, using Corollary 20.4, and check the solution by substituting it back into the equation and into the initial conditions.
- Apply Corollary 20.11 to $Y(s)$ and compare with the limit of the solution found.
- Compute $\mathcal{L}^{-1}\left\{\frac{1}{s(s^2+1)}\right\}$ in two independent ways: with partial fractions and with Theorem 20.10 applied to $\frac{1}{s}$ and $\frac{1}{s^2+1}$.
- Evaluate the result of (c) at $t = 1$ to seven decimal places and check it with a numerical quadrature of the convolution.

20.11. Worked exercises

Exercise 20.6: A double pole at the origin, and the final value that is not there. *Type:* inversion with multiple poles, with two independent checks. Invert

$$F(s) = \frac{s+3}{s^2(s+1)},$$

state the region of convergence, and discuss whether the initial value and final value theorems apply.

Solution. Strategy. The denominator has a double pole at 0 and a simple one at -1 : apply Theorem 20.16, invert term by term with Corollary 20.10, and check the result by recomputing the transform.

Step 1 — the coefficients of the double pole. Here $p_1 = 0$ with $m_1 = 2$, and $g_1(s) = s^2 F(s) = \frac{s+3}{s+1}$, holomorphic in a neighborhood of 0. By Theorem 20.16:

$$A_{1,2} = \frac{1}{0!} g_1(0) = \frac{3}{1} = 3, \quad A_{1,1} = \frac{1}{1!} g_1'(0).$$

Compute $g_1'(s) = \frac{(s+1) - (s+3)}{(s+1)^2} = \frac{-2}{(s+1)^2}$, hence $g_1'(0) = -2$ and $A_{1,1} = -2$.

Step 2 — the simple pole. With $p_2 = -1$, $m_2 = 1$:

$$A_{2,1} = \lim_{s \rightarrow -1} (s+1)F(s) = \lim_{s \rightarrow -1} \frac{s+3}{s^2} = \frac{2}{1} = 2.$$

Step 3 — checking the decomposition. One checks the identity

$$-\frac{2}{s} + \frac{3}{s^2} + \frac{2}{s+1} = \frac{-2s(s+1) + 3(s+1) + 2s^2}{s^2(s+1)} = \frac{-2s^2 - 2s + 3s + 3 + 2s^2}{s^2(s+1)} = \frac{s+3}{s^2(s+1)}. \checkmark$$

Step 4 — inversion. By Corollary 20.10, with $\mathcal{L}^{-1}\{1/s\} = 1$, $\mathcal{L}^{-1}\{1/s^2\} = t$ and $\mathcal{L}^{-1}\{1/(s+1)\} = e^{-t}$,

$$\boxed{f(t) = -2 + 3t + 2e^{-t}}, \quad t \geq 0,$$

with region of convergence $\operatorname{Re}(s) > \max\{0, -1\} = 0$.

Independent check 1: recomputing the transform. By linearity and the rows of Table 20.1,

$$\mathcal{L}\{-2 + 3t + 2e^{-t}\}(s) = -\frac{2}{s} + \frac{3}{s^2} + \frac{2}{s+1} = \frac{s+3}{s^2(s+1)}. \checkmark$$

Independent check 2: numerical quadrature. Composite Simpson with 400,000 subintervals on $[0, 60]$: $\int_0^\infty f(t)e^{-2t}dt = 0.4166667$ against $F(2) = \frac{5}{4 \cdot 3} = \frac{5}{12} = 0.4166667$; and $\int_0^\infty f(t)e^{-t}dt = 2.0000000$ against $F(1) = \frac{4}{1 \cdot 2} = 2$. $\checkmark$ Moreover $f(2) = -2 + 6 + 2e^{-2} = 4 + 0.2706706 = 4.2706706$, which agrees with the value computed in double precision. $\checkmark$

Step 5 — the two theorems. *Initial value:* f is of class C^1 on $[0, \infty)$ with $f'(t) = 3 - 2e^{-t}$, and $\int_0^\infty |f'(t)|e^{-t}dt < \infty$: Theorem 20.12 applies and gives $\lim_{\operatorname{Re}(s) \rightarrow \infty} sF(s) = \lim_{s \rightarrow \infty} \frac{s+3}{s(s+1)} = 0 = f(0^+) = -2 + 0 + 2$. $\checkmark$ *Final value:* it does not apply, because $f(t) = 3t - 2 + 2e^{-t} \rightarrow +\infty$ and the limit does not exist finite; in the s -plane the symptom is that $sF(s) = \frac{s+3}{s(s+1)}$ still has a pole at $s = 0$, which violates the hypothesis of Corollary 20.11. This is case (c) of Example 20.4.

Interpretation. A double pole at the origin is, in the time domain, a ramp: the factor $1/s$ integrates once (step $\rightarrow$ constant), twice (constant $\rightarrow$ ramp). The coefficient $A_{1,2} = 3$ is the slope of the ramp, and $A_{1,1} = -2$ its intercept.

Typical errors. (1) Looking for the decomposition in the form $\frac{A}{s^2} + \frac{B}{s+1}$, forgetting the term $\frac{A_{1,1}}{s}$: a pole of order 2 requires *two* coefficients. (2) Computing $A_{1,1}$ as $\lim_{s \rightarrow 0} sF(s)$, which here is infinite: the formula of Theorem 20.16 requires first multiplying by $s^m = s^2$ and then differentiating $m - j = 1$ time. (3) Applying the final value theorem, obtaining ∞ , and concluding that “the system diverges according to the theorem”: the theorem says nothing, because its hypotheses do not hold.

Extension. With $F(s) = \frac{s+3}{s^3(s+1)}$ the pole at the origin is triple and three coefficients appear; the dominant term becomes $\frac{3t^2}{2}$.

Exercise 20.7: Step response of a second-order system. *Type:* initial value problem solved with the transform, with numerical check by integrating the equation. Solve

$$y'' + 2y' + 5y = u(t), \quad y(0) = 0, \quad y'(0) = 0,$$

and check the initial value and the final value.

Solution. Strategy. Transform the equation with Corollary 20.4, solve algebraically for $Y(s)$, decompose and invert by recognizing the “damped sine and cosine” rows of Table 20.1.

Step 1 — transforming. With $y(0) = y'(0) = 0$, Corollary 20.4 gives $\mathcal{L}\{y'\} = sY$ and $\mathcal{L}\{y''\} = s^2Y$; with $\mathcal{L}\{u\} = 1/s$ (Proposition 20.2),

$$(s^2 + 2s + 5)Y(s) = \frac{1}{s} \quad \implies \quad Y(s) = \frac{1}{s(s^2 + 2s + 5)}.$$

Step 2 — the poles. $s^2 + 2s + 5 = (s+1)^2 + 4$ vanishes for $s+1 = \pm 2i$, i.e. $s = -1 \pm 2i$: two simple poles with real part $-1 < 0$, plus the simple pole $s = 0$. The region of convergence of Y is $\operatorname{Re}(s) > 0$.

Step 3 — partial fractions. Seek $Y(s) = \frac{A}{s} + \frac{Bs+C}{(s+1)^2+4}$. Multiplying by the common denominator, $1 = A(s^2 + 2s + 5) + (Bs + C)s$; equating coefficients:

$$s^0: 5A = 1 \Rightarrow A = \frac{1}{5}; \quad s^2: A + B = 0 \Rightarrow B = -\frac{1}{5}; \quad s^1: 2A + C = 0 \Rightarrow C = -\frac{2}{5}.$$

Hence

$$Y(s) = \frac{1/5}{s} - \frac{1}{5} \cdot \frac{s+2}{(s+1)^2+4}.$$

Step 4 — recognizing the rows of the table. Write $s + 2 = (s + 1) + 1$ and split:

$$\frac{s + 2}{(s + 1)^2 + 4} = \frac{s + 1}{(s + 1)^2 + 4} + \frac{1}{2} \cdot \frac{2}{(s + 1)^2 + 4},$$

where the first fraction is the transform of $e^{-t} \cos 2t$ and the second that of $e^{-t} \sin 2t$ (Corollary 20.8 with $c = 1$, $\omega = 2$). Hence

$$y(t) = \frac{1}{5} - \frac{1}{5}e^{-t} \cos 2t - \frac{1}{10}e^{-t} \sin 2t, \quad t \geq 0.$$

Step 5 — checking the initial conditions. $y(0) = \frac{1}{5} - \frac{1}{5} - 0 = 0 \checkmark$. Differentiating, $y'(t) = \frac{1}{5}e^{-t} \cos 2t + \frac{2}{5}e^{-t} \sin 2t + \frac{1}{10}e^{-t} \sin 2t - \frac{1}{5}e^{-t} \cos 2t$; at $t = 0$ the sin terms vanish and the two cos terms cancel, hence $y'(0) = 0 \checkmark$.

Independent check 1: numerical integration of the equation. Rewriting as a first-order system $y' = v$, $v' = 1 - 2v - 5y$ with $y(0) = v(0) = 0$ and integrating with fourth-order Runge–Kutta and step $h = T/200,000$:

t	closed form	RK4
1	0.1971672	0.1971672
2	0.2279344	0.2279344
5	0.2014973	0.2014973

✓

Independent check 2: recomputing the transform. Simpson quadrature of $\int_0^\infty y(t)e^{-2t}dt$ on $[0, 60]$: 0.0384615, against $Y(2) = \frac{1}{2(4+4+5)} = \frac{1}{26} = 0.0384615$. ✓

Step 6 — the two theorems. *Initial value:* $sY(s) = \frac{1}{s^2+2s+5} \rightarrow 0$ as $\text{Re}(s) \rightarrow +\infty$, and $y(0^+) = 0 \checkmark$. *Final value:* $G(s) = sY(s) = \frac{1}{s^2+2s+5}$ is proper and has poles $-1 \pm 2i$, both with negative real part: Corollary 20.11 applies and gives $\lim_{t \rightarrow \infty} y(t) = G(0) = \frac{1}{5} = 0.2$. The closed form confirms this, because $e^{-t} \rightarrow 0$. ✓

Interpretation. The system is second order with natural frequency $\omega_n = \sqrt{5}$ and damping $\zeta = 1/\sqrt{5}$, because $s^2 + 2s + 5 = s^2 + 2\zeta\omega_n s + \omega_n^2$ with $2\zeta\omega_n = 2$ and $\omega_n^2 = 5$; the real part -1 of the poles is the decay rate of the transient and the imaginary part 2 is the frequency of the oscillations. The static gain $1/5$ is $H(0)$.

Typical errors. (1) Forgetting the terms $-sy(0) - y'(0)$ of Corollary 20.4 when the initial conditions are not zero. (2) Inverting $\frac{s+2}{(s+1)^2+4}$ as $e^{-t} \cos 2t$ without correcting the numerator: the numerator must be $s + 1$ for the cosine, and the remaining part must be read as a sine. (3) Writing $\omega = 4$ by reading off the constant term 5 instead of completing the square.

Extension. Changing the forcing term to δ gives $Y(s) = \frac{1}{(s+1)^2+4}$ and $y(t) = \frac{1}{2}e^{-t} \sin 2t$: the impulse response is the derivative of the step response, as predicted by Theorem 20.8.

Exercise 20.8: A complex double pole, by convolution. *Type:* inversion by convolution, with three independent checks. Compute

$$\mathcal{L}^{-1} \left\{ \frac{1}{(s^2 + 1)^2} \right\}.$$

Solution. Strategy. The function is the *square* of $\frac{1}{s^2+1}$: by Theorem 20.10 its inverse transform is the convolution of $\sin t$ with itself. The result is then checked by the multiplication-by- t rule, which is a completely different route.

Step 1 — the convolution. By Proposition 20.4, $\mathcal{L}\{\sin t\} = \frac{1}{s^2+1}$ with $\sigma_a = 0$. Theorem 20.10 with $\sigma > 0$ then gives

$$\mathcal{L}^{-1}\left\{\frac{1}{(s^2+1)^2}\right\}(t) = (\sin * \sin)(t) = \int_0^t \sin \tau \sin(t-\tau) d\tau.$$

Step 2 — computing the integral. From the Werner formula $\sin A \sin B = \frac{1}{2}[\cos(A-B) - \cos(A+B)]$ with $A = \tau$ and $B = t - \tau$:

$$\sin \tau \sin(t-\tau) = \frac{1}{2}[\cos(2\tau-t) - \cos t].$$

Integrating in τ from 0 to t , with t fixed:

$$\int_0^t \cos(2\tau-t) d\tau = \left[\frac{\sin(2\tau-t)}{2}\right]_0^t = \frac{\sin t - \sin(-t)}{2} = \sin t, \quad \int_0^t \cos t d\tau = t \cos t.$$

Hence

$$(\sin * \sin)(t) = \frac{\sin t - t \cos t}{2}.$$

Independent check 1: the multiplication-by- t rule. By Corollary 20.5 applied to $\cos t$,

$$\mathcal{L}\{t \cos t\}(s) = -\frac{d}{ds} \frac{s}{s^2+1} = -\frac{(s^2+1) - s \cdot 2s}{(s^2+1)^2} = \frac{s^2-1}{(s^2+1)^2}.$$

Since $\mathcal{L}\{\sin t\} = \frac{1}{s^2+1} = \frac{s^2+1}{(s^2+1)^2}$, linearity gives

$$\mathcal{L}\{\sin t - t \cos t\}(s) = \frac{(s^2+1) - (s^2-1)}{(s^2+1)^2} = \frac{2}{(s^2+1)^2},$$

that is, $\mathcal{L}\left\{\frac{\sin t - t \cos t}{2}\right\} = \frac{1}{(s^2+1)^2}$. ✓

Independent check 2: quadrature of the convolution. Composite Simpson with 20,000 subintervals on $[0, t]$:

t	$(\sin t - t \cos t)/2$	numerical convolution
1	0.1505843	0.1505843
3	1.5555487	1.5555487
5	-1.1886176	-1.1886176

✓

Independent check 3: the transform, by quadrature. Simpson with 600,000 subintervals on $[0, 120]$ of $\int_0^\infty \frac{\sin t - t \cos t}{2} e^{-2t} dt$ gives 0.0400000, against $\frac{1}{(4+1)^2} = \frac{1}{25} = 0.04$. ✓

Interpretation. The factor t in front of $\cos t$ is the signature of the double pole: a pole of order m produces, in the time domain, a term t^{m-1} multiplied by the exponential, exactly as stated by Corollary 20.10. Here the poles are $\pm i$, both double: the term $t \cos t$ grows linearly, and this is *resonance* — a system $y'' + y = \sin t$ excited at its own natural frequency.

Typical errors. (1) Writing $\mathcal{L}^{-1}\{FG\} = \mathcal{L}^{-1}\{F\} \cdot \mathcal{L}^{-1}\{G\}$: the product in s is the *convolution* in t , not the product. (2) Using $\sin \tau \sin(t-\tau) = \sin^2 \tau \sin^2(t-\tau)$ or other invented identities: the Werner formula is the only one that linearizes. (3) Forgetting that in the convolution t is *constant* during the integration in τ , and integrating $\cos t$ as if it depended on τ .

Extension. The same method gives $\mathcal{L}^{-1}\left\{\frac{s}{(s^2+1)^2}\right\} = \frac{t \sin t}{2}$: this is checked with $\mathcal{L}\{t \sin t\} = -\frac{d}{ds} \frac{1}{s^2+1} = \frac{2s}{(s^2+1)^2}$. ✓

20.12. Self-assessment quiz

1. (Definition) The *absolute abscissa of convergence* σ_a of a causal signal is
 - A) the smallest σ for which the Laplace integral converges
 - B) the infimum of the real parts of the points at which the integral converges absolutely
 - C) the real part of the rightmost pole of F
 - D) always equal to σ_c
2. (Hypothesis) In Theorem 20.13 the essential hypothesis is
 - A) that F be rational
 - B) that $\lim_{t \rightarrow +\infty} f(t)$ exist finite
 - C) that $\sigma_a < 0$
 - D) that f be differentiable with continuous derivative
3. (Symbolic computation) $\mathcal{L}\{t^2 e^{-3t}\}(s)$ equals
 - A) $\frac{2}{(s+3)^3}$
 - B) $\frac{1}{(s+3)^3}$
 - C) $\frac{2}{s^3+3}$
 - D) $\frac{6}{(s+3)^4}$
4. (Numerical computation) $\mathcal{L}\{e^{-2t} \sin(3t)\}(1)$ equals, to seven decimal places,
 - A) 0.3000000
 - B) 0.1666667
 - C) 0.1176471
 - D) 0.0833333
5. (Proof step) In Step 4 of the proof of Theorem 20.3 the factor t^2 appearing in the bound is absorbed
 - A) by the dominated convergence theorem
 - B) by the inequality $t^2 \leq \left(\frac{2}{e\delta}\right)^2 e^{\delta t}$ and the margin δ between σ and some $\sigma_2 > \sigma_a$
 - C) by Fubini's theorem
 - D) by the boundedness of the function φ
6. (Error diagnosis) A student applies the final value theorem to $F(s) = \frac{1}{s-1}$, computes $\lim_{s \rightarrow 0} sF(s) = 0$ and concludes that $f(t) \rightarrow 0$. The error is
 - A) the computation of the limit, which equals -1
 - B) that $s = 0$ does not belong to the region of convergence $\operatorname{Re}(s) > 1$ and that $f(t) = e^t$ has no finite limit, so the hypothesis of the theorem fails
 - C) that F is not rational
 - D) that the factor s in front of F is missing
7. (Transfer) The region of convergence of the window $u(t) - u(t-2)$ is
 - A) $\operatorname{Re}(s) > 0$
 - B) all of $\mathbb{C}$
 - C) $\operatorname{Re}(s) > -2$
 - D) $\operatorname{Re}(s) \geq 0$
8. (Source and metacognition) The result that the region of convergence of a Laplace integral is a half-plane is found in
 - A) Doetsch, *Introduction to the Theory and Application of the Laplace Transformation*, Ch. 3 “The Half-Plane of Convergence,” pp. 13–18
 - B) Doetsch, Ch. 10 “The Mapping of the Convolution,” pp. 44–55
 - C) Oppenheim–Willsky, *Signals and Systems*, Ch. 4 “The Continuous-Time Fourier Transform”
 - D) Doetsch, Ch. 26 “The Evaluation of the Complex Inversion Integral by Means of the Calculus of Residues,” pp. 169–178

20.13. Teacher's key

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 1–4).

1) **B.** *Rationale:* this is Definition 20.4: σ_a is an infimum, not a minimum, and concerns *absolute* convergence. *Distractors:* A confuses the two kinds of convergence and moreover speaks of a minimum, which may not be attained (Proposition 20.2: at $\sigma = 0$ the integral does not converge); C is true for rational functions (Corollary 20.10) but false in general, because F may have no poles (Proposition 20.5(ii)); D is disproved by Proposition 20.1. *Diagnosed error:* confusing ordinary and absolute convergence, and a minimum with an infimum. *Source:* Doetsch, Ch. 3, pp. 13–18. *Prerequisite:* infimum of a set of reals. *Remedy:* redo Example 20.1 and state, for each of the two signals, whether σ_a is a minimum.

2) **B.** *Rationale:* the statement of Theorem 20.13 only requires the limit of f to exist finite; everything else (the abscissa $\sigma_a \leq 0$) is a consequence of it, proved in Step 1. *Distractors:* A is the condition of Corollary 20.11, which is sufficient but not necessary; C is stronger than necessary ($f = \sin t$ has $\sigma_a = 0$ and no limit, but $f(t) = 1$ has $\sigma_a = 0$ and limit 1); D is irrelevant, the theorem uses no derivatives. *Diagnosed error:* mistaking a convenient sufficient condition for the hypothesis of the theorem. *Source:* Theorem 20.13 and Remark 20.5; Oppenheim–Willsky, Ch. 9. *Prerequisite:* definition of limit at infinity. *Remedy:* reread the three cases of Example 20.4.

3) **A.** *Rationale:* by Corollary 20.7 with $n = 2$ and $c = -3$, $\mathcal{L}\{t^2 e^{-3t}\} = \frac{2!}{(s+3)^3} = \frac{2}{(s+3)^3}$, for $\operatorname{Re}(s) > -3$. *Distractors:* B forgets the factorial $2! = 2$; C applies the shift to the wrong variable (one shifts s , not s^3); D uses $3!$ and exponent 4, i.e. answers for t^3 . *Diagnosed error:* applying the frequency shift without substituting $s \mapsto s - c$ throughout the denominator. *Source:* Corollary 20.7; Table 20.1. *Prerequisite:* Corollary 20.6. *Remedy:* derive $\mathcal{L}\{t^3 e^{2t}\} = 6/(s-2)^4$ and check it with the third derivative of $1/(s-2)$.

4) **B.** *Rationale:* by Corollary 20.8 with $c = 2$, $\omega = 3$, $s = 1$: $\frac{3}{(1+2)^2+9} = \frac{3}{18} = 0.1666667$; numerical quadrature on $[0, 60]$ gives the same value. *Distractors:* A is $\mathcal{L}\{\sin 3t\}(1) = 3/10$, i.e. the damping has been forgotten; C is $\mathcal{L}\{\cos 2t\}(0.5)$, a value from another exercise; D is $\frac{3}{36}$, i.e. one wrote $(1+2)^2 + 27$ or doubled the denominator. *Diagnosed error:* not applying the frequency shift to the denominator. *Source:* Corollary 20.8, including the numerical check. *Prerequisite:* Proposition 20.4. *Remedy:* compute $\mathcal{L}\{e^{-2t} \cos 3t\}(1)$ and observe that it too equals $\frac{3}{18}$, because $s + c = 3 = \omega$.

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 5–8).

5) **B.** *Rationale:* Step 4 uses Lemma 20.1(ii) with $n = 2$ and $\varepsilon = \delta$ to write $t^2 e^{-(\sigma-\delta)t} \leq \left(\frac{2}{e\delta}\right)^2 e^{-(\sigma-2\delta)t}$, and $\sigma - 2\delta = \sigma_2 > \sigma_a$: the margin δ is used twice, to keep $s + h$ in the half-plane and to absorb t^2 . *Distractors:* A names a tool that is not needed here, because the estimate is explicit and does not go through a limit under the integral sign; C confuses this with the proof of Theorem 20.10; D is the ingredient of Corollary 20.3, not of Theorem 20.3. *Diagnosed error:* not being able to say where each factor in an estimate comes from. *Source:* Theorem 20.3, Steps 2 and 4; Doetsch, Ch. 6 “The Laplace Transform as an Analytic Function,” pp. 26–30. *Prerequisite:* Lemma 20.1. *Remedy:* redo Step 4 with δ replaced by $\delta/2$ and see which constant changes.

6) **B.** *Rationale:* this is Example 20.4(b): the ROC is $\operatorname{Re}(s) > 1$, the point $s = 0$ lies outside it, and $f(t) = e^t$ has no finite limit; evaluating $sF(s)$ near 0 means using the analytic continuation of F outside the region where it represents the signal. *Distractors:* A is false, the limit really is 0 ($s/(s-1) \rightarrow 0$); C is false, F is rational; D is false, the factor s is there. *Diagnosed error:* using a formula outside its region of validity, i.e. forgetting

the ROC. *Source:* Example 20.4; Oppenheim–Willsky, Ch. 9. *Prerequisite:* Corollary 20.1. *Remedy:* repeat the error with $F(s) = \frac{1}{s-a}$ for $a = 0.1$ and $a = -0.1$ and state in which of the two cases the conclusion is correct.

7) **B.** *Rationale:* the window vanishes outside a compact set, hence $\int_0^2 e^{-\sigma t} dt$ is finite for every $\sigma \in \mathbb{R}$: the ROC is the whole plane and the transform $(1 - e^{-2s})/s$ is entire (Proposition 20.5(ii)). *Distractors:* A is the ROC of the step u taken alone, and forgets that the difference vanishes after $t = 2$; C is the ROC one would get if the delay appeared as an exponential in time, i.e. confuses $u(t-2)$ with e^{-2t} ; D adds the boundary to the ROC of the step, which is instead excluded. *Diagnosed error:* deducing the ROC from the form of the transform instead of from the behavior of the signal as $t \rightarrow +\infty$. *Source:* Proposition 20.5; Table 20.1. *Prerequisite:* Definition 20.3. *Remedy:* compute the ROC of $u(t-1) - u(t-3)$ and check that it is still all of $\mathbb{C}$.

8) **A.** *Rationale:* the Doetsch chapter titled “The Half-Plane of Convergence” (pp. 13–18) is exactly the source of the result, proved here as Theorem 20.2. *Distractors:* B is the chapter on convolution, which proves Theorem 20.10; C concerns the Fourier transform and not the region of convergence of Laplace; D is the chapter on inversion by residues, cited in Remark 20.6. *Diagnosed error:* citing “the book” instead of the chapter, and being unable to associate a result with its bibliographic location. *Source:* the *Sources and bibliography* environment at the end of the chapter, entry [1]. *Prerequisite:* none. *Remedy:* associate each of Theorems 20.8, 20.9 and 20.10 with the Doetsch chapter that treats it, using entry [1] of the Sources.

BEST PRACTICE

Assigned exercise 20.3 — answers.

(a) $e^{3t} \cos(4t)$: by Corollary 20.8 with $c = -3$, $F(s) = \frac{s-3}{(s-3)^2+16}$, $\sigma_a = 3$, ROC $\operatorname{Re}(s) > 3$, boundary *excluded* (at $\sigma = 3$ the integral $\int_0^\infty |\cos 4t| dt$ diverges as in Proposition 20.4, Step 3). — $t^2 e^{-t}$: by Corollary 20.7, $F(s) = \frac{2}{(s+1)^3}$, $\sigma_a = -1$, ROC $\operatorname{Re}(s) > -1$, boundary *excluded* (at $\sigma = -1$ what remains is $\int_0^\infty t^2 dt = \infty$). — $u(t) - u(t-2)$: by Proposition 20.5(ii), $F(s) = \frac{1-e^{-2s}}{s}$ with value 2 at $s = 0$; ROC = $\mathbb{C}$, no boundary. — $t^{-1/2}$: by Example 20.2 with $\alpha = -\frac{1}{2}$, $F(s) = \sqrt{\pi}/s$, $\sigma_a = 0$, ROC $\operatorname{Re}(s) > 0$, boundary *excluded* because $\int_0^\infty t^{-1/2} dt = \infty$.

(b) $\mathcal{L}\{e^{3t} \cos 4t\}(5) = \frac{5-3}{(5-3)^2+16} = \frac{2}{20} = 0.1$; Simpson quadrature on $[0, 80]$ with 400,000 subintervals: 0.1000000. ✓ $\mathcal{L}\{t^2 e^{-t}\}(1) = \frac{2}{(1+1)^3} = \frac{2}{8} = 0.25$; quadrature: 0.2500000. ✓

(c) $f(t) = e^t + e^{-t}$ and $g(t) = -e^t$ both have $\sigma_a = 1$, but $f + g = e^{-t}$ has $\sigma_a = -1$. Theorem 20.4 states an inequality because the sum can *cancel* the fastest-growing part: the bound used in the proof (triangle inequality) does not see cancellations.

(d) The window is identically zero after $t = 2$: no factor $e^{-\sigma t}$ needs to “fight” a growth, and the integral extends over a compact set. The step, instead, remains equal to 1 forever, and $\sigma > 0$ is needed for $e^{-\sigma t}$ to make it integrable.

BEST PRACTICE

Assigned exercise 20.4 — answers.

(a) and (b). $F_1(s) = \frac{2s+1}{s(s+1)(s+2)}$: simple poles 0, -1 , -2 ; by Theorem 20.15, $A_0 = \frac{1}{1 \cdot 2} = \frac{1}{2}$, $A_{-1} = \frac{-1}{(-1)(1)} = 1$, $A_{-2} = \frac{-3}{(-2)(-1)} = -\frac{3}{2}$, hence $f_1(t) = \frac{1}{2} + e^{-t} - \frac{3}{2}e^{-2t}$, ROC $\operatorname{Re}(s) > 0$. Both theorems apply: $sF_1 = \frac{2s+1}{s^2+3s+2}$ is proper with poles $-1, -2$ in the left half-plane. $F_2(s) = \frac{5}{s(s^2+4)}$: $f_2(t) = \frac{5}{4}(1 - \cos 2t)$, ROC $\operatorname{Re}(s) > 0$. The initial value theorem applies; the final value theorem *does not*, because the poles of sF_2 are $\pm 2i$, on the imaginary axis. $F_3(s) = \frac{1}{(s-2)(s+3)}$: $A_2 = \frac{1}{5}$, $A_{-3} = -\frac{1}{5}$, hence $f_3(t) = \frac{1}{5}(e^{2t} - e^{-3t})$, ROC $\operatorname{Re}(s) > 2$. The

initial value theorem applies; the final value theorem *does not*, because sF_3 has the pole 2 in the right half-plane. $F_4(s) = \frac{s}{s+4}$: it is not proper, and does not invert to a function (point (d)).

(c) $\lim_{s \rightarrow \infty} sF_1 = 0 = f_1(0^+) = \frac{1}{2} + 1 - \frac{3}{2} \checkmark$; $\lim_{s \rightarrow 0} sF_1 = \frac{1}{2}$ and $f_1(t) \rightarrow \frac{1}{2} \checkmark$ (numerical check: $f_1(30) = 0.5000000$). $\lim_{s \rightarrow \infty} sF_2 = 0 = f_2(0^+) \checkmark$; $\lim_{s \rightarrow 0} sF_2 = \frac{5}{4}$, but f_2 oscillates between 0 and $\frac{5}{2}$ and has no limit: the number $\frac{5}{4}$ is the *average* of f_2 , not its final value. $\lim_{s \rightarrow \infty} sF_3 = 0 = f_3(0^+) \checkmark$; $\lim_{s \rightarrow 0} sF_3 = 0$, but $f_3(t) \rightarrow +\infty$: the formula gives a completely wrong number. $sF_4 = \frac{s^2}{s+4} \rightarrow \infty$: no finite initial value.

(d) $F_4(\sigma) = \frac{\sigma}{\sigma+4} \rightarrow 1 \neq 0$ as $\sigma \rightarrow +\infty$; by Proposition 20.7 F_4 is not the transform of any locally integrable function with finite abscissa. It is instead the transform of the measure $\mu = \delta - 4e^{-4t} dt$: indeed, by Proposition 20.6 and Proposition 20.3, $\mathcal{L}\{\mu\}(s) = 1 - \frac{4}{s+4} = \frac{s+4-4}{s+4} = \frac{s}{s+4} \checkmark$

BEST PRACTICE

Assigned exercise 20.5 — answers.

(a) With $y(0) = 0$ and $y'(0) = 1$, Corollary 20.4 gives $\mathcal{L}\{y'\} = sY$ and $\mathcal{L}\{y''\} = s^2Y - 1$, hence

$$(s^2 + 4s + 3)Y(s) = 1 + \frac{1}{s+2} = \frac{s+3}{s+2}, \quad Y(s) = \frac{s+3}{(s+2)(s+1)(s+3)} = \frac{1}{(s+1)(s+2)},$$

where the factor $s+3$ cancels because $s^2 + 4s + 3 = (s+1)(s+3)$. Then $Y = \frac{1}{s+1} - \frac{1}{s+2}$ and

$$y(t) = e^{-t} - e^{-2t}.$$

Check by substitution: $y(0) = 0 \checkmark$; $y'(t) = -e^{-t} + 2e^{-2t}$, $y'(0) = 1 \checkmark$; $y'' = e^{-t} - 4e^{-2t}$, and $y'' + 4y' + 3y = (1 - 4 + 3)e^{-t} + (-4 + 8 - 3)e^{-2t} = e^{-2t} \checkmark$. *Numerical check:* $y(1) = e^{-1} - e^{-2} = 0.2325442$, and $\int_0^\infty y(t)e^{-t} dt = 0.1666667 = \frac{1}{2.3} = Y(1)$ by quadrature. $\checkmark$

(b) $G(s) = sY(s) = \frac{s}{(s+1)(s+2)}$ is proper with poles $-1, -2$ in the left half-plane: Corollary 20.11 applies and gives $\lim_{t \rightarrow \infty} y(t) = G(0) = 0$, consistent with $e^{-t} - e^{-2t} \rightarrow 0$. $\checkmark$

(c) *Partial fractions:* $\frac{1}{s(s^2+1)} = \frac{1}{s} - \frac{s}{s^2+1}$ (checked by reducing to a common denominator: $\frac{(s^2+1)-s^2}{s(s^2+1)} = \frac{1}{s(s^2+1)}$), hence the inverse transform is $1 - \cos t$ by Proposition 20.2 and Proposition 20.4. *Convolution:* Theorem 20.10 applied to $\frac{1}{s} \cdot \frac{1}{s^2+1}$ gives $(u * \sin)(t) = \int_0^t \sin \tau d\tau = 1 - \cos t$. The two routes agree. $\checkmark$

(d) $1 - \cos 1 = 1 - 0.5403023 = 0.4596977$; Simpson quadrature of $\int_0^1 \sin \tau d\tau$ with 400,000 subintervals gives 0.4596977. $\checkmark$

20.14. Formulary of the chapter

Definition, convergence, holomorphy.

$$F(s) = \mathcal{L}\{f\}(s) = \int_0^\infty f(t)e^{-st} dt, \quad s = \sigma + i\omega, \quad |e^{-st}| = e^{-\sigma t}.$$

$$\sigma_c = \inf\{\operatorname{Re}(s) : \text{converges}\}, \quad \sigma_a = \inf\{\operatorname{Re}(s) : \text{converges absolutely}\}, \quad \sigma_c \leq \sigma_a.$$

Convergence at $s_0 \Rightarrow$ convergence on $\operatorname{Re}(s) > \operatorname{Re}(s_0)$, with

$$F(s) = (s - s_0) \int_0^\infty \varphi(t)e^{-(s-s_0)t} dt, \quad \varphi(t) = \int_0^t f(\tau)e^{-s_0\tau} d\tau.$$

F holomorphic on $\operatorname{Re}(s) > \sigma_c$; on $\operatorname{Re}(s) > \sigma_a$: $F^{(n)}(s) = (-1)^n \mathcal{L}\{t^n f\}(s)$ and $F(\sigma) \rightarrow 0$ as $\sigma \rightarrow +\infty$.

The eight rules, with the region.

$$\begin{aligned}\mathcal{L}\{\lambda f + \mu g\} &= \lambda F + \mu G; & \mathcal{L}\{f(t-a)u(t-a)\} &= e^{-as}F(s) \quad (a \geq 0, \text{ ROC unchanged}); \\ \mathcal{L}\{e^{-ct}f\} &= F(s+c) \quad (\text{ROC shifted by } -\operatorname{Re}(c)); & \mathcal{L}\{f(ct)\} &= \frac{1}{c}F(s/c) \quad (c > 0); \\ \mathcal{L}\{f'\} &= sF(s) - f(0^+); & \mathcal{L}\{f^{(n)}\} &= s^n F(s) - \sum_{k=0}^{n-1} s^{n-1-k} f^{(k)}(0^+); \\ \mathcal{L}\left\{\int_0^t f\right\} &= \frac{F(s)}{s} \quad (\operatorname{Re}(s) > \max\{\sigma_a, 0\}); & \mathcal{L}\{t^n f\} &= (-1)^n F^{(n)}(s); & \mathcal{L}\{f * g\} &= FG.\end{aligned}$$

Elementary pairs (ROC to the right of the arrow).

$$\begin{aligned}\delta &\mapsto 1 \quad (\mathbb{C}); & \delta_a &\mapsto e^{-as} \quad (\mathbb{C}); & u &\mapsto \frac{1}{s} \quad (\sigma > 0); & u(t-a) &\mapsto \frac{e^{-as}}{s} \quad (\sigma > 0); \\ t^n &\mapsto \frac{n!}{s^{n+1}} \quad (\sigma > 0); & t^\alpha &\mapsto \frac{\Gamma(\alpha+1)}{s^{\alpha+1}} \quad (\sigma > 0, \alpha > -1); & e^{ct} &\mapsto \frac{1}{s-c} \quad (\sigma > \operatorname{Re} c); \\ t^n e^{ct} &\mapsto \frac{n!}{(s-c)^{n+1}}; & \cos \omega t &\mapsto \frac{s}{s^2 + \omega^2}; & \sin \omega t &\mapsto \frac{\omega}{s^2 + \omega^2} \quad (\sigma > 0); \\ e^{-ct} \cos \omega t &\mapsto \frac{s+c}{(s+c)^2 + \omega^2}; & e^{-ct} \sin \omega t &\mapsto \frac{\omega}{(s+c)^2 + \omega^2} \quad (\sigma > -\operatorname{Re} c).\end{aligned}$$

Initial value, final value, inversion.

$$\begin{aligned}\lim_{\operatorname{Re}(s) \rightarrow +\infty} sF(s) &= f(0^+) \quad (f \text{ loc. abs. continuous, } \mathcal{L}\{f'\} \text{ abs. convergent}); \\ \lim_{s \rightarrow 0^+} sF(s) &= \lim_{t \rightarrow +\infty} f(t) \quad (\text{if the latter exists finite}); \\ F \text{ rational, poles of } sF \text{ in } \operatorname{Re}(s) < 0 &\implies \text{ it applies.} \\ R = \frac{N}{D} = \sum_k \sum_{j=1}^{m_k} \frac{A_{k,j}}{(s-p_k)^j}, & \quad A_{k,j} = \frac{1}{(m_k-j)!} \lim_{s \rightarrow p_k} \frac{d^{m_k-j}}{ds^{m_k-j}} \left[(s-p_k)^{m_k} R(s) \right], \\ f(t) = \sum_k \sum_j A_{k,j} \frac{t^{j-1}}{(j-1)!} e^{p_k t} &= \sum_k \operatorname{Res}_{s=p_k} \left[R(s) e^{st} \right]; & f(t) &= \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} F(s) e^{st} ds. \\ \text{Simple poles: } A_k &= \frac{N(p_k)}{D'(p_k)}. & \text{Fourier: if } f &\in L^1(0, \infty) \text{ then } \hat{f}(\xi) = F(2\pi i \xi) \text{ and } F(i\omega) = \hat{f}(\omega/2\pi).\end{aligned}$$

-
- [5] For the results of the treatise cited with \ref: Liouville's theorem, Riemann's theorem on removable singularities, the Laurent series, the residue theorem and the formulas for the residue at a pole are proved in Chapter 15; the Fourier transform, the inversion formula in L^1 , the convolution theorem and the Dirac delta as a tempered distribution in Chapter 19; the trigonometric Weierstrass approximation theorem in Chapter 17; Euler's Gamma function in Chapter 11; the Zeta transform, which is the discrete analogue of this chapter, and BIBO stability in the z -domain in Chapter 21; the systematic use of the transfer function and the stability criteria in Chapter 25. The table of notable transforms, inherited from Volume II, is in Appendix C; Theorem 20.11 proves every row of it and adds to it the region of convergence, which the appendix does not report.
- [6] Numerical checks: all values in the chapter were recomputed with an executed Python script (composite Simpson quadrature with $4 \cdot 10^5$ or $2 \cdot 10^6$ subintervals for the transforms; fourth-order Runge–Kutta with $2 \cdot 10^5$ steps for the differential equation of Worked Exercise 20.7), comparing them with the closed forms; every successful comparison is flagged in the text with $\checkmark$. The observed discrepancies are of the order of 10^{-13} for regular integrands and 10^{-7} where the integrand has unbounded derivative at the origin (Example 20.2).

The Z-transform and the discrete-time Fourier transform

A computer does not see a signal: it sees a sequence of samples. The Z-transform is the tool that carries a sequence $x[n]$ into a holomorphic function $X(z)$, and the discrete-time Fourier transform (DTFT) is what one reads of X on the unit circle. The two are not different tools: they are the same tool viewed on two different regions of the complex plane, and the second exists exactly when the circle $\mathbb{T} = \{|z| = 1\}$ belongs to the region of convergence of the first. This chapter proves this claim and everything around it.

The guiding thread is geometric. The region of convergence of a Z-transform is not an arbitrary set: it is always a *circular annulus* (Theorem 21.1), because the bilateral series $\sum_n x[n]z^{-n}$ splits into two power series, one in the variable $1/z$ and one in the variable z , and each has a disk as its domain of convergence. From this single observation everything follows: causality corresponds to the exterior of a circle (Corollary 21.1), anticausality to the interior of a circle (Corollary 21.2), and there are sequences whose annulus is *empty* (Example 21.1), that is, that have no Z-transform at any point of the plane. The algebraic expression of $X(z)$ does not suffice to pin down $x[n]$: one needs the expression *and* the annulus, and two completely different sequences can share the same rational expression (Example 21.2). It is the most common error in the entire subject, and Section 21.2 confronts it head-on.

Stability is decided on the inner or outer boundary of that annulus. A discrete linear time-invariant system is BIBO stable if and only if its impulse response is absolutely summable (Theorem 21.10, proved in both directions), which is equivalent to saying that $\mathbb{T}$ lies in the region of convergence of the transfer function (Corollary 21.4); and for a causal rational system this is equivalent to requiring that all poles lie *inside* the unit circle (Theorem 21.12). The unit circle of Chapter 12 is therefore not merely a geometric object: it is the stability boundary of every digital controller.

The last section closes the circle among the three planes. The sampling map $z = e^{sT}$ sends the left half-plane onto the punctured unit disk (Theorem 21.13), but it is not injective: this is the analytic reason for aliasing. Its rational approximation, Tustin's bilinear transform, is instead a Möbius transformation that sends the left half-plane *bijectively* onto the disk (Theorem 21.14), at the price of a deformation of the frequency axis that Corollary 21.5 computes in closed form.

The material that the Executive Plan moved here from Volume II (Chapter 4, §11 and §12, and Appendix A, §3) is preserved in full — definition, statements, worked examples, SCL listing, exercises, quiz and key — and is found in Definition 21.3, Theorem 21.6, Theorem 21.12, Section 21.7 and Section 21.8. What Volume II stated without proof (the annulus structure of the region of convergence, the inversion formula, uniqueness at fixed annulus, the summability criterion, the partial-fraction decomposition and the correspondence between the left half-plane and the disk) is here proved.

INFO

Level and prerequisites. Level **C** (undergraduate), with two passages of level **D** (the exact computation of the radius of convergence of a causal rational function in Theorem 21.11 and the proof of the partial-fraction decomposition, Lemma 21.3).

Internal prerequisites. Geometric series, complex numbers, modulus, polar form and complex exponential (Volume II, Chapter 3, and Chapter 6); Möbius transformations and generalized circles (Chapter 6); line integrals on the circle, Laurent series, uniqueness of the Laurent coefficients and the identity principle (Chapter 15, in particular Lemma 15.5 and Theorem 15.4); convergence in $L^2(\mathbb{T})$ and completeness of the trigonometric system (Chapter 17, Theorem 17.1); Fourier transform and Laplace transform (Chapter 19 and Chapter 20, Remark 20.1).

External prerequisites, assumed and not reproved:

- numerical series: the root test, the comparison test, properties of limit superior, absolute convergence and rearrangement, Fubini's theorem for absolutely convergent double series;
- power series: a power series defines a holomorphic function inside its own disk of convergence and may be differentiated term by term;
- uniform convergence: the Weierstrass criterion, continuity of the uniform limit of continuous functions, interchange of series and integral on a compact interval;
- polynomial algebra: division with remainder and Bézout's identity for coprime polynomials over $\mathbb{C}$; the fundamental theorem of algebra (Corollary 15.2, already proved in Chapter 15);
- measure theory, for the sole statement of Riesz–Fischer recalled as a panorama in Remark 21.7: the completeness of $L^2(\mathbb{T})$.

Everything else is proved here.

What is learned. Recognizing that a region of convergence is an annulus and computing its two radii; reading the causality of a signal off the shape of the annulus; inverting a rational function by choosing the annulus, and understanding why without it the answer is not unique; proving the five operational properties of the transform; passing from the zeta transform to the DTFT and back; deciding the BIBO stability of a system in three equivalent ways (summability, annulus, poles); and reading the s -plane, the z -plane and the frequency axis as three views of a single object.

Warning. Conventions of the chapter.

- A *signal* (or *sequence*) is a function $x : \mathbb{Z} \rightarrow \mathbb{C}$, written $x[n]$ with square brackets. The set of signals with $\|x\|_1 = \sum_{n \in \mathbb{Z}} |x[n]| < \infty$ is $\ell^1(\mathbb{Z})$; that with $\|x\|_2^2 = \sum_n |x[n]|^2 < \infty$ is $\ell^2(\mathbb{Z})$; that with $\|x\|_\infty = \sup_n |x[n]| < \infty$ is $\ell^\infty(\mathbb{Z})$.
- $\delta[n]$ is the *unit impulse* (1 for $n = 0$, 0 elsewhere) and $u[n]$ the *unit step* (1 for $n \geq 0$, 0 for $n < 0$); $u[-n-1]$ therefore equals 1 for $n \leq -1$ and 0 for $n \geq 0$.
- $\mathbb{D} = \{z \in \mathbb{C} : |z| < 1\}$ is the open unit disk and $\mathbb{T} = \{z \in \mathbb{C} : |z| = 1\}$ the unit circle. For $0 \leq a < b \leq +\infty$, $A(a, b) = \{z \in \mathbb{C} : a < |z| < b\}$ is the open *annulus* of radii a and b ; it is empty if $b \leq a$, and it is the punctured plane $\mathbb{C} \setminus \{0\}$ if $a = 0$ and $b = +\infty$.
- Every circle $|z| = r$ is understood to be traversed *once, counterclockwise*, that is, parametrized by $z(\theta) = re^{i\theta}$, $\theta \in [0, 2\pi]$; the notation $\oint_{|z|=r}$ carries this orientation.
- Ω always denotes the *normalized angular frequency* (in radians per sample), ω the physical angular frequency (in radians per second) and T the sampling period, so that $\Omega = \omega T$. The sampling frequency is $f_s = 1/T$ and the Nyquist frequency is $f_s/2$, corresponding to $\Omega = \pi$.
- “Proper rational system” means: transfer function $H(z) = N(z)/D(z)$ with N, D

polynomials, $D \neq 0$, $\deg N \leq \deg D$ and the fraction reduced to lowest terms; the *poles* are the roots of D .

- In numerical computations decimals are separated by a point and thousands by a comma in braces; values marked with $\checkmark$ have been computed twice by independent routes.

21.1. Discrete signals, LTI systems and convolution

A PLC does not work in continuous time: it reads inputs, computes and writes outputs at discrete intervals (the scan time). Before transforming anything it is worth fixing what is being transformed and what one wants to know about it.

Definition 21.1: Notable signals, causality and support. A **discrete signal** is a function $x : \mathbb{Z} \rightarrow \mathbb{C}$, denoted $x[n]$. Its **support** is $\text{supp } x = \{n \in \mathbb{Z} : x[n] \neq 0\}$. The signal is

- **causal** if $x[n] = 0$ for every $n < 0$;
- **anticausal** if $x[n] = 0$ for every $n \geq 0$;
- **bilateral** in the remaining cases;
- of **finite support** if $\text{supp } x$ is finite.

The **unit impulse** is $\delta[n] = 1$ for $n = 0$ and 0 elsewhere; the **unit step** is $u[n] = 1$ for $n \geq 0$ and 0 for $n < 0$. The signal **shifted** by n_0 is $(\sigma_{n_0}x)[n] = x[n - n_0]$.

Remark 21.1: Every signal is a sum of shifted impulses. For every n the pointwise identity

$$x[n] = \sum_{k \in \mathbb{Z}} x[k] \delta[n - k]$$

holds, because in the sum on the right only the term $k = n$ survives, the others having $\delta[n - k] = 0$. The sum is thus finite for each fixed n : there is no convergence issue at all. It is this identity, and nothing else, that makes convolution unavoidable.

Definition 21.2: Discrete linear time-invariant system. Let $\mathcal{S}$ be a set of signals closed under linear combinations and shifts. A map $\mathcal{T} : \mathcal{S} \rightarrow \mathcal{S}$ is a **linear time-invariant system** (LTI) if

(L) $\mathcal{T}(\alpha x + \beta y) = \alpha \mathcal{T}x + \beta \mathcal{T}y$ for every $x, y \in \mathcal{S}$ and $\alpha, \beta \in \mathbb{C}$;

(TI) $\mathcal{T}(\sigma_{n_0}x) = \sigma_{n_0}(\mathcal{T}x)$ for every x and every $n_0 \in \mathbb{Z}$.

Its **impulse response** is $h = \mathcal{T}\delta$. The system is **causal** if h is causal.

Proposition 21.1: An LTI system is convolution with its own impulse response.

Let $\mathcal{T}$ be an LTI system with impulse response h .

- If x has finite support, then $(\mathcal{T}x)[n] = \sum_{k \in \mathbb{Z}} h[k] x[n - k]$ for every n , and the sum has a finite number of nonzero terms.
- If $h \in \ell^1(\mathbb{Z})$ and $x \in \ell^\infty(\mathbb{Z})$, the series

$$(h * x)[n] := \sum_{k \in \mathbb{Z}} h[k] x[n - k]$$

converges absolutely for every n and $\|h * x\|_\infty \leq \|h\|_1 \|x\|_\infty$.

- Convolution is commutative: $(h * x)[n] = (x * h)[n]$ whenever one of the two series converges absolutely.

Proof. (i). Let $F = \text{supp } x$, finite. By Remark 21.1, $x = \sum_{k \in F} x[k] \sigma_k \delta$, a *finite* linear combination of shifts of δ . Applying (L) finitely many times and then (TI) to each term,

$$\mathcal{T}x = \sum_{k \in F} x[k] \mathcal{T}(\sigma_k \delta) = \sum_{k \in F} x[k] \sigma_k (\mathcal{T}\delta) = \sum_{k \in F} x[k] \sigma_k h,$$

that is, evaluating at n , $(\mathcal{T}x)[n] = \sum_{k \in F} x[k] h[n - k]$. Since $x[k] = 0$ outside F , the sum extends to all of $\mathbb{Z}$ without changing value; and by point (iii), proved below, it also equals $\sum_k h[k] x[n - k]$.

(ii). For every n and every k , $|h[k]x[n - k]| \leq |h[k]| \|x\|_\infty$. Since $\sum_k |h[k]| = \|h\|_1 < \infty$, the comparison test gives absolute convergence of the series and the bound

$$|(h * x)[n]| \leq \sum_{k \in \mathbb{Z}} |h[k]| |x[n - k]| \leq \|h\|_1 \|x\|_\infty,$$

valid for every n ; taking the supremum over n gives the claim.

(iii). The substitution $j = n - k$ is a bijection of $\mathbb{Z}$ onto itself, and an absolutely convergent series may be rearranged without changing its sum; hence $\sum_k h[k]x[n - k] = \sum_j h[n - j]x[j] = (x * h)[n]$. $\square$

Remark 21.2: What is needed for inputs without finite support. Point (i) of Proposition 21.1 is purely algebraic and requires nothing beyond (L) and (TI). For an input with infinite support the same conclusion additionally requires that $\mathcal{T}$ commute with the limit of the truncations $x_N[n] = x[n]$ for $|n| \leq N$ and 0 elsewhere — a continuity requirement of the system, which is here assumed whenever one writes $y = h * x$ for an arbitrary input. It is not a loss of generality in applications: a constant-coefficient difference equation, like those of this chapter, satisfies the requirement because every output $y[n]$ depends on a finite number of past values.

21.2. The Z-transform and its region of convergence

The Z-transform is the discrete analog of the Laplace transform, and is the tool with which stability and frequency response of digital control systems are analyzed.

Definition 21.3: Z-transform. For a sequence $x[n]$, $n \in \mathbb{Z}$ (bilateral) or $n \geq 0$ (unilateral, for causal sequences):

$$X(z) = \mathcal{Z}\{x[n]\} = \sum_n x[n] z^{-n}, \quad z \in \mathbb{C},$$

defined for z in the region of convergence ROC. For a causal sequence that does not grow faster than an exponential, ROC is the exterior of a circle, $|z| > r_0$.

Definition 21.3 leaves two things to be made precise, and they are exactly the two that make the subject treacherous: what “converges” means for a series indexed over all of $\mathbb{Z}$, and why the region of convergence must have the announced shape. We fix them here.

Definition 21.4: Region of convergence. The **region of convergence** of x , denoted $\text{ROC}(x)$, is the set of $z \in \mathbb{C}$ for which the family $\{x[n]z^{-n}\}_{n \in \mathbb{Z}}$ is *summable*, that is

$$\text{ROC}(x) = \left\{ z \in \mathbb{C} \setminus \{0\} : \sum_{n \in \mathbb{Z}} |x[n]| |z|^{-n} < +\infty \right\}.$$

For $z \in \text{ROC}(x)$ the sum $X(z) = \sum_{n \in \mathbb{Z}} x[n]z^{-n}$ is well defined and does not depend on the

order in which the terms are summed. One sets

$$X_+(z) = \sum_{n \geq 0} x[n]z^{-n}, \quad X_-(z) = \sum_{m \geq 1} x[-m]z^m,$$

the **causal part** and the **anticausal part** of the transform, so that $X = X_+ + X_-$ on $\text{ROC}(x)$.

Remark 21.3: Why absolute convergence is required. A series indexed over $\mathbb{Z}$ has no natural order of summation: one could sum symmetrically, $\lim_N \sum_{|n| \leq N}$, or in blocks, and the two limits generally differ. Requiring absolute summability removes the ambiguity (an absolutely convergent series has the same sum in every order) and it is what makes licit every manipulation of the chapter: the interchange of two sums in Theorem 21.5(v), the interchange of sum and integral in Theorem 21.3, the Weierstrass criterion in Theorem 21.2. It is also the convention of Oppenheim and Schaffer (*Discrete-Time Signal Processing*, 3rd ed., Ch. 3), which defines the ROC as the set of z for which the series converges absolutely.

21.2.1 The Cauchy–Hadamard lemma and the annulus structure

Lemma 21.1: Cauchy–Hadamard. Let $(c_k)_{k \geq 0}$ be a complex sequence and let $\lambda = \limsup_{k \rightarrow \infty} |c_k|^{1/k} \in [0, +\infty]$. Setting $R = 1/\lambda$, with the conventions $1/0 = +\infty$ and $1/(+\infty) = 0$, the power series $\sum_{k \geq 0} c_k w^k$

(i) converges absolutely for every w with $|w| < R$;

(ii) has an unbounded general term, and thus does not converge, for every w with $|w| > R$.

R is called the **radius of convergence** of the series.

Proof. (i). Let $|w| < R$; the case $w = 0$ is trivial, so assume $w \neq 0$. Choose a number t with $|w| < t < R$; then $1/t > 1/R = \lambda$. By the characterization of the limit superior, the set of indices k with $|c_k|^{1/k} > 1/t$ is finite: there exists K such that $|c_k|^{1/k} \leq 1/t$ for every $k \geq K$. For such k ,

$$|c_k w^k| = (|c_k|^{1/k} |w|)^k \leq \left(\frac{|w|}{t}\right)^k,$$

and $q = |w|/t < 1$. The geometric series $\sum_k q^k$ converges, hence by the comparison test $\sum_k |c_k w^k|$ converges.

(ii). Let $|w| > R$, that is $1/|w| < \lambda$. By the characterization of the limit superior, there are infinitely many indices k with $|c_k|^{1/k} > 1/|w|$, and for each of them $|c_k w^k| > 1$. The general term does not tend to zero (indeed, it is not bounded when $|w| > t > R$ and the argument is repeated with t), hence the series does not converge. $\square$

Theorem 21.1: The region of convergence is a circular annulus. Let $x : \mathbb{Z} \rightarrow \mathbb{C}$ be a signal and set

$$\rho_+ = \limsup_{n \rightarrow +\infty} |x[n]|^{1/n} \in [0, +\infty], \quad \rho_- = \left(\limsup_{m \rightarrow +\infty} |x[-m]|^{1/m} \right)^{-1} \in [0, +\infty],$$

with the conventions $1/0 = +\infty$ and $1/(+\infty) = 0$ (and $\rho_+ = 0$, $\rho_- = +\infty$ when the corresponding sequence is eventually zero). Then

$$A(\rho_+, \rho_-) \subseteq \text{ROC}(x) \subseteq \{z : \rho_+ \leq |z| \leq \rho_-\}.$$

In particular:

- (i) if $\rho_- < \rho_+$, then $\text{ROC}(x) = \emptyset$: the signal has no Z-transform at any point;
- (ii) $\text{ROC}(x)$ is rotation invariant: membership of z depends only on $|z|$, so $\text{ROC}(x)$ contains a whole circle $|z| = r$ or none of its points;
- (iii) if $\rho_+ < \rho_-$, then $\text{ROC}(x)$ is the open annulus $A(\rho_+, \rho_-)$, possibly united with one or both of the boundary circles $|z| = \rho_+$ and $|z| = \rho_-$ (the latter only if $\rho_- < \infty$); in every case it is path-connected.

Proof. Step 1 — summability splits in two. Fix $z \neq 0$; the family $\{x[n]z^{-n}\}_{n \in \mathbb{Z}}$ is summable if and only if the two sub-families of indices $n \geq 0$ and $n < 0$ are summable separately, because a family of non-negative numbers is summable if and only if each part of a finite partition of the indices is, and in that case the sum is the sum of the partial sums. Hence

$$z \in \text{ROC}(x) \iff \sum_{n \geq 0} |x[n]| |z|^{-n} < \infty \text{ and } \sum_{m \geq 1} |x[-m]| |z|^m < \infty.$$

Step 2 — the causal part. Setting $w = 1/z$, the first series is $\sum_{n \geq 0} |c_n| |w|^n$ with $c_n = x[n]$. By Lemma 21.1, it converges if $|w| < 1/\rho_+$ and does not converge if $|w| > 1/\rho_+$; that is, going back to z , it converges if $|z| > \rho_+$ and does not converge if $|z| < \rho_+$.

Step 3 — the anticausal part. The second series is $\sum_{m \geq 1} |d_m| |z|^m$ with $d_m = x[-m]$, a power series in the variable z whose radius of convergence is, by Lemma 21.1, $(\limsup_m |d_m|^{1/m})^{-1} = \rho_-$. It therefore converges if $|z| < \rho_-$ and does not converge if $|z| > \rho_-$.

Step 4 — conclusion. Putting Steps 1–3 together: if $\rho_+ < |z| < \rho_-$ both series converge, hence $z \in \text{ROC}(x)$, which gives the first inclusion; if $|z| < \rho_+$ the first series does not converge, and if $|z| > \rho_-$ the second does not, so in both cases $z \notin \text{ROC}(x)$, which gives the second inclusion.

(i). If $\rho_- < \rho_+$ the set $\{\rho_+ \leq |z| \leq \rho_-\}$ is empty, and so is $\text{ROC}(x)$.

(ii). The condition $\sum_n |x[n]| |z|^{-n} < \infty$ of Definition 21.4 involves z only through $|z|$: if it is satisfied by z it is satisfied by every z' with $|z'| = |z|$.

(iii). If $\rho_+ < \rho_-$, the two inclusions say that $\text{ROC}(x)$ contains the open annulus and is contained in the closed annulus: only the points on the two boundaries remain undetermined, and by (ii) each of the two boundary circles either belongs to it entirely or not at all. The resulting set is path-connected, because two of its points can be joined by first traversing an arc of the circle through the first point and then a radial segment, both contained in the closed annulus and, by (ii), in the set. $\square$

Corollary 21.1: Causal signals: the ROC is the exterior of a circle. If x is causal and not identically zero, then $\rho_- = +\infty$ and

$$\{z : |z| > \rho_+\} \subseteq \text{ROC}(x) \subseteq \{z : |z| \geq \rho_+\}.$$

If moreover $\rho_+ < \infty$, the function X admits a finite limit as $|z| \rightarrow \infty$, and precisely $X(z) \rightarrow x[0]$.

Proof. If x is causal, $x[-m] = 0$ for every $m \geq 1$: the limit superior of $|x[-m]|^{1/m} = 0$ equals 0, hence $\rho_- = 1/0 = +\infty$, and Theorem 21.1 gives the two inclusions. For the limit: fix $r > \rho_+$; for $|z| \geq r$ one has $|x[n]z^{-n}| \leq |x[n]|r^{-n}$ with $\sum_n |x[n]|r^{-n} < \infty$, hence the series $\sum_{n \geq 0} x[n]z^{-n}$ converges *uniformly* on $\{|z| \geq r\}$ by the Weierstrass criterion. The limit as $|z| \rightarrow \infty$ can thus be interchanged with the sum: every term with $n \geq 1$ tends to 0, the term $n = 0$ is constantly $x[0]$, and the sum tends to $x[0]$. $\square$

Figure 21.1: The region of convergence of $x[n] = (\frac{1}{2})^n u[n] - 2^n u[-n-1]$: the annulus $A(\frac{1}{2}, 2)$ of Theorem 21.1. The inner boundary is dictated by the causal part, the outer one by the anticausal part, and the two poles of $X(z) = \frac{z}{z-1/2} + \frac{z}{z-2}$ lie exactly on the two circles. Since $\rho_+ = \frac{1}{2} < 1 < 2 = \rho_-$, the unit circle $\mathbb{T}$ (dashed) is contained in the annulus: the signal is summable and has a DTFT.

Corollary 21.2: Anticausal signals: the ROC is a disk. If x is anticausal and not identically zero, then $\rho_+ = 0$ and

$$\{z : 0 < |z| < \rho_-\} \subseteq \text{ROC}(x) \subseteq \{z : 0 < |z| \leq \rho_-\},$$

and X extends continuously to $z = 0$ by setting $X(0) = 0$.

Proof. If $x[n] = 0$ for $n \geq 0$, the limit superior of $|x[n]|^{1/n}$ equals 0, that is $\rho_+ = 0$, and Theorem 21.1 gives the inclusions. Moreover $X(z) = X_-(z) = \sum_{m \geq 1} x[-m]z^m$ is a power series in z with no constant term, convergent for $|z| < \rho_-$: it equals 0 at $z = 0$ and is continuous there. $\square$

Corollary 21.3: Finite support. If x has finite support, contained in $\{N_1, \dots, N_2\}$, then X is the Laurent polynomial $X(z) = \sum_{n=N_1}^{N_2} x[n]z^{-n}$ and

$$\text{ROC}(x) = \mathbb{C} \setminus \{0\}.$$

The series also converges at $z = 0$ — and X extends there by continuity — if and only if $x[n] = 0$ for every $n > 0$.

Proof. A finite sum always converges, provided each term is defined: the only term not defined at $z = 0$ is $x[n]z^{-n}$ with $n > 0$. The sum is thus defined for every $z \neq 0$, and at $z = 0$ exactly when no negative powers occur, that is, when $x[n] = 0$ for $n > 0$. $\square$

Example 21.1: Two empty annuli. *First example.* Let $x[n] = 2^{|n|}$. For $n \geq 0$ one has $|x[n]|^{1/n} = 2$ for every $n \geq 1$, hence $\rho_+ = 2$; for $m \geq 1$ one has $|x[-m]|^{1/m} = 2$, hence $\rho_- = 1/2$. Since $\rho_- = \frac{1}{2} < 2 = \rho_+$, Theorem 21.1(i) gives $\text{ROC}(x) = \emptyset$: there is no $z \in \mathbb{C}$ for which the series $\sum_n 2^{|n|}z^{-n}$ converges. A direct check confirms this: for $|z| \leq 1$ the causal part $\sum_{n \geq 0} 2^n |z|^{-n}$ has general term $\geq 2^n$, which does not tend to zero; for $|z| > 1$ the anticausal part $\sum_{m \geq 1} 2^m |z|^m$ has general term $\geq 2^m$, and that does not tend to zero either. $\checkmark$

Second example (the general case). Let $x[n] = a^n u[n] + b^n u[-n-1]$ with $a, b \in \mathbb{C} \setminus \{0\}$. Then $\rho_+ = |a|$ (because $|x[n]|^{1/n} = |a|$ for $n \geq 1$) and, since $x[-m] = b^{-m}$, $\limsup_m |x[-m]|^{1/m} = |b|^{-1}$ and hence $\rho_- = |b|$. The region of convergence is then the annulus $A(|a|, |b|)$, non-empty if and only if $|a| < |b|$: **the annulus is empty exactly when the causal part grows at least as fast as the anticausal part decreases**. The first example is the case $a = 2$, $b = 1/2$.

21.2.2 Holomorphy, inversion and uniqueness

Theorem 21.2: On the annulus the transform is holomorphic, and the series is its Laurent series. Let x be a signal with $\rho_+ < \rho_-$ and let $A = A(\rho_+, \rho_-)$. Then

- (i) the series $\sum_{n \in \mathbb{Z}} x[n] z^{-n}$ converges uniformly on every closed annulus $\{r_1 \leq |z| \leq r_2\}$ with $\rho_+ < r_1 \leq r_2 < \rho_-$;
- (ii) X is holomorphic on A ;
- (iii) $\sum_{n \in \mathbb{Z}} x[n] z^{-n}$ is the Laurent series of X centered at 0 on the annulus A , and the coefficients $x[n]$ are uniquely determined by it.

Proof. (i). Let $\rho_+ < r_1 \leq r_2 < \rho_-$ and let z satisfy $r_1 \leq |z| \leq r_2$. For $n \geq 0$ one has $|x[n] z^{-n}| \leq |x[n]| r_1^{-n} =: M_n$, and $\sum_{n \geq 0} M_n < \infty$ because $r_1 > \rho_+$ (Step 2 of the proof of Theorem 21.1). For $n = -m < 0$ one has $|x[-m] z^m| \leq |x[-m]| r_2^m =: M_{-m}$, and $\sum_{m \geq 1} M_{-m} < \infty$ because $r_2 < \rho_-$ (Step 3 of the same proof). The majorants M_n do not depend on z and their series converges: the Weierstrass criterion gives uniform convergence.

(ii). The function X_+ is, in the variable $w = 1/z$, the sum of the power series $\sum_{n \geq 0} x[n] w^n$, whose radius of convergence is $1/\rho_+$ (Lemma 21.1); a power series is holomorphic inside its own disk of convergence, hence $w \mapsto X_+(1/w)$ is holomorphic on $|w| < 1/\rho_+$ and, composing with the inversion $z \mapsto 1/z$, which is holomorphic on $\mathbb{C} \setminus \{0\}$, one obtains that X_+ is holomorphic on $\{|z| > \rho_+\}$. Similarly X_- is the sum of the power series $\sum_{m \geq 1} x[-m] z^m$, holomorphic on $\{|z| < \rho_-\}$. On the annulus A both are defined and holomorphic, and so is their sum X .

(iii). By the Laurent expansion theorem (Theorem 15.4), a function holomorphic on an annulus admits one and only one expansion of the form $\sum_{k \in \mathbb{Z}} a_k z^k$ convergent on the annulus. Setting $k = -n$, the series $\sum_n x[n] z^{-n}$ has that form, with $a_{-n} = x[n]$; by the uniqueness of the expansion it is the Laurent series of X , and its coefficients are determined by X and the annulus. $\square$

Theorem 21.3: Inversion formula. Let x be a signal with $\rho_+ < \rho_-$ and let r be such that $\rho_+ < r < \rho_-$. Then for every $n \in \mathbb{Z}$

$$x[n] = \frac{1}{2\pi i} \oint_{|z|=r} X(z) z^{n-1} dz = \frac{1}{2\pi} \int_0^{2\pi} X(re^{i\theta}) r^n e^{in\theta} d\theta.$$

Proof. Step 1 — the elementary integral. For every $k \in \mathbb{Z}$,

$$\oint_{|z|=r} z^{k-1} dz = \begin{cases} 2\pi i, & k = 0, \\ 0, & k \neq 0, \end{cases}$$

which is Lemma 15.5 of Chapter 15; it is checked in two lines by parametrizing $z = re^{i\theta}$, $dz = ire^{i\theta} d\theta$:

$$\oint_{|z|=r} z^{k-1} dz = \int_0^{2\pi} r^{k-1} e^{i(k-1)\theta} ire^{i\theta} d\theta = i r^k \int_0^{2\pi} e^{ik\theta} d\theta,$$

and the last integral equals 2π for $k = 0$ and $[e^{ik\theta}/(ik)]_0^{2\pi} = 0$ for $k \neq 0$.

Step 2 — interchange of series and integral. On the circle $|z| = r$, which is a degenerate closed annulus with $r_1 = r_2 = r$, the series $\sum_k x[k]z^{-k}$ converges uniformly by Theorem 21.2(i). Multiplying by the continuous and bounded function $z \mapsto z^{n-1}$ the convergence remains uniform, hence one may integrate term by term:

$$\oint_{|z|=r} X(z)z^{n-1}dz = \sum_{k \in \mathbb{Z}} x[k] \oint_{|z|=r} z^{n-1-k} dz.$$

Step 3 — conclusion. By Step 1 with k replaced by $n - k$, the integral on the right equals $2\pi i$ if $k = n$ and 0 otherwise: only the term $k = n$ survives, giving $\oint X(z)z^{n-1}dz = 2\pi i x[n]$. The second form of the statement is obtained by parametrizing $z = re^{i\theta}$: $z^{n-1}dz = r^{n-1}e^{i(n-1)\theta}ir e^{i\theta}d\theta = i r^n e^{in\theta}d\theta$, and dividing by $2\pi i$. $\square$

Theorem 21.4: Uniqueness of the inverse transform at fixed annulus. Let x and y be two signals whose regions of convergence both contain a common circle $|z| = r$, and suppose $X(z) = Y(z)$ for every z with $|z| = r$. Then $x[n] = y[n]$ for every $n \in \mathbb{Z}$.

Proof. The hypotheses say that $r \in (\rho_+^x, \rho_-^x)$ or r lies on a boundary of the annulus of x , and likewise for y ; in both cases the series of x and that of y converge absolutely on $|z| = r$ and, by the Weierstrass criterion applied with the constant majorants $|x[n]|r^{-n}$, uniformly on that circle. Steps 2 and 3 of the proof of Theorem 21.3 thus hold identically and give, for every n ,

$$x[n] = \frac{1}{2\pi i} \oint_{|z|=r} X(z)z^{n-1}dz = \frac{1}{2\pi i} \oint_{|z|=r} Y(z)z^{n-1}dz = y[n],$$

having used $X = Y$ on $|z| = r$ in the middle step. $\square$

Example 21.2: Two different signals with the same rational expression. Let $a \in \mathbb{C} \setminus \{0\}$ and consider the rational expression

$$X(z) = \frac{z}{z-a} = \frac{1}{1-az^{-1}}.$$

It is the Z-transform of *two* different signals, according to the annulus chosen.

Outer annulus, $|z| > |a|$. For $|az^{-1}| < 1$ the geometric series of ratio az^{-1} converges absolutely and

$$\frac{1}{1-az^{-1}} = \sum_{n \geq 0} a^n z^{-n},$$

which is the transform of the *causal* signal $x_1[n] = a^n u[n]$. Consistently, $\rho_+ = |a|$ and $\rho_- = +\infty$ (Corollary 21.1).

Inner annulus, $|z| < |a|$. Here $|a^{-1}z| < 1$ and it is convenient to collect terms differently:

$$\frac{z}{z-a} = \frac{z}{-a(1-a^{-1}z)} = -a^{-1}z \sum_{m \geq 0} a^{-m} z^m = - \sum_{m \geq 1} a^{-m} z^m.$$

The coefficient of z^m , that is of z^{-n} with $n = -m$, equals $-a^{-m} = -a^n$: this is the transform of the *anticausal* signal

$$x_2[n] = -a^n u[-n-1].$$

Consistently $\rho_+ = 0$ and $\rho_- = |a|$ (Corollary 21.2).

Comparison. The two signals differ at every index: $x_1[0] = 1$ and $x_2[0] = 0$; $x_1[-1] = 0$ and $x_2[-1] = -a^{-1}$. Yet their rational expression is the same. With $a = 2$ one has $x_1 = (1, 2, 4, 8, \dots)$ for $n \geq 0$ and $x_2 = (\dots, -\frac{1}{8}, -\frac{1}{4}, -\frac{1}{2})$ for $n \leq -1$: one explodes into the

future, the other into the past. Only x_1 is summable when $|a| < 1$, only x_2 is when $|a| > 1$, and for $|a| = 1$ neither is.

Independent check. The inversion formula of Theorem 21.3 was evaluated numerically on $X(z) = [(1 - \frac{1}{2}z^{-1})(1 - 2z^{-1})]^{-1}$, which has poles at $\frac{1}{2}$ and 2 and hence *three* possible annuli; with 200,000 points on the circle one obtained, for the three radii $r = 3$, $r = 1$, $r = \frac{1}{4}$ and for $n = -2, \dots, 3$:

annulus	$n = -2$	$n = -1$	$n = 0$	$n = 1$	$n = 2$	$n = 3$
$ z > 2$	0	0	1	2.5	5.25	10.625
$\frac{1}{2} < z < 2$	-0.333 333	-0.666 667	-0.333 333	-0.166 667	-0.083 333	-0.041 667
$ z < \frac{1}{2}$	1	0	0	0	0	0

Each row agrees, up to $2 \cdot 10^{-15}$, with the analytic value obtained by partial fractions ($-\frac{1}{3} \cdot \frac{1}{1-\frac{1}{2}z^{-1}} + \frac{4}{3} \cdot \frac{1}{1-2z^{-1}}$, see Exercise 21.7); three different signals, one single expression. ✓

Warning. The error to avoid. Writing “the inverse transform of $\frac{z}{z-a}$ is $a^n u[n]$ ” is incorrect until the annulus is stated. The correct notation is

$$\mathcal{Z}^{-1}\left\{\frac{z}{z-a}, |z| > |a|\right\} = a^n u[n], \quad \mathcal{Z}^{-1}\left\{\frac{z}{z-a}, |z| < |a|\right\} = -a^n u[-n-1].$$

Theorem 21.4 guarantees uniqueness *only* at fixed annulus: a rational function with p poles of distinct moduli admits $p+1$ annuli of convergence and hence $p+1$ different inverse transforms.

21.3. The five operational properties

The properties that follow are what makes the Z-transform a computational tool and not merely a definition. Each carries with it a statement about the region of convergence, and neglecting it is the second source of error in the subject, after that of Example 21.2.

Theorem 21.5: Linearity, delay, modulation, differentiation in z , convolution.

Let x, y be signals with $\mathcal{R}_x = \text{ROC}(x)$ and $\mathcal{R}_y = \text{ROC}(y)$, and let $\alpha, \beta, a \in \mathbb{C}$ with $a \neq 0$, $n_0 \in \mathbb{Z}$.

(i) (Linearity) For every $z \in \mathcal{R}_x \cap \mathcal{R}_y$ the series of $\alpha x + \beta y$ converges absolutely and

$$\mathcal{Z}\{\alpha x + \beta y\}(z) = \alpha X(z) + \beta Y(z);$$

hence $\text{ROC}(\alpha x + \beta y) \supseteq \mathcal{R}_x \cap \mathcal{R}_y$, and this inclusion can be strict.

(ii) (Delay) $\mathcal{Z}\{x[n - n_0]\}(z) = z^{-n_0} X(z)$ for every $z \in \mathcal{R}_x$, and $\text{ROC}(\sigma_{n_0} x) = \mathcal{R}_x$.

(iii) (Multiplication by an exponential) $\mathcal{Z}\{a^n x[n]\}(z) = X(z/a)$, and $\text{ROC}(a^n x) = |a| \mathcal{R}_x = \{|a|z : z \in \mathcal{R}_x\}$; in particular the radii are multiplied by $|a|$.

(iv) (Differentiation in z) On the open annulus $A(\rho_+, \rho_-)$ the function X is differentiable and

$$\mathcal{Z}\{n x[n]\}(z) = -z X'(z),$$

with the same open annulus of convergence.

(v) (Convolution) If $z \in \mathcal{R}_x \cap \mathcal{R}_y$, then for every n the series $(x * y)[n] = \sum_k x[k]y[n-k]$ converges absolutely, the signal $x * y$ has $z \in \text{ROC}(x * y)$ and

$$\mathcal{Z}\{x * y\}(z) = X(z)Y(z).$$

Proof. (i). Let $z \in \mathcal{R}_x \cap \mathcal{R}_y$. Then

$$\sum_n |\alpha x[n] + \beta y[n]| |z|^{-n} \leq |\alpha| \sum_n |x[n]| |z|^{-n} + |\beta| \sum_n |y[n]| |z|^{-n} < \infty,$$

by the triangle inequality and the comparison test: hence $z \in \text{ROC}(\alpha x + \beta y)$. Since these are absolutely convergent series, the sum of the linear combination is the linear combination of the sums. The inclusion can be strict: with $y = x$, $\alpha = 1$, $\beta = -1$ one obtains the zero signal, whose region of convergence is $\mathbb{C} \setminus \{0\}$; and with $x[n] = u[n]$, $y[n] = u[n-1]$ (both with $\mathcal{R} = \{|z| > 1\}$) one has $x - y = \delta$, with region $\mathbb{C} \setminus \{0\}$.

(ii). With the substitution $m = n - n_0$, which is a bijection of $\mathbb{Z}$ onto itself,

$$\sum_n x[n - n_0] z^{-n} = \sum_m x[m] z^{-(m+n_0)} = z^{-n_0} \sum_m x[m] z^{-m} = z^{-n_0} X(z),$$

and the same substitution shows $\sum_n |x[n - n_0]| |z|^{-n} = |z|^{-n_0} \sum_m |x[m]| |z|^{-m}$: the two series with positive terms converge or diverge together, because the factor $|z|^{-n_0}$ is finite and nonzero for $z \neq 0$. Hence the two regions of convergence coincide (in $\mathbb{C} \setminus \{0\}$).

(iii). Since $a \neq 0$,

$$\sum_n a^n x[n] z^{-n} = \sum_n x[n] \left(\frac{z}{a}\right)^{-n} = X\left(\frac{z}{a}\right),$$

and the computation with moduli gives $\sum_n |a^n x[n]| |z|^{-n} = \sum_n |x[n]| |z/a|^{-n}$: the series converges at z if and only if the series of x converges at z/a , that is if and only if $z/a \in \mathcal{R}_x$, that is $z \in a\mathcal{R}_x$. Since $\mathcal{R}_x$ is rotation invariant (Theorem 21.1(ii)), $a\mathcal{R}_x = |a|\mathcal{R}_x$.

(iv). By Theorem 21.2, on $A(\rho_+, \rho_-)$ one has $X = X_+ + X_-$ with $X_+(z) = \sum_{n \geq 0} x[n] z^{-n}$ and $X_-(z) = \sum_{m \geq 1} x[-m] z^m$, and each of the two is obtained from a convergent power series. A power series is differentiated term by term inside its own disk of convergence; composing with $z \mapsto 1/z$ (chain rule, $\frac{d}{dz} z^{-n} = -n z^{-n-1}$) and differentiating X_- term by term as well, one obtains, for every $z \in A(\rho_+, \rho_-)$,

$$X'(z) = \sum_{n \in \mathbb{Z}} x[n] (-n) z^{-n-1}, \quad \text{hence} \quad -z X'(z) = \sum_{n \in \mathbb{Z}} n x[n] z^{-n},$$

which is by definition $\mathcal{Z}\{n x[n]\}(z)$. It remains to check that the radii do not change. For $n \geq 1$ one has $|n x[n]|^{1/n} = n^{1/n} |x[n]|^{1/n}$, and $n^{1/n} \rightarrow 1$ with $n^{1/n} \geq 1$. Setting $b_n = |x[n]|^{1/n} \geq 0$: from $b_n \leq n^{1/n} b_n$ it follows that $\limsup_n b_n \leq \limsup_n n^{1/n} b_n$; and fixing $\varepsilon > 0$, eventually $n^{1/n} \leq 1 + \varepsilon$, hence $\limsup_n n^{1/n} b_n \leq (1 + \varepsilon) \limsup_n b_n$. By the arbitrariness of ε (and with equality trivially holding when $\limsup_n b_n = +\infty$) one concludes $\limsup_n |n x[n]|^{1/n} = \limsup_n b_n = \rho_+$. The same argument with $|(-m)x[-m]|^{1/m} = m^{1/m} |x[-m]|^{1/m}$ leaves ρ_- unchanged as well.

(v). Let $z \in \mathcal{R}_x \cap \mathcal{R}_y$ and consider the double family

$$t_{k,n} = x[k] z^{-k} \cdot y[n-k] z^{-(n-k)}, \quad (k, n) \in \mathbb{Z}^2.$$

It is absolutely summable: summing first over n (with k fixed) and then over k , and using the bijection $m = n - k$,

$$\sum_{k \in \mathbb{Z}} \sum_{n \in \mathbb{Z}} |t_{k,n}| = \sum_k |x[k] z^{-k}| \sum_m |y[m] z^{-m}| = \left(\sum_k |x[k]| |z|^{-k} \right) \left(\sum_m |y[m]| |z|^{-m} \right) < \infty,$$

a product of two finite numbers by hypothesis. By Fubini's theorem for absolutely summable double series, the two iterated sums exist and agree with the sum of the family. Summing first over k :

$$\sum_n \left(\sum_k t_{k,n} \right) = \sum_n z^{-n} \sum_k x[k] y[n-k] = \sum_n (x * y)[n] z^{-n},$$

where the absolute convergence of the inner sum, for every n , follows from the summability of the family; and the absolute summability of the family also gives $\sum_n |(x * y)[n]| |z|^{-n} \leq \sum_{k,n} |t_{k,n}| < \infty$, that is $z \in \text{ROC}(x * y)$. Summing instead first over n one obtains $X(z)Y(z)$, as computed above without the moduli. The two iterated sums coincide, hence $\mathcal{Z}\{x * y\}(z) = X(z)Y(z)$. $\square$

Remark 21.4: Why annuli can grow larger. In points (i) and (v) the inclusion $\text{ROC} \supseteq \mathcal{R}_x \cap \mathcal{R}_y$ can be strict, and the reason is always the same: a cancellation. In (i) coefficients cancel; in (v) a pole is simplified against a zero. Example of (v): $x[n] = a^n u[n]$ has $X(z) = \frac{z}{z-a}$ with $\mathcal{R}_x = \{|z| > |a|\}$, and $y = \delta - a\sigma_1\delta$, that is $y[0] = 1$, $y[1] = -a$, has $Y(z) = 1 - az^{-1} = \frac{z-a}{z}$ with $\mathcal{R}_y = \mathbb{C} \setminus \{0\}$. The product equals $X(z)Y(z) = 1$, the transform of δ , whose region is $\mathbb{C} \setminus \{0\}$: the pole at a has been cancelled by the zero of Y . And indeed $(x * y)[n] = a^n u[n] - a \cdot a^{n-1} u[n-1] = \delta[n]$. $\checkmark$

Example 21.3: The table of notable transforms, proved. Every row of the table of Appendix C, §3, follows from Theorem 21.5 and Example 21.2. Let always $a \in \mathbb{C} \setminus \{0\}$.

- (1) $\mathcal{Z}\{\delta[n]\} = 1$ on $\mathbb{C} \setminus \{0\}$: the only nonzero term is $n = 0$, giving $\delta[0]z^0 = 1$ (Corollary 21.3).
- (2) $\mathcal{Z}\{a^n u[n]\} = \frac{z}{z-a}$ on $|z| > |a|$: this is Example 21.2.
- (3) $\mathcal{Z}\{u[n]\} = \frac{z}{z-1}$ on $|z| > 1$: this is (2) with $a = 1$.
- (4) $\mathcal{Z}\{n a^n u[n]\} = \frac{az}{(z-a)^2}$ on $|z| > |a|$. Indeed, by Theorem 21.5(iv) applied to (2),

$$\mathcal{Z}\{n a^n u[n]\}(z) = -z \frac{d}{dz} \left(\frac{z}{z-a} \right) = -z \cdot \frac{(z-a) - z}{(z-a)^2} = -z \cdot \frac{-a}{(z-a)^2} = \frac{az}{(z-a)^2}.$$

- (5) $\mathcal{Z}\{\cos(\Omega_0 n) u[n]\} = \frac{z^2 - z \cos \Omega_0}{z^2 - 2z \cos \Omega_0 + 1}$ and $\mathcal{Z}\{\sin(\Omega_0 n) u[n]\} = \frac{z \sin \Omega_0}{z^2 - 2z \cos \Omega_0 + 1}$, on $|z| > 1$. Indeed $\cos(\Omega_0 n) = \frac{1}{2}(e^{i\Omega_0 n} + e^{-i\Omega_0 n})$ (Euler's formula), hence by linearity and by (2) with $a = e^{\pm i\Omega_0}$ (both of modulus 1, whence the annulus $|z| > 1$):

$$\mathcal{Z}\{\cos(\Omega_0 n) u[n]\} = \frac{1}{2} \left(\frac{z}{z - e^{i\Omega_0}} + \frac{z}{z - e^{-i\Omega_0}} \right) = \frac{z}{2} \cdot \frac{2z - (e^{i\Omega_0} + e^{-i\Omega_0})}{z^2 - z(e^{i\Omega_0} + e^{-i\Omega_0}) + 1},$$

and substituting $e^{i\Omega_0} + e^{-i\Omega_0} = 2 \cos \Omega_0$ gives the announced formula. The computation for the sine is identical starting from $\sin(\Omega_0 n) = \frac{1}{2i}(e^{i\Omega_0 n} - e^{-i\Omega_0 n})$.

Independent numerical check. Formulas (4) and (5) were verified by directly summing the defining series. For (4) with $a = 0.8$ and $z = 1.25$: the partial sum over 20,000 terms equals 4.938 271 605, and the closed formula $az/(z-a)^2 = \frac{0.8 \cdot 1.25}{(0.45)^2} = 4.938 271 605$. $\checkmark$ For (5) with $\Omega_0 = 0.7$: at $z = 1.5$ the series gives 1.154 125 981 and the closed formula 1.154 125 981; at $z = 2$, 1.272 944 370 against 1.272 944 370; at $z = 1.3i$, 0.709 464 252 - 0.603 678 916 i against 0.709 464 252 - 0.603 678 916 i . $\checkmark$

21.4. The DTFT as the restriction of the zeta transform to the unit circle

Definition 21.5: Discrete-time Fourier transform (DTFT). Let $x : \mathbb{Z} \rightarrow \mathbb{C}$ be a signal. Its **discrete-time Fourier transform** is the function

$$\hat{x}(\Omega) = \sum_{n \in \mathbb{Z}} x[n] e^{-in\Omega}, \quad \Omega \in \mathbb{R},$$

defined at those Ω for which the series converges absolutely. The variable Ω is called the **normalized angular frequency** and is measured in radians per sample.

Theorem 21.6: The Z-transform on the unit circle is the DTFT. If ROC includes $\mathbb{T} = \{|z| = 1\}$, then

$$X(e^{i\Omega}) = \sum_n x[n] e^{-in\Omega}$$

is the discrete-time Fourier transform (DTFT) of $x[n]$: the Z-transform restricted to $\mathbb{T}$ is exactly the discrete analog of Remark 20.1. More precisely, for an arbitrary signal x the following three conditions are equivalent:

- (i) $\mathbb{T} \subseteq \text{ROC}(x)$;
 - (ii) $\mathbb{T} \cap \text{ROC}(x) \neq \emptyset$;
 - (iii) $x \in \ell^1(\mathbb{Z})$, that is $\sum_n |x[n]| < \infty$;
- and in that case $\hat{x}$ is defined for every $\Omega \in \mathbb{R}$ and equals $\hat{x}(\Omega) = X(e^{i\Omega})$.

Proof. Step 1 — (ii) $\Rightarrow$ (iii). Let $z_0 \in \mathbb{T} \cap \text{ROC}(x)$. Since $|z_0| = 1$, one has $|z_0|^{-n} = 1$ for every $n \in \mathbb{Z}$, hence the condition of Definition 21.4 becomes

$$+\infty > \sum_{n \in \mathbb{Z}} |x[n]| |z_0|^{-n} = \sum_{n \in \mathbb{Z}} |x[n]|,$$

that is $x \in \ell^1(\mathbb{Z})$.

Step 2 — (iii) $\Rightarrow$ (i). If $\sum_n |x[n]| < \infty$, then for every z with $|z| = 1$ the same chain of equalities of Step 1, read backwards, gives $\sum_n |x[n]| |z|^{-n} = \sum_n |x[n]| < \infty$: every point of $\mathbb{T}$ belongs to $\text{ROC}(x)$.

Step 3 — (i) $\Rightarrow$ (ii). Immediate, because $\mathbb{T} \neq \emptyset$. The three conditions are thus equivalent.

Step 4 — the identification. Suppose the three equivalent conditions hold and set $z = e^{i\Omega}$ in Definition 21.3: one obtains the series $\sum_n x[n] e^{-in\Omega}$, which is by definition the DTFT of $x[n]$. Every point of $\mathbb{T}$ has the form $e^{i\Omega}$ for some $\Omega \in \mathbb{R}$ (surjectivity of the complex exponential onto the unit circle, Chapter 6), and by Step 2 the series converges absolutely for each of them: $\hat{x}(\Omega)$ is defined for every real Ω and coincides with $X(e^{i\Omega})$.

Step 5 — the reading as a Fourier series. The series $\sum_n x[n] e^{-in\Omega}$ is, not by coincidence, formally identical to the Fourier series of the Theorem (Volume II, Chapter 4), with the roles of n and θ swapped: here $x[n]$ are the “coefficients” and Ω the continuous variable. Precisely, setting $c_n = x[-n]$, the function $\hat{x}$ is the sum of the Fourier series $\sum_n c_n e^{in\Omega}$ of the 2π -periodic function $\hat{x}$, and the Fourier coefficients of $\hat{x}$ are exactly the c_n : this is the content of Theorem 21.8. The connection with the Laplace transform is the same: there, restriction to the imaginary axis gives the Fourier transform when the axis lies in the region of convergence (Remark 20.1); here, restriction to the unit circle gives the DTFT when the circle lies in the annulus. $\square$

Proposition 21.2: The DTFT is 2π -periodic. If $x \in \ell^1(\mathbb{Z})$, then $\hat{x}(\Omega + 2\pi) = \hat{x}(\Omega)$ for every $\Omega \in \mathbb{R}$. Consequently $\hat{x}$ is completely determined by its restriction to any interval of length 2π , for instance $[-\pi, \pi)$.

Proof. For every $n \in \mathbb{Z}$ one has $e^{-in(\Omega+2\pi)} = e^{-in\Omega}e^{-2\pi in} = e^{-in\Omega}$, because $e^{-2\pi in} = 1$ for integer n . Since the series converges absolutely (Theorem 21.6), substituting term by term gives $\hat{x}(\Omega + 2\pi) = \sum_n x[n]e^{-in\Omega} = \hat{x}(\Omega)$. The second statement follows because every real number is written as $\Omega_0 + 2\pi k$ with $\Omega_0 \in [-\pi, \pi)$ and $k \in \mathbb{Z}$. $\square$

Remark 21.5: Periodicity is not an accident: it is the circle. The reason for periodicity is geometric, not algebraic. The DTFT is the restriction of X to $\mathbb{T}$ (Theorem 21.6) read through the parametrization $\Omega \mapsto e^{i\Omega}$, which is the universal covering $\mathbb{R} \rightarrow \mathbb{T}$ studied in Chapter 12: two parameters Ω and Ω' identify the same point of $\mathbb{T}$ if and only if they differ by a multiple of 2π . The function truly defined on the circle is $X|_{\mathbb{T}}$; $\hat{x}$ is its lift, and the periodicity is the fiber of the covering. It is the same reason why, in the discrete case, the frequency $\Omega = \pi$ (half the sampling frequency, that is the Nyquist frequency) is the highest that makes sense: beyond it, one goes back down the circle.

Theorem 21.7: Uniform convergence and continuity of the DTFT. Let $x \in \ell^1(\mathbb{Z})$. Then the series of Definition 21.5 converges uniformly on $\mathbb{R}$, $\hat{x}$ is continuous and 2π -periodic, and

$$\|\hat{x}\|_{\infty} = \sup_{\Omega \in \mathbb{R}} |\hat{x}(\Omega)| \leq \|x\|_1.$$

Proof. For every n and every Ω one has $|x[n]e^{-in\Omega}| = |x[n]|$, because $|e^{-in\Omega}| = 1$. The constants $M_n = |x[n]|$ do not depend on Ω and $\sum_n M_n = \|x\|_1 < \infty$: the Weierstrass criterion gives uniform convergence on $\mathbb{R}$ of the series. Every symmetric partial sum $\sum_{|n| \leq N} x[n]e^{-in\Omega}$ is a continuous function of Ω (a finite sum of continuous functions); the uniform limit of a sequence of continuous functions is continuous, hence $\hat{x}$ is continuous. Periodicity is Proposition 21.2. Finally, for every Ω , $|\hat{x}(\Omega)| \leq \sum_n |x[n]e^{-in\Omega}| = \sum_n |x[n]| = \|x\|_1$, and taking the supremum over Ω gives the bound. $\square$

Theorem 21.8: DTFT inversion formula. Let $x \in \ell^1(\mathbb{Z})$. Then for every $n \in \mathbb{Z}$

$$x[n] = \frac{1}{2\pi} \int_{-\pi}^{\pi} \hat{x}(\Omega) e^{in\Omega} d\Omega.$$

Proof. Step 1 — orthogonality. For $k \in \mathbb{Z}$,

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} e^{ik\Omega} d\Omega = \begin{cases} 1, & k = 0, \\ \frac{1}{2\pi} \left[\frac{e^{ik\Omega}}{ik} \right]_{-\pi}^{\pi} = \frac{e^{ik\pi} - e^{-ik\pi}}{2\pi ik} = \frac{2i \sin(k\pi)}{2\pi ik} = 0, & k \neq 0, \end{cases}$$

since $\sin(k\pi) = 0$ for integer k .

Step 2 — interchange of series and integral. By Theorem 21.7 the series $\sum_k x[k]e^{-ik\Omega}$ converges uniformly on $[-\pi, \pi]$; multiplying it by the continuous, modulus-1 function $\Omega \mapsto e^{in\Omega}$ the convergence remains uniform, hence one may integrate term by term over the compact interval $[-\pi, \pi]$:

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} \hat{x}(\Omega) e^{in\Omega} d\Omega = \sum_{k \in \mathbb{Z}} x[k] \cdot \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{i(n-k)\Omega} d\Omega.$$

Step 3 — conclusion. By Step 1 with k replaced by $n - k$, the integral equals 1 if $k = n$ and 0 otherwise: only the term $k = n$ remains, that is $x[n]$. $\square$

Remark 21.6: Inversion of the DTFT is inversion of the zeta transform. The formulas of Theorems 21.3 and 21.8 are the same formula. Taking $r = 1$ in Theorem 21.3 and parametrizing $z = e^{i\Omega}$, one obtains $x[n] = \frac{1}{2\pi} \int_0^{2\pi} X(e^{i\Omega}) e^{in\Omega} d\Omega$; and since the integrand is 2π -periodic (Proposition 21.2 and $e^{in(\Omega+2\pi)} = e^{in\Omega}$), the integral over $[0, 2\pi]$ equals that over $[-\pi, \pi]$. The inversion formula of the zeta transform is thus the inversion formula of the DTFT written on a circle of radius r instead of 1, with the correction factor r^n .

Theorem 21.9: Parseval's identity for the DTFT. Let $x, y \in \ell^1(\mathbb{Z})$. Then

$$\sum_{n \in \mathbb{Z}} x[n] \overline{y[n]} = \frac{1}{2\pi} \int_{-\pi}^{\pi} \hat{x}(\Omega) \overline{\hat{y}(\Omega)} d\Omega,$$

and in particular, for $y = x$,

$$\sum_{n \in \mathbb{Z}} |x[n]|^2 = \frac{1}{2\pi} \int_{-\pi}^{\pi} |\hat{x}(\Omega)|^2 d\Omega.$$

In particular $\ell^1(\mathbb{Z}) \subseteq \ell^2(\mathbb{Z})$ and the two quantities are finite.

Proof. Step 1 — finiteness. If $x \in \ell^1$ then $|x[n]| \leq \|x\|_1$ for every n , hence $\sum_n |x[n]|^2 \leq \|x\|_1 \sum_n |x[n]| = \|x\|_1^2 < \infty$: $x \in \ell^2$. The right-hand side is finite because $\hat{x}$ and $\hat{y}$ are continuous and bounded (Theorem 21.7) on a compact interval.

Step 2 — the double family. Consider

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} \hat{x}(\Omega) \overline{\hat{y}(\Omega)} d\Omega = \frac{1}{2\pi} \int_{-\pi}^{\pi} \left(\sum_n x[n] e^{-in\Omega} \right) \overline{\left(\sum_m y[m] e^{-im\Omega} \right)} d\Omega.$$

The double family $(x[n] \overline{y[m]} e^{-i(n-m)\Omega})_{(n,m) \in \mathbb{Z}^2}$ is bounded in modulus, uniformly in Ω , by $|x[n]| |y[m]|$, whose sum equals $\|x\|_1 \|y\|_1 < \infty$: by the Weierstrass criterion the double series converges uniformly in Ω and may be integrated term by term.

Step 3 — orthogonality. By Step 1 of the proof of Theorem 21.8, $\frac{1}{2\pi} \int_{-\pi}^{\pi} e^{-i(n-m)\Omega} d\Omega$ equals 1 if $n = m$ and 0 otherwise. Only the terms with $n = m$ remain:

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} \hat{x} \overline{\hat{y}} d\Omega = \sum_{n \in \mathbb{Z}} x[n] \overline{y[n]},$$

which is the claim. The second formula is the case $y = x$, with $x[n] \overline{x[n]} = |x[n]|^2$ and $\hat{x} \overline{\hat{x}} = |\hat{x}|^2$. $\square$

Remark 21.7: What is imported: Parseval for finite-energy signals. Theorem 21.9 is proved here for $x, y \in \ell^1(\mathbb{Z})$, a hypothesis needed in two places: to define $\hat{x}$ pointwise and to justify the interchange of series and integral. The correct statement, however, is that the DTFT extends to a **surjective isometry** $\ell^2(\mathbb{Z}) \rightarrow L^2(\mathbb{T})$, and this is not proved here in full: the “injective and isometric” half follows from the completeness of the trigonometric system, which Chapter 17 proves (Theorem 17.1); the “surjective” half — every sequence in ℓ^2 is the sequence of Fourier coefficients of a function in $L^2(\mathbb{T})$ — is the Riesz–Fischer theorem, whose proof requires the completeness of the metric space $L^2(\mathbb{T})$, that is the Riesz–Fischer theorem on the convergence of Cauchy sequences in L^p . That completeness is here **imported** from measure theory and not reproved: it is the only missing link. Whoever wishes to fill it will find the proof in W. Rudin, *Real and Complex Analysis*, 3rd ed., Chapter 3 (“ L^p -spaces”, Riesz–Fischer theorem). No result of this chapter depends

on the missing link: every statement used elsewhere is proved under the ℓ^1 hypothesis.

21.5. BIBO stability: summability, annulus, poles

Definition 21.6: BIBO stability. A discrete LTI system $\mathcal{T}$ (Definition 21.2) is called **BIBO stable** (*bounded input, bounded output*) if there exists a constant $M < \infty$ such that

$$\|x\|_\infty \leq 1 \implies \|\mathcal{T}x\|_\infty \leq M$$

for every bounded input x . By linearity this is equivalent to: every bounded input produces a bounded output, with $\|\mathcal{T}x\|_\infty \leq M\|x\|_\infty$.

Theorem 21.10: BIBO $\iff$ absolutely summable impulse response. Let $\mathcal{T}$ be a discrete LTI system with impulse response h , with $\mathcal{T}x = h * x$ for every bounded input. Then

$$\mathcal{T} \text{ is BIBO stable } \iff h \in \ell^1(\mathbb{Z}),$$

and in that case the optimal constant of Definition 21.6 is exactly $M = \|h\|_1$.

Proof. Step 1 — sufficiency ($\Leftarrow$). Let $h \in \ell^1$. By Proposition 21.1(ii), for every bounded input the convolution series converges absolutely and

$$|y[n]| = \left| \sum_k h[k]x[n-k] \right| \leq \sum_k |h[k]| |x[n-k]| \leq \|x\|_\infty \sum_k |h[k]| = \|h\|_1 \|x\|_\infty$$

for every n : the system is BIBO stable with $M = \|h\|_1$.

Step 2 — necessity ($\Rightarrow$): construction of the critical input. Suppose the system is BIBO stable with constant M . Fix $N \in \mathbb{N}$ and define the signal

$$x_N[n] = \begin{cases} \frac{\overline{h[-n]}}{|h[-n]|}, & |n| \leq N \text{ and } h[-n] \neq 0, \\ 0, & \text{otherwise.} \end{cases}$$

It has finite support and $|x_N[n]| \leq 1$ for every n , hence $\|x_N\|_\infty \leq 1$ and by hypothesis $\|\mathcal{T}x_N\|_\infty \leq M$.

Step 3 — evaluating the output at time 0. By Proposition 21.1(i), applicable because x_N has finite support,

$$(\mathcal{T}x_N)[0] = \sum_{k \in \mathbb{Z}} h[k] x_N[-k] = \sum_{\substack{|k| \leq N \\ h[k] \neq 0}} h[k] \cdot \frac{\overline{h[k]}}{|h[k]|} = \sum_{\substack{|k| \leq N \\ h[k] \neq 0}} \frac{|h[k]|^2}{|h[k]|} = \sum_{|k| \leq N} |h[k]|,$$

having used $h[k]\overline{h[k]} = |h[k]|^2$ and being able to reinsert the indices with $h[k] = 0$, which contribute 0.

Step 4 — conclusion. The number just computed is a non-negative real number and by hypothesis does not exceed M :

$$\sum_{|k| \leq N} |h[k]| = (\mathcal{T}x_N)[0] \leq \|\mathcal{T}x_N\|_\infty \leq M \quad \text{for every } N.$$

The partial sums of the series with non-negative terms $\sum_k |h[k]|$ are thus uniformly bounded by M : the series converges and $\|h\|_1 \leq M$. Hence $h \in \ell^1(\mathbb{Z})$.

Step 5 — optimality of the constant. Step 1 gives $M \leq \|h\|_1$ as an admissible constant, and Step 4 gives $\|h\|_1 \leq M$ for every admissible constant M : the minimal constant is exactly $\|h\|_1$. $\square$

Corollary 21.4: BIBO $\iff$ the unit circle lies in the annulus. Under the hypotheses of Theorem 21.10 and setting $H = \mathcal{Z}\{h\}$, the system is BIBO stable if and only if $\mathbb{T} \subseteq \text{ROC}(h)$; and in that case H restricted to $\mathbb{T}$ is the **frequency response** $\hat{h}(\Omega) = H(e^{i\Omega})$, continuous, 2π -periodic and bounded by $\|h\|_1$.

Proof. By Theorem 21.10 BIBO stability is equivalent to $h \in \ell^1(\mathbb{Z})$, which by Theorem 21.6 is equivalent to $\mathbb{T} \subseteq \text{ROC}(h)$. The properties of the restriction are Theorem 21.7. $\square$

21.5.1 Causal rational systems: the location of the poles

To reach the pole criterion three algebraic tools are needed, all proved.

Lemma 21.2: Negative binomial series. For every integer $j \geq 1$ and every $w \in \mathbb{C}$ with $|w| < 1$,

$$\frac{1}{(1-w)^j} = \sum_{k \geq 0} \binom{j+k-1}{k} w^k,$$

with absolute convergence.

Proof. By induction on j .

Base case $j = 1$. $\binom{k}{k} = 1$ and the formula is the geometric series $\frac{1}{1-w} = \sum_k w^k$, absolutely convergent for $|w| < 1$.

Induction step. Suppose the formula holds for j . A power series is differentiated term by term inside its disk of convergence, which here is $|w| < 1$; on the left $\frac{d}{dw}(1-w)^{-j} = j(1-w)^{-j-1}$, on the right

$$\frac{d}{dw} \sum_{k \geq 0} \binom{j+k-1}{k} w^k = \sum_{k \geq 1} k \binom{j+k-1}{k} w^{k-1} = \sum_{k \geq 0} (k+1) \binom{j+k}{k+1} w^k.$$

Now, for every $k \geq 0$,

$$(k+1) \binom{j+k}{k+1} = (k+1) \cdot \frac{(j+k)!}{(k+1)!(j-1)!} = \frac{(j+k)!}{k!(j-1)!} = j \cdot \frac{(j+k)!}{k!j!} = j \binom{j+k}{k}.$$

Equating and dividing by $j \neq 0$ gives $\frac{1}{(1-w)^{j+1}} = \sum_{k \geq 0} \binom{j+k}{k} w^k$, which is the formula for $j+1$ since $\binom{(j+1)+k-1}{k} = \binom{j+k}{k}$. Absolute convergence for $|w| < 1$ is that of the differentiated series, which has the same radius as the original series. $\square$

Lemma 21.3: Partial fraction decomposition. Let N, D be polynomials with complex coefficients with $\deg N < \deg D =: d$ and $D(z) = c \prod_{\ell=1}^r (z - p_\ell)^{m_\ell}$, with $p_1, \dots, p_r$ distinct, $c \neq 0$ and $\sum_\ell m_\ell = d$. Then there exist, and are unique, complex numbers $A_{\ell,j}$ ($1 \leq \ell \leq r$, $1 \leq j \leq m_\ell$) such that

$$\frac{N(z)}{D(z)} = \sum_{\ell=1}^r \sum_{j=1}^{m_\ell} \frac{A_{\ell,j}}{(z - p_\ell)^j} \quad \text{for every } z \notin \{p_1, \dots, p_r\}.$$

Proof. Existence, by induction on r .

Case $r = 1$, that is $D(z) = c(z - p)^m$ with $m = d$. A polynomial N of degree $< m$ is rewritten in powers of $z - p$ (Taylor expansion of a polynomial, which is an exact finite sum): $N(z) = \sum_{i=0}^{m-1} \gamma_i (z - p)^i$ with $\gamma_i = N^{(i)}(p)/i!$. Dividing by D ,

$$\frac{N(z)}{D(z)} = \frac{1}{c} \sum_{i=0}^{m-1} \gamma_i (z - p)^{i-m} = \sum_{j=1}^m \frac{\gamma_{m-j}/c}{(z - p)^j},$$

which has the desired form with $A_{1,j} = \gamma_{m-j}/c$.

Induction step. Let $r \geq 2$ and write $D = D_1 D_2$ with $D_1(z) = (z - p_1)^{m_1}$ and $D_2(z) = c \prod_{\ell \geq 2} (z - p_\ell)^{m_\ell}$. The two polynomials are coprime, having no common roots (the p_ℓ are distinct); by Bézout's identity there exist polynomials U, V with $UD_1 + VD_2 = 1$. Then

$$\frac{N}{D} = \frac{N(UD_1 + VD_2)}{D_1 D_2} = \frac{NU}{D_2} + \frac{NV}{D_1}.$$

Divide with remainder: $NU = Q_2 D_2 + R_2$ with $\deg R_2 < \deg D_2$, and $NV = Q_1 D_1 + R_1$ with $\deg R_1 < \deg D_1$. Substituting,

$$\frac{N}{D} = (Q_1 + Q_2) + \frac{R_2}{D_2} + \frac{R_1}{D_1}.$$

The three fractions N/D , R_2/D_2 , R_1/D_1 are proper, that is they tend to 0 as $|z| \rightarrow \infty$ (numerator of strictly smaller degree than the denominator); hence the polynomial $Q_1 + Q_2$ tends to 0 at infinity and is therefore identically zero. What remains is $N/D = R_1/D_1 + R_2/D_2$: to the first term one applies the case $r = 1$, to the second the induction hypothesis (the denominator D_2 has $r - 1$ distinct roots), and one obtains the desired form.

Uniqueness. Reducing the sum $\sum_{\ell,j} A_{\ell,j} (z - p_\ell)^{-j}$ to a common denominator D/c gives a fraction whose numerator is a polynomial of degree $< d$; the map

$$\Phi : \mathbb{C}^d \rightarrow \{\text{polynomials of degree } < d\}, \quad (A_{\ell,j}) \mapsto \text{numerator of the sum},$$

is linear between two complex vector spaces of the same dimension d (recall $\sum_\ell m_\ell = d$), and is surjective by the existence part just proved: hence it is injective, and the coefficients $A_{\ell,j}$ are determined by N . $\square$

Lemma 21.4: Causal inverse transform of a pole of order j . Let $p \in \mathbb{C} \setminus \{0\}$ and $j \geq 1$ be integers. On the annulus $|z| > |p|$,

$$\frac{1}{(z - p)^j} = \sum_{n \geq j} \binom{n-1}{j-1} p^{n-j} z^{-n},$$

that is $\frac{1}{(z-p)^j} = \mathcal{Z}\{g_j\}$ with $g_j[n] = \binom{n-1}{j-1} p^{n-j} u[n-j]$. In particular g_j is causal and, setting $q_j(n) = \binom{n-1}{j-1}$, one has $g_j[n] = q_j(n) p^{n-j} p^n$ for $n \geq j$, with q_j a polynomial in n of degree $j - 1$.

Proof. For $|z| > |p|$ one has $|p/z| < 1$; collecting z and applying Lemma 21.2 with $w = p/z$:

$$\frac{1}{(z - p)^j} = \frac{1}{z^j (1 - \frac{p}{z})^j} = z^{-j} \sum_{k \geq 0} \binom{j+k-1}{k} \left(\frac{p}{z}\right)^k = \sum_{k \geq 0} \binom{j+k-1}{k} p^k z^{-(k+j)}.$$

Setting $n = k + j$, that is $k = n - j \geq 0$, and using $\binom{j+k-1}{k} = \binom{n-1}{n-j} = \binom{n-1}{j-1}$ (symmetry of the binomial coefficient), one obtains the formula. Convergence is absolute for $|z| > |p|$, hence

$\{|z| > |p|\} \subseteq \text{ROC}(g_j)$. Finally

$$q_j(n) = \binom{n-1}{j-1} = \frac{(n-1)(n-2)\cdots(n-j+1)}{(j-1)!}$$

is, for $j \geq 1$, a polynomial in n of degree exactly $j-1$ (for $j=1$ it is the constant 1). $\square$

Theorem 21.11: The annulus of a causal rational system. Let $H = N/D$ be proper rational and reduced to lowest terms, with poles $p_1, \dots, p_r$ nonzero and distinct, of multiplicities $m_1, \dots, m_r$, and let $\rho^* = \max_\ell |p_\ell|$. Let h be the causal signal with $\mathcal{Z}\{h\} = H$ on the annulus $\{|z| > \rho^*\}$. Then

(i) h exists and is given by

$$h[n] = c_0 \delta[n] + \sum_{\ell=1}^r \sum_{j=1}^{m_\ell} A_{\ell,j} \binom{n-1}{j-1} p_\ell^{n-j} u[n-j],$$

with $c_0 = \lim_{|z| \rightarrow \infty} H(z)$ and $A_{\ell,j}$ the coefficients of Lemma 21.3 applied to $H - c_0$;

(ii) $\text{ROC}(h) = \{|z| > \rho^*\}$ exactly: no point with $|z| \leq \rho^*$ belongs to it.

Proof. (i). Since H is proper, $\deg N \leq \deg D$; dividing with remainder, $N = c_0 D + \tilde{N}$ with $c_0 \in \mathbb{C}$ and $\deg \tilde{N} < \deg D$, so that $H = c_0 + \tilde{N}/D$ and $c_0 = \lim_{|z| \rightarrow \infty} H(z)$. Lemma 21.3 decomposes $\tilde{N}/D$ into partial fractions, and Lemma 21.4 inverts each fraction on the annulus $|z| > |p_\ell|$; since $\{|z| > \rho^*\} \subseteq \{|z| > |p_\ell|\}$ for every ℓ , all the series converge absolutely on $\{|z| > \rho^*\}$, and by linearity (Theorem 21.5(i)) their combination, added to $c_0 = \mathcal{Z}\{c_0 \delta\}$, gives exactly H on that annulus. The resulting signal is causal because each term is.

(ii). By Corollary 21.1 the region of convergence of h is $\{|z| > \rho_+\}$ or its closure, with $\rho_+ = \limsup_n |h[n]|^{1/n}$, and point (i) shows $\rho_+ \leq \rho^*$. Suppose for contradiction that there exists $z_1 \in \text{ROC}(h)$ with $|z_1| \leq \rho^*$; by rotation invariance (Theorem 21.1(ii)) the whole circle $|z| = |z_1| =: s \leq \rho^*$ lies in $\text{ROC}(h)$, and since h is causal, for every $|z| \geq s$ one has $|h[n]z^{-n}| \leq |h[n]|s^{-n}$, hence

$$|G(z)| := \left| \sum_{n \geq 0} h[n]z^{-n} \right| \leq \sum_{n \geq 0} |h[n]| s^{-n} =: C < \infty \quad \text{for every } |z| \geq s.$$

Now let p be a pole with $|p| = \rho^*$ and, for $t > 1$, consider the point $z_t = tp$. Then $|z_t| = t\rho^* > \rho^* \geq s$, hence z_t lies in the annulus $\{|z| > \rho^*\}$ where $G = H$ by hypothesis, and together $|G(z_t)| \leq C$. But $z_t \rightarrow p$ as $t \rightarrow 1^+$ and p is a pole of H : since $H = N/D$ is reduced to lowest terms, $N(p) \neq 0$ and $D(p) = 0$, hence $|H(z_t)| = |N(z_t)|/|D(z_t)| \rightarrow +\infty$ (numerator with limit $|N(p)| > 0$, denominator infinitesimal and nonzero for $t > 1$ close enough to 1, because the zeros of D are isolated). This contradicts $|H(z_t)| = |G(z_t)| \leq C$. Hence no z with $|z| \leq \rho^*$ belongs to $\text{ROC}(h)$, and by Corollary 21.1 $\text{ROC}(h) = \{|z| > \rho^*\}$. $\square$

Theorem 21.12: BIBO stability in the Z-domain. A causal discrete LTI system with transfer function $H(z) = \mathcal{Z}\{h[n]\}$ is BIBO stable if and only if all poles of $H(z)$ lie strictly inside the unit circle: $|z| < 1$.

Proof. Recall the criterion in the time domain: a discrete LTI system is BIBO stable if and only if its impulse response is *summable*, that is $\sum_{n \geq 0} |h[n]| < \infty$. (Sufficiency is immediate: if $|x[n]| \leq M$ then $|y[n]| = |\sum_k h[k]x[n-k]| \leq M \sum_k |h[k]|$. Necessity is obtained by choosing the bounded input $x[n-k] = \bar{h}[k]/|h[k]|$ where $h[k] \neq 0$, which makes $y[n] = \sum_k |h[k]|$.) Both directions are proved in full in Theorem 21.10. It thus suffices to show that summability

of h is equivalent to the location of the poles. It is assumed, as is implicit in speaking of “poles”, that H is proper rational and reduced to lowest terms, with nonzero poles $p_1, \dots, p_r$; set $\rho^* = \max_\ell |p_\ell|$.

Step 1 — structure of h . Let $H(z) = N(z)/D(z)$ be proper rational with poles $p_1, \dots, p_r$ of multiplicities $m_1, \dots, m_r$. Decomposing into partial fractions and inverting term by term, the causal impulse response is a finite linear combination of sequences of the form

$$n^j p_\ell^n u[n], \quad 0 \leq j \leq m_\ell - 1.$$

This is exactly the content of Theorem 21.11(i), proved starting from Lemma 21.3 (existence and uniqueness of partial fractions) and Lemma 21.4 (causal inverse transform of a pole of order j): the coefficient $\binom{n-1}{j-1}$ appearing there is a polynomial in n of degree $j-1 \leq m_\ell - 1$, that is a linear combination of $1, n, \dots, n^{m_\ell-1}$.

Step 2 — interior poles $\Rightarrow$ summability. If $|p_\ell| < 1$ for every ℓ , then for every fixed j

$$\sum_{n \geq 0} n^j |p_\ell|^n < \infty,$$

because the ratio test gives $|p_\ell| < 1$ as its limit (the polynomial factor $((n+1)/n)^j \rightarrow 1$ does not alter the limit); equivalently, the root test gives $(n^j |p_\ell|^n)^{1/n} = (n^{1/n})^j |p_\ell| \rightarrow |p_\ell| < 1$, since $n^{1/n} \rightarrow 1$. A finite linear combination of absolutely convergent series converges absolutely, hence $\sum_n |h[n]| < \infty$ and, by Theorem 21.10, the system is BIBO stable.

Step 3 — a non-interior pole $\Rightarrow$ non-summability. Let p be a pole of maximal modulus $\rho^* = |p| \geq 1$. If h were summable, the series $H(z) = \sum_{n \geq 0} h[n]z^{-n}$ would converge absolutely for every $|z| \geq 1$ — since $|h[n]z^{-n}| \leq |h[n]|$ — and would define a continuous and bounded function on $\{|z| \geq 1\}$. But H has a pole at p with $|p| \geq 1$, hence $|H(z)| \rightarrow \infty$ as $z \rightarrow p$: a contradiction. In full: summability of h means $1 \in \text{ROC}(h)$ in the sense that $\mathbb{T} \subseteq \text{ROC}(h)$ (Theorem 21.6), while Theorem 21.11(ii) states $\text{ROC}(h) = \{|z| > \rho^*\}$, a set containing no point of $\mathbb{T}$ when $\rho^* \geq 1$. Hence h is not summable and the system is not BIBO stable.

Conclusion. Summability of $h \iff$ all poles in $|z| < 1$, and by the criterion recalled at the beginning this is equivalent to BIBO stability. Note that poles *on* the unit circle give BIBO instability even though they produce bounded responses (for example $h[n] = u[n]$ for $p = 1$): the system is *marginally* stable, and this is why $\mathbb{T}$ is the boundary and not part of the region of stability. $\square$

Example 21.4: The pole on the boundary: bounded response, unstable system.

Let $H(z) = \frac{z}{z-1}$, that is the discrete integrator $y[n] = y[n-1] + x[n]$, with a simple pole at $p = 1$. The impulse response is $h[n] = u[n]$ (Example 21.2 with $a = 1$), *bounded*: $\|h\|_\infty = 1$. Yet $\sum_n |h[n]| = \sum_{n \geq 0} 1 = +\infty$, hence by Theorem 21.10 the system is not BIBO stable. One sees this also directly: the bounded input $x[n] = u[n]$ produces $y[n] = \sum_{k=0}^n 1 = n+1 \rightarrow +\infty$. The annulus is $\{|z| > 1\}$, which does not contain $\mathbb{T}$, in agreement with Corollary 21.4. This is the case cited in the *Conclusion* of the proof of Theorem 21.12: a pole on the unit circle is already too much.

Example 21.5: A second-order system, verified three times. Let $y[n] = y[n-1] - 0.24y[n-2] + x[n]$, that is

$$H(z) = \frac{1}{1 - z^{-1} + 0.24z^{-2}} = \frac{z^2}{z^2 - z + 0.24} = \frac{z^2}{(z - 0.6)(z - 0.4)},$$

since $z^2 - z + 0.24$ has discriminant $1 - 0.96 = 0.04$ and roots $\frac{1 \pm 0.2}{2} = 0.6$ and 0.4 . Both poles have modulus < 1 : by Theorem 21.12 the system is BIBO stable.

Impulse response. Since H is proper with $\deg N = \deg D$, one applies Theorem 21.11(i). It is convenient to decompose $H(z)/z$:

$$\frac{H(z)}{z} = \frac{z}{(z-0.6)(z-0.4)} = \frac{A}{z-0.6} + \frac{B}{z-0.4},$$

with $A = \frac{0.6}{0.6-0.4} = 3$ and $B = \frac{0.4}{0.4-0.6} = -2$; multiplying by z and inverting with Example 21.2 (outer annulus, the system is causal):

$$H(z) = \frac{3z}{z-0.6} - \frac{2z}{z-0.4}, \quad h[n] = (3 \cdot 0.6^n - 2 \cdot 0.4^n)u[n].$$

First check (recursion). Iterating the difference equation with $x = \delta$ gives $h[0] = 1$, $h[1] = 1$, $h[2] = 0.76$, $h[3] = 0.52$, $h[4] = 0.3376$, $h[5] = 0.2128$; the closed formula gives $3 - 2 = 1$, $1.8 - 0.8 = 1$, $1.08 - 0.32 = 0.76$, $0.648 - 0.128 = 0.52$, $0.3888 - 0.0512 = 0.3376$, $0.23328 - 0.02048 = 0.2128$. Over 200 samples the maximum discrepancy between the two routes is $2.2 \cdot 10^{-16}$. ✓

Second check (ℓ^1 norm and DC gain). Since $3 \cdot 0.6^n > 2 \cdot 0.4^n$ for every $n \geq 0$ (the ratio equals $1.5 \cdot 1.5^n \geq 1.5$), one has $h[n] > 0$ and hence

$$\|h\|_1 = \sum_{n \geq 0} h[n] = \frac{3}{1-0.6} - \frac{2}{1-0.4} = 7.5 - \frac{10}{3} = \frac{25}{6} = 4.166\,666\,7,$$

which coincides with $H(1) = \frac{1}{1-1+0.24} = \frac{1}{0.24} = 4.166\,666\,7$, as it must because $H(1) = \sum_n h[n]$ and the terms are positive. ✓

Third check (Parseval). Summing the series, $\sum_n |h[n]|^2 = 3.034\,931\,077\,7$; the closed formula $\frac{9}{1-0.36} - \frac{12}{1-0.24} + \frac{4}{1-0.16} = 3.034\,931\,077\,7$; and the integral $\frac{1}{2\pi} \int_{-\pi}^{\pi} |H(e^{i\Omega})|^2 d\Omega$, evaluated with 200,000 points, 3.0349310777: three independent routes, the same number, in agreement with Theorem 21.9. ✓

Worked example — geometric sequence and first-order digital filter. Let $x[n] = a^n u[n]$ (causal sequence, $u[n]$ discrete step). Then

$$X(z) = \sum_{n=0}^{\infty} a^n z^{-n} = \sum_{n=0}^{\infty} \left(\frac{a}{z}\right)^n = \frac{1}{1-a/z} = \frac{z}{z-a}, \quad \text{ROC: } |z| > |a|,$$

(geometric series of ratio a/z , convergent for $|a/z| < 1$). Consider now the first-order recursive digital filter $y[n] = ay[n-1] + bx[n]$ (for instance an exponential moving average, often used to filter sensor noise before PID computation). Transforming (with the delay property, analogous to Laplace, that is Theorem 21.5(ii)):

$$Y(z) = az^{-1}Y(z) + bX(z) \implies H(z) = \frac{Y(z)}{X(z)} = \frac{b}{1-az^{-1}} = \frac{bz}{z-a},$$

with a single pole at $z = a$: the filter is BIBO stable if and only if $|a| < 1$. Note the parallel with the Worked example of Section 4.8 (Volume II, Chapter 4): if this discrete filter samples, with period T , the first-order continuous system with time constant τ , the discrete pole is $a = e^{-T/\tau}$, which automatically satisfies $|a| < 1$ for every $T, \tau > 0$ — the stability of the continuous system is transmitted to the sampled system, exactly as predicted by Remark 21.8.

21.6. The three planes: Laplace, zeta and Fourier

The s -plane of the Laplace transform (Chapter 20), the z -plane of the Z-transform and the frequency axis of the Fourier transform are not three separate worlds: they are three views of

one and the same object, linked by two maps that we study here in full. The first is exact but not injective, the second is injective but approximate.

Theorem 21.13: The exponential sampling map. Let $T > 0$ and let $\Phi : \mathbb{C} \rightarrow \mathbb{C}$, $\Phi(s) = e^{sT}$. Then

(i) $|\Phi(s)| = e^{T \operatorname{Re}(s)}$, and hence

$$\operatorname{Re}(s) < 0 \iff |\Phi(s)| < 1, \quad \operatorname{Re}(s) = 0 \iff |\Phi(s)| = 1,$$

$$\operatorname{Re}(s) > 0 \iff |\Phi(s)| > 1;$$

(ii) $\Phi(\mathbb{C}) = \mathbb{C} \setminus \{0\}$: the map is surjective onto the punctured plane;

(iii) $\Phi(s) = \Phi(s')$ if and only if $s - s' \in \frac{2\pi i}{T}\mathbb{Z}$;

(iv) the restriction of Φ to the strip $S = \{s : -\pi/T < \operatorname{Im}(s) \leq \pi/T\}$ is a bijection onto $\mathbb{C} \setminus \{0\}$, which sends $S \cap \{\operatorname{Re} s < 0\}$ onto the punctured disk $\{0 < |z| < 1\}$ and $S \cap \{\operatorname{Re} s = 0\}$ onto $\mathbb{T}$.

Proof. Write $s = \sigma + i\omega$ with $\sigma, \omega \in \mathbb{R}$.

(i). $e^{sT} = e^{\sigma T} e^{i\omega T}$ and $|e^{i\omega T}| = 1$, hence $|\Phi(s)| = e^{\sigma T}$. Since $t \mapsto e^t$ is strictly increasing with $e^0 = 1$, one has $e^{\sigma T} < 1 \iff \sigma T < 0 \iff \sigma < 0$ (since $T > 0$), and similarly for the other two cases.

(ii). Let $z \neq 0$. Writing $z = \rho e^{i\theta}$ with $\rho > 0$ and $\theta \in \mathbb{R}$ (polar form, Chapter 6), set $s = \frac{\ln \rho}{T} + i\frac{\theta}{T}$: then $\Phi(s) = e^{\ln \rho} e^{i\theta} = \rho e^{i\theta} = z$. Conversely $\Phi(s) \neq 0$ for every s , because $|\Phi(s)| = e^{\sigma T} > 0$.

(iii). $\Phi(s) = \Phi(s')$ is equivalent to $e^{(s-s')T} = 1$; and the complex exponential equals 1 exactly at integer multiples of $2\pi i$, hence $(s - s')T \in 2\pi i\mathbb{Z}$, that is $s - s' \in \frac{2\pi i}{T}\mathbb{Z}$.

(iv). Two distinct points of S have imaginary parts differing by less than $2\pi/T$ in absolute value, hence they cannot differ by a nonzero multiple of $2\pi i/T$: by (iii) $\Phi|_S$ is injective. It is surjective onto $\mathbb{C} \setminus \{0\}$ because, given $z \neq 0$, the point s constructed in (ii) is brought into S by choosing the unique argument $\theta \in (-\pi, \pi]$ of z . The two final statements follow from (i) and from $|z| > 0$. $\square$

Remark 21.8: Why precisely the unit circle. If a continuous signal $x_c(t)$ is sampled with period T obtaining $x[n] = x_c(nT)$, the (ideal) correspondence between the s and z planes is $z = e^{sT}$: the imaginary axis $s = i\omega$ (stability boundary in continuous time) maps to $z = e^{i\omega T}$, which is precisely $\mathbb{T}$ (stability boundary in discrete time), while the left half-plane $\operatorname{Re}(s) < 0$ (continuous stability) maps to the interior of the unit circle $|z| = |e^{sT}| = e^{\operatorname{Re}(s)T} < 1$. The unit circle $\mathbb{T}$ of Chapter 3 is therefore not merely an abstract geometric object: it is literally the stability boundary of every digital control system, including PLCs. This is also exactly the geometric phenomenon encountered in Corollary 3.3 of Chapter 3, where the Möbius transformation $w = (z - 1)/(z + 1)$ mapped $\mathbb{T}$ to the imaginary axis: that is, up to a scaling factor $2/T$, the bilinear transform used to approximate $z = e^{sT}$ in digital control practice. All the statements listed here are points (i) and (iv) of Theorem 21.13, and the two references to “Chapter 3” are to Volume II, Chapter 3.

Remark 21.9: Non-injectivity is aliasing. Theorem 21.13(iii) says that Φ identifies with each other all points that differ by a multiple of $2\pi i/T$: in particular the angular frequencies ω and $\omega + 2\pi/T = \omega + 2\pi f_s$ produce the same point of the z -plane, and hence the same sampled sequence. This is **aliasing**: two continuous sinusoids whose frequencies differ by a multiple of the sampling frequency are indistinguishable after sampling. The strip S of point (iv) is the canonical choice of a representative for each class, and corresponds

exactly to the frequency interval $(-f_s/2, f_s/2]$: the Nyquist band. The periodicity of the DTFT (Proposition 21.2) is the same thing read from the other side: on the circle there is room for no more than a single lap.

21.6.1 The bilinear transform

Definition 21.7: Bilinear transform (Tustin's). Let $T > 0$. The **bilinear transform** of step T is the map

$$\beta(s) = \frac{1 + \frac{T}{2}s}{1 - \frac{T}{2}s}, \quad s \neq \frac{2}{T},$$

with inverse map

$$\beta^{-1}(z) = \frac{2}{T} \cdot \frac{z - 1}{z + 1}, \quad z \neq -1.$$

It is the Möbius transformation $s \mapsto \frac{as+b}{cs+d}$ with $a = \frac{T}{2}$, $b = 1$, $c = -\frac{T}{2}$, $d = 1$, of determinant $ad - bc = \frac{T}{2} + \frac{T}{2} = T \neq 0$ (Chapter 6).

Theorem 21.14: The bilinear transform sends the left half-plane to the unit disk.

Let β be as in Definition 21.7 and let $\mathbb{H}^- = \{s \in \mathbb{C} : \operatorname{Re}(s) < 0\}$. Then

(i) for every $s \neq 2/T$ the identity holds

$$|\beta(s)|^2 - 1 = \frac{2T \operatorname{Re}(s)}{|1 - \frac{T}{2}s|^2};$$

(ii) β is a bijection from $\mathbb{H}^-$ onto $\mathbb{D}$, with inverse β^{-1} ;

(iii) β is a bijection from the imaginary axis $i\mathbb{R}$ onto $\mathbb{T} \setminus \{-1\}$, and $\beta(s) \rightarrow -1$ as $|s| \rightarrow \infty$ along $i\mathbb{R}$;

(iv) β sends $\{\operatorname{Re}(s) > 0\} \setminus \{2/T\}$ onto $\{|z| > 1\}$.

Proof. Step 1 — an elementary identity. For every $w \in \mathbb{C}$,

$$\begin{aligned} |1 + w|^2 - |1 - w|^2 &= (1 + w)(\overline{1 + w}) - (1 - w)(\overline{1 - w}) \\ &= (1 + w + \bar{w} + |w|^2) - (1 - w - \bar{w} + |w|^2) = 2(w + \bar{w}) = 4 \operatorname{Re}(w). \end{aligned}$$

(Numerical check: for $w = 0.3 + 0.4i$ the left-hand side equals $|1.3 + 0.4i|^2 - |0.7 - 0.4i|^2 = 1.85 - 0.65 = 1.2$ and the right-hand side $4 \cdot 0.3 = 1.2$. ✓)

Step 2 — (i). Setting $w = \frac{T}{2}s$, one has $\beta(s) = \frac{1+w}{1-w}$ with $1 - w \neq 0$, hence

$$|\beta(s)|^2 - 1 = \frac{|1 + w|^2 - |1 - w|^2}{|1 - w|^2} = \frac{4 \operatorname{Re}(w)}{|1 - w|^2} = \frac{4 \cdot \frac{T}{2} \operatorname{Re}(s)}{|1 - \frac{T}{2}s|^2} = \frac{2T \operatorname{Re}(s)}{|1 - \frac{T}{2}s|^2}.$$

Step 3 — (ii). The denominator in (i) is positive and $2T > 0$, hence $|\beta(s)| < 1 \iff \operatorname{Re}(s) < 0$. It remains to prove bijectivity. Observe that $s \in \mathbb{H}^-$ implies $\operatorname{Re}(1 - \frac{T}{2}s) = 1 - \frac{T}{2} \operatorname{Re}(s) > 1 > 0$, hence β is defined on all of $\mathbb{H}^-$. For $z \neq -1$ one has

$$\beta(\beta^{-1}(z)) = \frac{1 + \frac{T}{2} \cdot \frac{2}{T} \frac{z-1}{z+1}}{1 - \frac{T}{2} \cdot \frac{2}{T} \frac{z-1}{z+1}} = \frac{\frac{(z+1)+(z-1)}{z+1}}{\frac{(z+1)-(z-1)}{z+1}} = \frac{2z}{2} = z,$$

and, symmetrically, $\beta^{-1}(\beta(s)) = s$ for every $s \neq 2/T$ (same computation with roles swapped). Since $-1 \notin \mathbb{D}$, the map β^{-1} is defined on all of $\mathbb{D}$; and for $z \in \mathbb{D}$ the point $s = \beta^{-1}(z)$ satisfies

$|\beta(s)| = |z| < 1$, hence $\operatorname{Re}(s) < 0$ by (i), that is $s \in \mathbb{H}^-$. The two maps are thus inverse to each other between $\mathbb{H}^-$ and $\mathbb{D}$.

Step 4 — (iii). By (i), $|\beta(s)| = 1 \iff \operatorname{Re}(s) = 0$; and $\beta(i\omega) = -1$ would require $1 + \frac{T}{2}i\omega = -1 + \frac{T}{2}i\omega$, that is $1 = -1$, impossible: hence $\beta(i\mathbb{R}) \subseteq \mathbb{T} \setminus \{-1\}$. Conversely every $z \in \mathbb{T} \setminus \{-1\}$ has preimage $s = \beta^{-1}(z)$, which by (i) has zero real part. Finally, dividing numerator and denominator by s , $\beta(s) = \frac{1/s + T/2}{1/s - T/2} \rightarrow \frac{T/2}{-T/2} = -1$ as $|s| \rightarrow \infty$.

Step 5 — (iv). Again by (i): $|\beta(s)| > 1 \iff \operatorname{Re}(s) > 0$. □

Corollary 21.5: Deformation of the frequency axis, or warping. For $\omega \in \mathbb{R}$ one has $\beta(i\omega) = e^{i\Omega}$ with

$$\Omega = 2 \arctan\left(\frac{\omega T}{2}\right), \quad \text{equivalently} \quad \omega = \frac{2}{T} \tan\left(\frac{\Omega}{2}\right), \quad \Omega \in (-\pi, \pi).$$

The correspondence $\omega \mapsto \Omega$ is a strictly increasing bijection of $\mathbb{R}$ onto $(-\pi, \pi)$, with $\Omega \simeq \omega T$ for small ωT and $\Omega \rightarrow \pm\pi$ as $\omega \rightarrow \pm\infty$.

Proof. Setting $u = \frac{\omega T}{2} \in \mathbb{R}$, one has $\beta(i\omega) = \frac{1+iu}{1-iu}$. The numerator has modulus $\sqrt{1+u^2}$ and argument $\arctan u$ (it lies in the right half-plane, where the arctangent gives the principal argument); the denominator is its conjugate, hence has the same modulus and argument $-\arctan u$. The quotient thus has modulus 1 and argument $\arctan u - (-\arctan u) = 2 \arctan u$:

$$\beta(i\omega) = e^{i2 \arctan u} = e^{i\Omega}, \quad \Omega = 2 \arctan \frac{\omega T}{2}.$$

The function $\arctan$ is a strictly increasing bijection of $\mathbb{R}$ onto $(-\frac{\pi}{2}, \frac{\pi}{2})$, hence so is $\Omega = 2 \arctan u$ of $\mathbb{R}$ onto $(-\pi, \pi)$, and inverting, $\tan(\Omega/2) = u = \omega T/2$, that is $\omega = \frac{2}{T} \tan(\Omega/2)$. As $u \rightarrow 0$ one has $\arctan u = u + O(u^3)$, hence $\Omega = \omega T + O((\omega T)^3)$; and $\arctan u \rightarrow \pm\frac{\pi}{2}$ as $u \rightarrow \pm\infty$ gives $\Omega \rightarrow \pm\pi$. □

Figure 21.2: The bilinear transform of Theorem 21.14: the left half-plane goes to the unit disk, the imaginary axis to the unit circle minus -1 (empty circle). The correspondences drawn are exact: $0 \mapsto 1$, $-\frac{1}{2} \mapsto \frac{1}{3}$, $-1 \mapsto 0$, $\frac{i}{2} \mapsto \frac{3}{5} + \frac{4}{5}i$, $\pm i \mapsto \pm i$; and indeed $\frac{1+i/2}{1-i/2} = \frac{(1+i/2)^2}{5/4} = \frac{3/4+i}{5/4} = \frac{3}{5} + \frac{4}{5}i$, of modulus 1. The radius of the disk is 1.6 cm and the points are placed by multiplying the exact coordinates by 1.6.

Remark 21.10: The two maps compared. The exact map $\Phi(s) = e^{sT}$ and the rational approximation β agree to first order, because $e^{w'} = 1 + w' + O(w'^2)$ and $\frac{1+w}{1-w} = 1 + 2w + O(w^2)$ give, with $w = \frac{T}{2}s$ and $w' = sT$, the same expansion $1 + sT + O((sT)^2)$; but they differ

Figure 21.3: The *warping* of Corollary 21.5. The values used to draw the curve are computed exactly: $2 \arctan u$ equals 0, 0.927 295 2, 1.570 796 3, 1.965 587 4, 2.214 297 4, 2.498 091 5, 2.651 635 3 and 2.694 639 5 for $u = 0; 0.5; 1; 1.5; 2; 3; 4; 4.4$, with asymptote $\pi = 3.141 592 7$; in the drawing the unit on the ordinate axis is 1.2 cm, so that $\pi \mapsto 3.77$ cm and $\pi/2 \mapsto 1.885$ cm, and the unit on the abscissa is 1.2 cm. For small u the curve is indistinguishable from the line $\Omega = 2u = \omega T$; higher up it saturates at π , that is at the Nyquist frequency: the bilinear transform compresses the whole real axis of continuous frequencies into a single Nyquist band, without aliasing but with deformation.

globally in an essential way. Φ respects moduli exactly and destroys injectivity (aliasing, Remark 21.9); β is injective and preserves the stability boundary exactly, but deforms frequencies (Corollary 21.5). Numerically, with $T = 10^{-3}$:

s	e^{sT}	$ e^{sT} $	$\beta(s)$
-100	0.904 837 4	0.904 837 4	0.904 761 9
-1,000	0.367 879 4	0.367 879 4	0.333 333 3
$1,000 i$	$0.540 302 3 + 0.841 471 0 i$	1	$0.6 + 0.8 i$
+500	1.648 721 3	1.648 721 3	1.666 666 7

Both columns of moduli respect the criterion: modulus < 1 for $\operatorname{Re} s < 0$, $= 1$ on the axis, > 1 on the right. The value $\beta(1,000 i) = 0.6 + 0.8i$ is exact (it is the point of Figure 21.2), and $|0.6 + 0.8i| = 1$ because $0.36 + 0.64 = 1$. ✓

Remark 21.11: Beyond Tustin: the generalized bilinear transform. Tustin’s bilinear transform of Corollary 3.3 (Volume II, Chapter 3) is not the only way to discretize a continuous system: it is the particular case $\alpha = 1/2$ of a one-parameter family, the **generalized bilinear transform** (GBT), which also includes as extreme cases the forward Euler method ($\alpha = 0$) and the backward Euler method ($\alpha = 1$). The choice of α governs a well-known trade-off in digital control between frequency accuracy and the numerical stability margin of the discretized system, and is still the subject of active research: a 2025 paper by a Chinese research group (Chen, Li, Cui et al., reference *unverified*: see the warning below) explicitly addresses the problem of choosing α optimally, showing that the physical interpretation of the parameter and its optimal selection had remained, surprisingly, little explored in the literature until recent times. It is a good reminder that the elementary geometry of the circle and digital control are neither closed topics nor far apart.

Warning. An inherited, unverified reference. The reference to the 2025 paper cited in Remark 21.11 comes from Volume II, where it was given as “cited in the bibliography”; the check made for this chapter shows that that entry does *not* appear in the bibliography of Volume III, and it was not possible to verify its authors, title or venue. The reference is therefore kept but marked as unverified, and remains an open point of the chapter. No statement, computation or proof of this chapter relies on it: the GBT family is defined and verified directly in Exercise 21.2, whose three particular cases are computed in full in the solution.

The three planes in one line.

$$\underbrace{s = \sigma + i\omega}_{\text{Laplace}} \xrightarrow{z=e^{sT}} \underbrace{z \in \mathbb{C}}_{\text{zeta}} \xrightarrow{z=e^{i\Omega}} \underbrace{\Omega \in \mathbb{R}}_{\text{Fourier}}$$

$$\operatorname{Re}(s) < 0 \longleftrightarrow |z| < 1, \quad \operatorname{Re}(s) = 0 \longleftrightarrow |z| = 1,$$

$$\Omega = \omega T \text{ (exact sampling)}, \quad \Omega = 2 \arctan \frac{\omega T}{2} \text{ (bilinear)}.$$

21.7. Digital filter design: from continuous to discrete

We now put to work together the Laplace transform, the Z-transform and the (generalized) bilinear transform of Remark 21.11, to solve a problem that arises in virtually every automation project: filtering the noise of an analog sensor (temperature, pressure, level, a 4–20 mA signal) before using it in a PID control loop.

From analog filter to digital filter in four steps Step 1. Specify the filter in the continuous domain: for a first-order Butterworth low-pass with cutoff frequency $\omega_c = 2\pi f_c$, $H(s) = \frac{\omega_c}{s + \omega_c}$ (unity DC gain, -3 dB at ω_c).

Step 2. Apply the bilinear transform (Corollary 3.3 of Volume II, Chapter 3; here Definition 21.7 and Theorem 21.14, case $\alpha = 1/2$ of the family of Remark 21.11): $s = \frac{2}{T} \cdot \frac{z-1}{z+1}$, where $T = 1/f_s$ is the sampling period.

Step 3. Obtain $H(z)$ and rewrite it in the form $H(z) = b_0 \frac{1+z^{-1}}{1-pz^{-1}}$, yielding the difference equation $y[n] = py[n-1] + b_0(x[n] + x[n-1])$, immediately implementable in a PLC scan cycle.

Step 4. Verify stability ($|p| < 1$, Theorem 21.12) and the frequency response of the resulting discrete filter. $\square$

Worked example — anti-noise filter for a 4–20 mA sensor. A PLC samples a level sensor at $f_s = 1000$ Hz ($T = 1$ ms, a typical fast scan time) and must attenuate electrical noise above $f_c = 10$ Hz (the useful level dynamics are much slower). Applying Step 2 to $H(s) = \omega_c/(s + \omega_c)$ with $\omega_c = 2\pi \cdot 10 \approx 62.83$ rad/s and $K = 2/T = 2000$:

$$H(z) = \frac{\omega_c}{\frac{2}{T} \cdot \frac{z-1}{z+1} + \omega_c} = \frac{\omega_c(z+1)}{(K + \omega_c)z + (\omega_c - K)}.$$

Dividing numerator and denominator by $(K + \omega_c)$ yields the standard form with

$$b_0 = \frac{\omega_c}{K + \omega_c} \approx \frac{62.83}{2062.83} \approx 0.03046, \quad p = \frac{K - \omega_c}{K + \omega_c} \approx \frac{1937.17}{2062.83} \approx 0.93908.$$

Since $|p| \approx 0.939 < 1$, the filter is BIBO stable (Theorem 21.12). The final difference equation is

$$y[n] = 0.93908 y[n-1] + 0.03046(x[n] + x[n-1]).$$

Direct numerical checks: the DC gain is $H(1) = 1$ exact (no offset introduced); at the cutoff frequency, $|H(e^{i\omega_c T})| \approx 0.707$ (−3.01 dB, as expected by construction); and at typical industrial electrical noise frequencies the filter attenuates strongly: −14.2 dB at 50 Hz, −20.3 dB at 100 Hz, −27.3 dB at 200 Hz (a factor of ≈ 23 in amplitude).

Remark 21.12: The filter’s numbers, recomputed twice. The values of the worked example were recomputed by two independent routes.

First route — closed formula. With $\omega_c = 62.831\,853$ and $K = 2,000$: $b_0 = 0.030\,459\,03$ and $p = 0.939\,081\,94$; and $|H(e^{i2\pi f T})|$ with $H(z) = b_0 \frac{1+z^{-1}}{1-pz^{-1}}$ equals

f (Hz)	0	10	50	100	200
$ H $	1.000 000 0	0.706 990 4	0.194 561 9	0.096 239 5	0.043 199 9
dB	0.00	−3.01	−14.22	−20.33	−27.29

Second route — simulation of the difference equation. Running $y[n] = p y[n-1] + b_0(x[n] + x[n-1])$ over 400,000 samples with input $x[n] = \cos(2\pi f T n)$ and measuring the steady-state amplitude gives 0.706 6 at 10 Hz, 0.193 2 at 50 Hz, 0.094 0 at 100 Hz and 0.041 6 at 200 Hz: the two routes agree within the residual transient and discretization of the maximum (< 0.003 in amplitude, < 0.33 dB). ✓ In particular the attenuation at 200 Hz is a factor $1/0.043\,1999 = 23.15$ in amplitude, consistent with the “ ≈ 23 ” of the worked example. ✓

Remark 21.13: A warning: frequency warping. The bilinear transform is not an exact correspondence between continuous and discrete frequencies: the true relation is $\omega_d = \frac{2}{T} \arctan(\omega_c T/2)$ (frequency warping), not $\omega_d = \omega_c T$. For $f_c \ll f_s$ as in the previous example (10 Hz versus 1000 Hz) the effect is negligible (the numerical check $|H(e^{i\omega_c T})| \approx 0.707$ confirms it), but for cutoffs near the Nyquist frequency the designer must pre-warp the analog specification, that is design $H(s)$ not for ω_c but for $\omega'_c = \frac{2}{T} \tan(\omega_c T/2)$, so that after the warping of the bilinear transform the cutoff falls exactly where desired.

The formula used here is proved in Corollary 21.5: with $\Omega = \omega_d T$ the relation $\Omega = 2 \arctan(\omega_c T/2)$ becomes precisely $\omega_d = \frac{2}{T} \arctan(\omega_c T/2)$, and its inverse is the pre-warping rule $\omega'_c = \frac{2}{T} \tan(\omega_c T/2)$. The numerical check confirms the estimate on the example: for $f_c = 10$ Hz and $f_s = 1000$ Hz one has $\omega_c T = 0.062\,831\,9$ and $\Omega = 0.062\,811\,2$, a relative gap of $3.3 \cdot 10^{-4}$; for $f_c = 200$ Hz at the same sampling frequency one instead has $\omega_c T = 1.256\,637\,1$ against $\Omega = 1.121\,964\,2$, a relative gap of 11%, and without pre-warping the cutoff would fall at 178.566 2 Hz instead of 200 Hz. ✓ (The full computation is Worked exercise 21.9.)

END_FUNCTION_BLOCK

```

Remark 21.14: Implementation note for a PLC. Unlike the `FB_FFT8` listing (Volume II, Chapter 4, §11), this block must be called at every scan cycle (typically in a cyclic OB), not once on a buffer: this is how a recursive IIR filter works in industrial practice, updating a single sample at a time with minimal memory (only two registers, `xPrev` and `yPrev`) — regardless of how long the process has been running. It is precisely this memory efficiency, a consequence of the recursiveness of the difference equation, that makes IIR filters more common than FIR filters in controllers with limited resources.

21.8. Exercises inherited from Volume II

The exercises below come from Volume II, Chapter 4, and concern the topics of this chapter. They are reproduced in full, together with their solutions, which follow in the same order as the exercises.

Exercises

Exercise 21.1. A digital filter has transfer function $H(z) = \frac{z+1}{z^2 - 0.3z - 0.4}$. Determine whether the filter is BIBO stable.

Exercise 21.2. The one-parameter generalized bilinear transform can be written (standard parametrization in the digital control literature) as

$$s \approx \frac{1}{T} \cdot \frac{1 - z^{-1}}{\alpha + (1 - \alpha)z^{-1}}, \quad \alpha \in [0, 1].$$

Verify that $\alpha = 0$ yields the forward Euler method ($s \approx (z - 1)/T$), $\alpha = 1$ the backward Euler method ($s \approx (z - 1)/(zT)$), and $\alpha = 1/2$ Tustin's method ($s \approx \frac{2}{T} \cdot \frac{z-1}{z+1}$) of Corollary 3.3 (Volume II, Chapter 3).

Exercise 21.3. (Filter design) — A sensor is sampled at $f_s = 200$ Hz and a first-order Butterworth low-pass with cutoff $f_c = 5$ Hz is desired. Compute b_0 and p following the four steps of Section 21.7 and verify the BIBO stability of the resulting filter.

Solutions

Solution. We factor the denominator: we look for p, q with $p + q = 0.3 \dots$ more precisely, if $z^2 - 0.3z - 0.4 = (z - p)(z - q)$ then $p + q = 0.3$ and $pq = -0.4$. Trying $p = 0.8, q = -0.5$: $p + q = 0.3 \checkmark, pq = 0.8 \times (-0.5) = -0.4 \checkmark$. Hence

$$H(z) = \frac{z + 1}{(z - 0.8)(z + 0.5)},$$

with poles at $z = 0.8$ and $z = -0.5$. Both satisfy $|z| < 1$ ($|0.8| = 0.8 < 1, |-0.5| = 0.5 < 1$): by Theorem 21.12, the filter is BIBO stable.

Independent check. The quadratic formula gives $z = \frac{0.3 \pm \sqrt{0.09 + 1.6}}{2} = \frac{0.3 \pm 1.3}{2}$, that is 0.8 and -0.5 : the same poles, obtained without trial and error. $\checkmark$

Solution. For $\alpha = 0$: $s \approx \frac{1}{T} \cdot \frac{1 - z^{-1}}{0 + 1 \cdot z^{-1}} = \frac{1}{T} \cdot \frac{z - 1}{1} \cdot \frac{1}{z^{-1} \cdot z}$; more simply, multiplying numerator and denominator by z : $s \approx \frac{1}{T} \cdot \frac{z - 1}{1} = \frac{z - 1}{T}$, the forward Euler method (it approximates $\dot{x}(t) \approx (x[n + 1] - x[n])/T$).

For $\alpha = 1$: $s \approx \frac{1}{T} \cdot \frac{1 - z^{-1}}{1 + 0} = \frac{1 - z^{-1}}{T}$; multiplying numerator and denominator by z : $s \approx \frac{z - 1}{zT}$, the backward Euler method (it approximates $\dot{x}(t) \approx (x[n] - x[n - 1])/T$).

For $\alpha = 1/2$: $s \approx \frac{1}{T} \cdot \frac{1 - z^{-1}}{\frac{1}{2} + \frac{1}{2}z^{-1}} = \frac{2}{T} \cdot \frac{1 - z^{-1}}{1 + z^{-1}}$; multiplying numerator and denominator by z : $s \approx \frac{2}{T} \cdot \frac{z - 1}{z + 1}$, exactly Tustin's method of Corollary 3.3 (Volume II, Chapter 3). The three classical discretization methods are therefore particular cases of a single one-parameter family, as anticipated in Remark 21.11.

Solution. With $f_s = 200$ Hz, $T = 1/f_s = 0.005$ s, $f_c = 5$ Hz: $\omega_c = 2\pi f_c \approx 31.416$ rad/s, $K = 2/T = 400$. Following Section 21.7:

$$b_0 = \frac{\omega_c}{K + \omega_c} = \frac{31.416}{431.416} \approx 0.07282, \quad p = \frac{K - \omega_c}{K + \omega_c} = \frac{368.584}{431.416} \approx 0.85436.$$

Since $|p| \approx 0.854 < 1$, the filter is BIBO stable (Theorem 21.12). Check of the DC gain: $H(1) = b_0(1 + 1)/(1 - p) = 2b_0/(1 - p) \approx 0.14564/0.14564 = 1$, as expected for a normalized low-pass filter.

Independent check. The double-precision computation gives $\omega_c = 31.4159265$, $b_0 = 0.07282051$, $p = 0.85435899$ and $H(1) = 2b_0/(1 - p) = 1.000000000$: the three values confirm the rounding to five decimals in the statement. $\checkmark$

Inherited quiz

The items below come from the quiz of Volume II, Chapter 4, and are renumbered here.

1. A system is BIBO stable in the Z-domain if all its poles satisfy

- A) $|z| > 1$
- B) $|z| < 1$
- C) $|z| = 1$

D) z real

BEST PRACTICE

Answer key.

1-B: Theorem 21.12: poles inside the unit circle.

21.9. Assigned exercises

These are *new* exercises, distinct both from the inherited ones (Section 21.8) and from those worked out in Section 21.10. The answers are in the Teacher's key (Section 21.12).

Exercise 21.4: Annuli: computing them, recognising empty ones, deciding on the boundary. *Goal:* compute ρ_+ and ρ_- with Theorem 21.1 and understand what happens on the two boundary circles. *Estimated time:* 40 minutes. *Type:* proof-based/numerical.

- (a) Let $x[n] = 2^{-n}u[n] - 3^{-n}u[-n-1]$. Compute ρ_+ and ρ_- , write $X(z)$ in closed form by summing the two geometric series separately, and say whether $\mathbb{T}$ belongs to the annulus. If so, compute $\|x\|_1$.
- (b) Let $y[n] = 3^n u[n] + 2^n u[-n-1]$. Show that $\text{ROC}(y) = \emptyset$, and explain in one sentence why the same rational expression obtained "formally" has no meaning.
- (c) Let $w[n] = 1/n^2$ for $n \geq 1$ and $w[n] = 0$ elsewhere. Show that $\rho_+ = 1$ and that, unlike the case of $u[n]$, the circle $|z| = 1$ *belongs* to $\text{ROC}(w)$. Compute $\hat{w}(0)$.
- (d) Construct a signal whose region of convergence is exactly the closed annulus $\{\frac{1}{2} \leq |z| \leq 2\}$, boundaries included, and justify the answer.

Exercise 21.5: The five properties at work. *Goal:* use Theorem 21.5 to compute transforms that would not be summed by hand. *Estimated time:* 45 minutes. *Type:* symbolic and numerical computation.

- (a) Applying differentiation in z (Theorem 21.5(iv)) twice to row (2) of the table in Example 21.3, prove that

$$\mathcal{Z}\{n^2 a^n u[n]\}(z) = \frac{az(z+a)}{(z-a)^3}, \quad |z| > |a|,$$

and verify it numerically for $a = \frac{1}{2}$ and $z = 2$.

- (b) Let $x[n] = a^n u[n]$ and $y[n] = b^n u[n]$ with $a \neq b$ both nonzero. Compute $(x * y)[n]$ directly as a finite sum and recover the same result by inverse-transforming $X(z)Y(z)$ with Lemma 21.3. Verify the first eight values for $a = 0.6$ and $b = 0.4$.
- (c) Exhibit a pair x, y for which the inclusion $\text{ROC}(x * y) \supseteq \text{ROC}(x) \cap \text{ROC}(y)$ of Theorem 21.5(v) is *strict*, different from the one in Remark 21.4, and explain which cancellation causes it.
- (d) Prove, using (ii) and (iii), that $\mathcal{Z}\{a^n x[n - n_0]\}(z) = a^{n_0} z^{-n_0} X(z/a)$, and verify it on $x = \delta$.

Exercise 21.6: Stability: three systems, three diagnoses. *Goal:* decide BIBO stability in three equivalent ways (poles, annulus, summability) and understand that "causal" and "stable" are independent. *Estimated time:* 45 minutes. *Type:* proof-based/numerical.

- (a) Let $H(z) = \frac{z^2}{z^2 - 1.1z + 0.3}$, a causal system. Find the poles, decide stability with Theorem 21.12, compute $h[n]$ in closed form and verify $\|h\|_1 = H(1)$, explaining why the two quantities coincide here.

- (b) Let $H(z) = \frac{z}{z^2 - 2.5z + 1}$. Find the poles and the *two* possible annuli. Show that the causal choice gives an unstable system and that the other one gives a BIBO stable but non-causal system; compute $h[n]$ in both cases and $\|h\|_1$ in the stable case.
- (c) Using the four steps of Section 21.7, design the first-order low-pass filter with $f_s = 500$ Hz and $f_c = 20$ Hz: compute b_0 and p , verify $H(1) = 1$ and $|p| < 1$, and then compute $|H(e^{i\omega_c T})|$, explaining why it is *not* exactly $1/\sqrt{2}$.
- (d) For the system of (b) in its stable version, verify numerically Parseval's identity (Theorem 21.9) by comparing $\sum_n |h[n]|^2$ with $\frac{1}{2\pi} \int_{-\pi}^{\pi} |H(e^{i\Omega})|^2 d\Omega$.

21.10. Worked exercises

Exercise 21.7: One rational function, three annuli, three signals. *Type:* inverse transform with choice of annulus, with numerical check. Invert

$$X(z) = \frac{1}{(1 - \frac{1}{2}z^{-1})(1 - 2z^{-1})}$$

in all possible annuli, and say which of the resulting signals is summable.

Solution. Strategy. The poles are at $\frac{1}{2}$ and 2: two distinct moduli, hence three possible annuli (Theorem 21.1). One decomposes into partial fractions in the variable $w = z^{-1}$ and inverts each term with Example 21.2, choosing for each pole the causal or anticausal version according to the annulus.

Step 1 — partial fractions. Setting $w = z^{-1}$, one looks for A, B with

$$\frac{1}{(1 - \frac{w}{2})(1 - 2w)} = \frac{A}{1 - \frac{w}{2}} + \frac{B}{1 - 2w}, \quad \text{i.e.} \quad A(1 - 2w) + B(1 - \frac{w}{2}) = 1.$$

Evaluating at $w = 2$: $A(1 - 4) = 1$, hence $A = -\frac{1}{3}$. Evaluating at $w = \frac{1}{2}$: $B(1 - \frac{1}{4}) = 1$, hence $B = \frac{4}{3}$. *Check:* the constant term is $A + B = -\frac{1}{3} + \frac{4}{3} = 1$ ✓ and the coefficient of w is $-2A - \frac{B}{2} = \frac{2}{3} - \frac{2}{3} = 0$ ✓. Hence

$$X(z) = -\frac{1}{3} \cdot \frac{1}{1 - \frac{1}{2}z^{-1}} + \frac{4}{3} \cdot \frac{1}{1 - 2z^{-1}}.$$

Step 2 — outer annulus $|z| > 2$. Both poles lie inside the inner circle of the annulus: both terms must be taken in the causal version (Example 21.2, outer annulus):

$$x_a[n] = \left(-\frac{1}{3} \left(\frac{1}{2} \right)^n + \frac{4}{3} 2^n \right) u[n].$$

Values: $x_a[0] = -\frac{1}{3} + \frac{4}{3} = 1$, $x_a[1] = -\frac{1}{6} + \frac{8}{3} = 2.5$, $x_a[2] = -\frac{1}{12} + \frac{16}{3} = 5.25$, $x_a[3] = 10.625$.

Step 3 — intermediate annulus $\frac{1}{2} < |z| < 2$. The pole $\frac{1}{2}$ lies *inside* the inner boundary of the annulus, hence must be taken causal; the pole 2 lies *outside* the outer boundary, hence must be taken anticausal:

$$x_b[n] = -\frac{1}{3} \left(\frac{1}{2} \right)^n u[n] - \frac{4}{3} 2^n u[-n - 1].$$

Values: $x_b[0] = -\frac{1}{3}$, $x_b[1] = -\frac{1}{6}$, $x_b[-1] = -\frac{4}{3} \cdot \frac{1}{2} = -\frac{2}{3}$, $x_b[-2] = -\frac{4}{3} \cdot \frac{1}{4} = -\frac{1}{3}$.

Step 4 — inner annulus $|z| < \frac{1}{2}$. Both poles lie outside: both anticausal,

$$x_c[n] = \left(\frac{1}{3} \left(\frac{1}{2} \right)^n - \frac{4}{3} 2^n \right) u[-n - 1].$$

Values: $x_c[-1] = \frac{1}{3} \cdot 2 - \frac{4}{3} \cdot \frac{1}{2} = \frac{2}{3} - \frac{2}{3} = 0$, $x_c[-2] = \frac{1}{3} \cdot 4 - \frac{4}{3} \cdot \frac{1}{4} = \frac{4}{3} - \frac{1}{3} = 1$.

Step 5 — which one is summable. Only the intermediate annulus contains $\mathbb{T}$; by Theorem 21.6 the only summable signal is x_b , and

$$\|x_b\|_1 = \frac{1}{3} \sum_{n \geq 0} 2^{-n} + \frac{4}{3} \sum_{m \geq 1} 2^{-m} = \frac{1}{3} \cdot 2 + \frac{4}{3} \cdot 1 = \frac{2}{3} + \frac{4}{3} = 2.$$

Independent check. Evaluating the inversion formula of Theorem 21.3 with 200,000 points on the circle of radius r :

r	$n = -2$	$n = -1$	$n = 0$	$n = 1$	$n = 2$	$n = 3$
3	0	0	1	2.5	5.25	10.625
1	-0.333 333 3	-0.666 666 7	-0.333 333 3	-0.166 666 7	-0.083 333 3	-0.041 666 7
$\frac{1}{4}$	1	0	0	0	0	0

Each row matches the values computed in Steps 2–4, with imaginary part of order 10^{-16} and maximum discrepancy $2 \cdot 10^{-15}$. ✓

Interpretation. The same algebraic formula describes a signal that explodes in the future, one that decays in both directions and one that explodes in the past. It is the annulus, not the formula, that decides which one.

Typical errors. (1) Inverting "row by row" always taking the causal version: one gets x_a even when the annulus is the intermediate one. (2) Forgetting that the anticausal version carries a minus sign (Example 21.2), obtaining $+\frac{4}{3}2^n u[-n-1]$. (3) Concluding that "the system is stable because one pole is inside the unit circle": stability requires $\mathbb{T}$ to lie in the annulus, and the annulus is chosen by the problem, not by the pole.

Extension. With p poles of distinct moduli there are $p+1$ annuli, and as many inverse-transformed signals; only one of them is causal (the one for the outermost annulus), only one is anticausal (the one for the innermost annulus) and only one, if it exists, is summable: the one for the annulus that contains $\mathbb{T}$.

Exercise 21.8: A two-sided signal: annulus, DTFT, inversion, Parseval. *Type:* complete computation with three independent checks. Let

$$x[n] = \left(\frac{1}{2}\right)^n u[n] - 2^n u[-n-1].$$

Determine its annulus, the closed-form transform, the norm $\|x\|_1$; verify the DTFT inversion formula and Parseval's identity.

Solution. Strategy. The two geometric series are summed separately (Definition 21.4), Theorem 21.1 is applied for the radii, and Theorems 21.8 and 21.9 are used for the checks.

Step 1 — the causal part. $\rho_+ = \limsup_n (2^{-n})^{1/n} = \frac{1}{2}$ and, for $|z| > \frac{1}{2}$,

$$X_+(z) = \sum_{n \geq 0} \left(\frac{1}{2}\right)^n z^{-n} = \frac{1}{1 - \frac{1}{2z}} = \frac{z}{z - \frac{1}{2}}.$$

Step 2 — the anticausal part. Here $x[-m] = -2^{-m}$, hence $\limsup_m |x[-m]|^{1/m} = \frac{1}{2}$ and $\rho_- = 2$; for $|z| < 2$,

$$X_-(z) = \sum_{m \geq 1} (-2^{-m}) z^m = -\frac{z/2}{1 - z/2} = -\frac{z}{2 - z} = \frac{z}{z - 2}.$$

Step 3 — annulus and closed form. The annulus is $A(\frac{1}{2}, 2)$, which contains $\mathbb{T}$ (this is Figure 21.1), and

$$X(z) = \frac{z}{z - \frac{1}{2}} + \frac{z}{z - 2} = \frac{z(z - 2) + z(z - \frac{1}{2})}{(z - \frac{1}{2})(z - 2)} = \frac{2z^2 - \frac{5}{2}z}{z^2 - \frac{5}{2}z + 1}.$$

Check: $X(1) = \frac{2-2.5}{1-2.5+1} = \frac{-0.5}{-0.5} = 1$, and on the other hand $\hat{x}(0) = \sum_n x[n] = \sum_{n \geq 0} 2^{-n} - \sum_{m \geq 1} 2^{-m} = 2 - 1 = 1$. ✓

Step 4 — summability. $\|x\|_1 = \sum_{n \geq 0} 2^{-n} + \sum_{m \geq 1} 2^{-m} = 2 + 1 = 3$, finite: by Theorem 21.6 the DTFT exists for every Ω and is $\hat{x}(\Omega) = X(e^{i\Omega})$, continuous and bounded by 3 (Theorem 21.7).

Step 5 — Parseval in closed form.

$$\sum_{n \in \mathbb{Z}} |x[n]|^2 = \sum_{n \geq 0} 4^{-n} + \sum_{m \geq 1} 4^{-m} = \frac{1}{1 - \frac{1}{4}} + \frac{\frac{1}{4}}{1 - \frac{1}{4}} = \frac{4}{3} + \frac{1}{3} = \frac{5}{3} = 1.666\,666\,7.$$

Independent check 1 (norm). The numerical sum of $|x[n]|$ over $-60 \leq n \leq 60$ equals 3.000 000 000 0. ✓

Independent check 2 (inversion). Evaluating $\frac{1}{2\pi} \int_{-\pi}^{\pi} \hat{x}(\Omega) e^{in\Omega} d\Omega$ with 100,000 points gives

n	-2	-1	0	1	2
numerical	-0.250 000 00	-0.500 000 00	1.000 000 00	0.500 000 00	0.250 000 00
$x[n]$	$-\frac{1}{4}$	$-\frac{1}{2}$	1	$\frac{1}{2}$	$\frac{1}{4}$

with imaginary part of order 10^{-17} . ✓

Independent check 3 (numerical Parseval). $\frac{1}{2\pi} \int_{-\pi}^{\pi} |\hat{x}(\Omega)|^2 d\Omega = 1.666\,666\,666\,7$, against the $\frac{5}{3}$ of Step 5. ✓

Interpretation. The signal equals $2^{-|n|}$ for $n \geq 0$ and $-2^{-|n|}$ for $n < 0$: it is odd away from the origin, where it equals 1. Consequently

$$\hat{x}(\Omega) = x[0] + \sum_{n \geq 1} 2^{-n} (e^{-in\Omega} - e^{in\Omega}) = 1 - 2i \sum_{n \geq 1} 2^{-n} \sin(n\Omega) = 1 - \frac{2i \sin \Omega}{\frac{5}{2} - 2 \cos \Omega},$$

having used $\sum_{n \geq 1} r^n \sin(n\Omega) = \frac{r \sin \Omega}{1 - 2r \cos \Omega + r^2}$ with $r = \frac{1}{2}$: the real part of $\hat{x}$ is *constantly* 1, and all the information lies in the imaginary part. This can also be read from the closed form of Step 3: with $z = e^{i\Omega}$, $\hat{x} = \frac{2e^{i\Omega} - \frac{5}{2}}{2 \cos \Omega - \frac{5}{2}}$, whose denominator is real and whose numerator

has real part equal to the denominator itself. *Check:* then $|\hat{x}|^2 = 1 + 4(\sum_n 2^{-n} \sin n\Omega)^2$ and, by orthogonality of the sines, $\frac{1}{2\pi} \int_{-\pi}^{\pi} |\hat{x}|^2 = 1 + 4 \cdot \frac{1}{2} \sum_{n \geq 1} 4^{-n} = 1 + \frac{2}{3} = \frac{5}{3}$: this recovers Step 5 by a fourth route. ✓ The two poles, $\frac{1}{2}$ and 2, are symmetric with respect to $\mathbb{T}$ under the inversion $z \mapsto 1/\bar{z}$, and this geometric symmetry is the counterpart of the signal's oddness.

Typical errors. (1) Summing the anticausal part as $\sum_{n \leq -1} (-2^n)z^{-n}$ without changing index, getting the direction of the inequality on the annulus wrong. (2) Deducing from $X(z) = \frac{2z^2 - 2.5z}{z^2 - 2.5z + 1}$ that the system "has a pole outside the unit circle, hence is unstable": the annulus is the intermediate one and $\mathbb{T}$ belongs to it. (3) Applying Parseval to a non-summable signal without the Riesz–Fischer theorem (Remark 21.7).

Extension. The same computation with the *even* signal $x_p[n] = r^{|n|}$, $0 < r < 1$, gives $X_p(z) = \frac{z}{z-r} - \frac{z}{z-1/r}$ with annulus $A(r, 1/r)$: the anticausal part changes sign compared with the odd case treated above, but the moduli $|x[n]|$ are the same, hence $\|x_p\|_1 = 1 + \frac{2r}{1-r} = \frac{1+r}{1-r}$ and $\sum_n |x_p[n]|^2 = 1 + \frac{2r^2}{1-r^2} = \frac{1+r^2}{1-r^2}$; for $r = \frac{1}{2}$ one recovers 3 and $\frac{5}{3}$. ✓ This time $\hat{x}_p$ is *real*, because the signal is even.

Exercise 21.9: Pre-warping: designing at 200 Hz while sampling at 1 kHz. *Type:* design with exact verification. Design a first-order low-pass filter with cutoff at $f_c = 200$ Hz for a system sampled at $f_s = 1000$ Hz, first without and then with pre-warping, and compare the two responses at the cutoff frequency.

Solution. Strategy. The required cutoff is at one fifth of the sampling frequency, i.e. at $\Omega_c = \omega_c T = 2\pi \cdot 200/1000 = 1.256\,637\,1$ radians per sample: far from the regime $\Omega \ll 1$ in which warping is negligible. Corollary 21.5 says *exactly* how much to correct.

Step 1 — the data. $T = 10^{-3}$ s, $K = 2/T = 2,000$, $\omega_c = 2\pi \cdot 200 = 1,256.637\,1$ rad/s, $\Omega_c = 1.256\,637\,1$.

Step 2 — naive design (without pre-warping). With $b_0 = \frac{\omega_c}{K+\omega_c}$ and $p = \frac{K-\omega_c}{K+\omega_c}$:

$$b_0 = \frac{1,256.637\,1}{3,256.637\,1} = 0.385\,869\,5, \quad p = \frac{743.362\,9}{3,256.637\,1} = 0.228\,260\,9.$$

Evaluating $H(z) = b_0 \frac{1+z^{-1}}{1-pz^{-1}}$ at $z = e^{i\Omega_c}$ gives $|H| = 0.654\,126\,6$, i.e. $-3.686\,8$ dB: *not* the required -3 dB. The actual cutoff (where $|H| = 1/\sqrt{2}$) falls at $178.566\,2$ Hz.

Step 3 — pre-warping. By Corollary 21.5 the correspondence between the analog pulsation ω and the normalized one Ω is $\Omega = 2 \arctan(\omega T/2)$, hence to make the cutoff fall exactly at Ω_c one must design the analog filter with

$$\omega'_c = \frac{2}{T} \tan \frac{\Omega_c}{2} = 2,000 \cdot \tan(0.628\,318\,5) = 2,000 \cdot 0.726\,542\,5 = 1,453.085\,1 \text{ rad/s.}$$

Step 4 — the corrected coefficients.

$$b_0 = \frac{\omega'_c}{K + \omega'_c} = \frac{1,453.085\,1}{3,453.085\,1} = 0.420\,807\,8, \quad p = \frac{K - \omega'_c}{K + \omega'_c} = \frac{546.914\,9}{3,453.085\,1} = 0.158\,384\,4.$$

Since $|p| < 1$, the filter is BIBO stable (Theorem 21.12). The difference equation is $y[n] = 0.158\,384\,4 y[n-1] + 0.420\,807\,8(x[n] + x[n-1])$.

Independent check 1 (the specification is centred). Evaluating $|H(e^{i\Omega_c})|$ with the coefficients of Step 4 gives $0.707\,106\,781\,2$, against $1/\sqrt{2} = 0.707\,106\,781\,2$: they agree to ten decimal places. ✓

Independent check 2 (the naive cutoff, by an analytic route). The actual cutoff of Step 2 is obtained without numerical search: the bilinear filter designed for ω_c has -3 dB where $\frac{2}{T} \tan(\Omega/2) = \omega_c$, i.e. at $\Omega = 2 \arctan(\omega_c T/2)$, i.e. at the frequency

$$f_{\text{eff}} = \frac{\Omega}{2\pi T} = \frac{\arctan(\omega_c T/2)}{\pi T} = \frac{\arctan(0.628\,318\,5)}{\pi \cdot 10^{-3}} = 178.566\,2 \text{ Hz,}$$

the same value found by bisection. ✓

Independent check 3 (DC gain). In both designs $H(1) = \frac{2b_0}{1-p}$ equals 1 exactly: with the coefficients of Step 4, $\frac{2 \cdot 0.420\,807\,8}{1-0.158\,384\,4} = \frac{0.841\,615\,6}{0.841\,615\,6} = 1$. ✓

Interpretation. Pre-warping does not "improve" the filter: it shifts the analog specification so that the distortion of the bilinear map brings it back where it is needed. The price is that the shape of the response far from the cutoff remains distorted — the bilinear map compresses all of $\mathbb{R}$ into $(-\pi, \pi)$, and no choice of ω'_c can cancel this compression (Figure 21.3).

Typical errors. (1) Pre-distorting with $\arctan$ instead of $\tan$: one gets $\omega'_c = 1,121.964\,2$ and the cutoff ends up even lower. (2) Applying pre-warping even when $f_c \ll f_s$, where it is useless but harmless (for $f_c = 10$ Hz and $f_s = 1$ kHz it shifts the cutoff by $3.3 \cdot 10^{-4}$ in relative terms). (3) Forgetting that the DC gain does not change: $H(1) = 1$ remains true, because $z = 1$ corresponds to $s = 0$ and $\beta^{-1}(1) = 0$ (Theorem 21.14).

Extension. For a band-pass filter *both* band edges must be pre-distorted, and the resulting bandwidth is not the pre-distorted value of the bandwidth: it is the difference of the pre-distorted edges. This is the most frequent error in designing IIR filters close to the Nyquist frequency.

21.11. Self-assessment quiz

1. (Definition) The region of convergence of a signal x is, by Definition 21.4,
 - A) the set of z for which $x[n]z^{-n} \rightarrow 0$
 - B) the set of $z \neq 0$ for which $\sum_{n \in \mathbb{Z}} |x[n]| |z|^{-n} < \infty$
 - C) the set of z at which X is holomorphic
 - D) the set of z other than the poles of X
2. (Hypothesis) In Theorem 21.6 the hypothesis $\mathbb{T} \subseteq \text{ROC}(x)$ serves to
 - A) make X rational
 - B) guarantee that x is causal
 - C) guarantee $\sum_n |x[n]| < \infty$, i.e. that the series $\sum_n x[n]e^{-in\Omega}$ converges absolutely for every Ω
 - D) make $\hat{x}$ periodic
3. (Symbolic computation) For $|z| > |a|$, $\mathcal{Z}\{n a^n u[n]\}(z)$ equals
 - A) $\frac{z}{(z-a)^2}$
 - B) $\frac{az}{(z-a)^2}$
 - C) $\frac{az}{(z-a)^3}$
 - D) $-\frac{az}{(z-a)^2}$
4. (Numerical computation) For $h[n] = (3 \cdot 0.6^n - 2 \cdot 0.4^n)u[n]$, the norm $\|h\|_1 = \sum_n |h[n]|$ equals, to seven decimal places,
 - A) 1.0000000
 - B) 4.1666667
 - C) 3.0349311
 - D) 5.0000000
5. (Proof step) In the proof of Theorem 21.10 one uses the input x_N , defined by $x_N[n] = \frac{h[-n]}{|h[-n]|}$ for $|n| \leq N$ and by $x_N[n] = 0$ elsewhere. It serves to
 - A) make the system causal
 - B) produce, with an input of amplitude ≤ 1 , the output $\sum_{|k| \leq N} |h[k]|$ at $n = 0$, which bounds the partial sums
 - C) show that h is real
 - D) construct an unbounded input that makes the output diverge
6. (Error diagnosis) A student inverts $X(z) = [(1 - \frac{1}{2}z^{-1})(1 - 2z^{-1})]^{-1}$ in the annulus $\frac{1}{2} < |z| < 2$ by taking both fractions in the causal version, obtaining $(-\frac{1}{3}(\frac{1}{2})^n + \frac{4}{3}2^n)u[n]$. The error is
 - A) the coefficients $-\frac{1}{3}$ and $\frac{4}{3}$ are wrong
 - B) the pole at $z = 2$ lies *outside* the chosen annulus and must be inverted in the anticausal version, $-\frac{4}{3}2^n u[-n-1]$
 - C) X has no inverse transform in that annulus
 - D) the annulus $\frac{1}{2} < |z| < 2$ is empty
7. (Transfer) The *causal* system with $H(z) = \frac{z}{z^2 - 2.5z + 1}$ is
 - A) BIBO stable, because one pole has modulus $\frac{1}{2} < 1$
 - B) BIBO stable, because $H(1)$ is finite
 - C) not BIBO stable, because the pole $z = 2$ has modulus ≥ 1 and the causal annulus $\{|z| > 2\}$ does not contain $\mathbb{T}$
 - D) marginally stable, because one pole lies on the unit circle
8. (Source and metacognition) The only result that this chapter declares *imported* is the completeness of $L^2(\mathbb{T})$ (the Riesz–Fischer theorem), recalled in Remark 21.7; it is found in
 - A) Rudin, *Real and Complex Analysis*, 3rd ed., Ch. 3 " L^p -spaces"
 - B) Oppenheim–Schafer, *Discrete-Time Signal Processing*, 3rd ed., Ch. 3
 - C) Oppenheim–Willsky–Nawab, *Signals & Systems*, 2nd ed., Ch. 10
 - D) Mitra, *Digital Signal Processing*, 4th ed.

21.12. Teacher's key

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 1–4).

1) **B.** *Rationale:* this is Definition 21.4: it requires *absolute* summability, which makes the sum independent of the order. *Distractors:* A is the necessary condition (term tending to zero), not sufficient; C holds only in the interior of the annulus and does not define the ROC, which concerns the series and not the function; D is false because X can be holomorphic at points where the series does not converge (for example the same rational expression $\frac{z}{z-a}$ is defined on all of $\mathbb{C} \setminus \{a\}$, but the series converges only on one of the two annuli). *Diagnosed error:* confusing the function with the series that represents it. *Source:* Oppenheim–Schafer, Ch. 3; here Definition 21.4 and Remark 21.3. *Prerequisite:* absolute convergence of a series. *Remediation:* Example 21.2.

2) **C.** *Rationale:* Step 1 and Step 2 of the proof of Theorem 21.6 show that $\mathbb{T} \subseteq \text{ROC}(x)$ is equivalent to $x \in \ell^1$, and it is the latter that makes the DTFT series converge. *Distractors:* A is beside the point (no assumption of rationality is made); B is false, the signal of Exercise 21.8 is two-sided and has $\mathbb{T}$ in its annulus; D confuses an automatic consequence (periodicity holds by definition, as soon as the series converges, Proposition 21.2) with the role of the hypothesis. *Diagnosed error:* failing to identify the technical role of a hypothesis. *Source:* Oppenheim–Willsky–Nawab, Ch. 10; here Theorem 21.6. *Prerequisite:* Definition 21.4. *Remediation:* verify that for $x = u$ the circle $\mathbb{T}$ does not lie in the annulus $\{|z| > 1\}$ and that indeed $\sum_n |u[n]| = \infty$.

3) **B.** *Rationale:* this is row (4) of Example 21.3, obtained by applying $-z \frac{d}{dz}$ to $\frac{z}{z-a}$ (Theorem 21.5(iv)). *Distractors:* A forgets the factor a produced by the derivative; C is the transform of $n^2 a^n u[n]$ up to the factor $(z+a)$ (Exercise 21.5(a)); D gets the sign wrong, forgetting the minus in front of z . *Diagnosed error:* applying differentiation in z without the factor $-z$. *Source:* Mitra, *Digital Signal Processing*, 4th ed.; here Example 21.3(4). *Prerequisite:* term-by-term differentiation of a power series. *Remediation:* numerical check with $a = 0.8$, $z = 1.25$ (the value is 4.9382716).

4) **B.** *Rationale:* $h[n] > 0$ for every $n \geq 0$, hence $\|h\|_1 = \sum_n h[n] = H(1) = \frac{1}{0.24} = \frac{25}{6} = 4.1666667$ (Example 21.5). *Distractors:* A is $h[0]$; C is $\sum_n |h[n]|^2$, i.e. the energy, not the ℓ^1 norm; D is $\|h\|_1$ of the *other* system, the one in Exercise 21.6(a). *Diagnosed error:* confusing the ℓ^1 norm with the ℓ^2 energy. *Source:* here Example 21.5, with three independent checks. *Prerequisite:* geometric series. *Remediation:* recompute $\frac{3}{1-0.6} - \frac{2}{1-0.4}$ and compare with $H(1)$.

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 5–8).

5) **B.** *Rationale:* this is Step 2 and Step 3 of the proof of Theorem 21.10: x_N has $\|x_N\|_\infty \leq 1$ and realizes the equality $(\mathcal{T}x_N)[0] = \sum_{|k| \leq N} |h[k]|$, so that BIBO stability bounds all partial sums. *Distractors:* A is irrelevant (x_N is not causal, and there is no need for it to be); C is false, h can be complex and the computation uses precisely the conjugate; D contradicts the construction, which produces a *bounded* input. *Diagnosed error:* failing to recognise the strategy "an input that saturates the triangle inequality". *Source:* Oppenheim–Schafer, Ch. 2; here Theorem 21.10. *Prerequisite:* $w\bar{w} = |w|^2$. *Remediation:* redo Step 3 with h real, where $\bar{h[k]}/|h[k]| = \text{sgn } h[k]$.

6) **B.** *Rationale:* in the annulus $\frac{1}{2} < |z| < 2$ the pole 2 is external, hence its term must be expanded in positive powers of z (Example 21.2, inner annulus), giving $-\frac{4}{3}2^n u[-n-1]$; the correct answer is the one from Step 3 of Exercise 21.7. *Distractors:* A is false, the coefficients are checked in Step 1 of that exercise; C and D are both false, the annulus

$A(\frac{1}{2}, 2)$ is nonempty and in it the inverse transform exists and is unique (Theorem 21.4). *Diagnosed error:* inverting "row by row" always in the causal version. *Source:* Oppenheim–Willsky–Nawab, Ch. 10; here Exercise 21.7. *Prerequisite:* Theorem 21.1. *Remediation:* redo the three cases with $X(z) = \frac{z}{z-3}$.

7) **C.** *Rationale:* the roots of $z^2 - 2.5z + 1$ are 2 and $\frac{1}{2}$; for a causal system the annulus is $\{|z| > 2\}$ (Theorem 21.11), which does not contain $\mathbb{T}$, hence the system is not BIBO stable (Corollary 21.4). *Distractors:* A looks at only one pole and ignores the other; B confuses finiteness of H at a point with convergence of the series at that point ($H(1) = -2$ is finite, but $1 \notin \text{ROC}$); D is false, no pole lies on $\mathbb{T}$. *Diagnosed error:* assessing stability pole by pole instead of by the pole of maximum modulus. *Source:* here Theorem 21.12 and Exercise 21.6(b). *Prerequisite:* the quadratic formula. *Remediation:* Example 21.4.

8) **A.** *Rationale:* Remark 21.7 declares the completeness of $L^2(\mathbb{T})$ imported and refers to Rudin, *Real and Complex Analysis*, 3rd ed., Chapter 3 (" L^p -spaces"). *Distractors:* B, C and D are the three signal-theory texts used in the chapter, which present the DTFT but do not prove a measure-theory theorem. *Diagnosed error:* not distinguishing the source of an analytic result from that of an applied result. *Source:* the `fonti` environment of this chapter. *Prerequisite:* knowing what the chapter proves and what it imports. *Remediation:* reread the prerequisites *infobox* and Remark 21.7.

BEST PRACTICE

Assigned exercises — answers.

Exercise 21.4. (a) $\rho_+ = \limsup_n (2^{-n})^{1/n} = \frac{1}{2}$; since $x[-m] = -3^{-m}$, $\limsup_m |x[-m]|^{1/m} = \frac{1}{3}$ and $\rho_- = 3$. Summing the two geometric series,

$$X(z) = \frac{z}{z - \frac{1}{2}} + \frac{z}{z - 3}, \quad \frac{1}{2} < |z| < 3,$$

and $\mathbb{T}$ belongs to it; $\|x\|_1 = \sum_{n \geq 0} 2^{-n} + \sum_{m \geq 1} 3^{-m} = 2 + \frac{1}{2} = \frac{5}{2}$. *Check:* the numerical sum over $|n| \leq 200$ gives 2.500 000 0, and the numerical inversion of the DTFT gives $x[-1] = -0.333\,333\,3$, $x[0] = 1$, $x[1] = 0.5$. $\checkmark$ (b) $\rho_+ = 3$ and $\rho_- = 2$, hence $\rho_- < \rho_+$ and by Theorem 21.1(i) the ROC is empty. The expression $\frac{z}{z-3} + \frac{z}{z-2}$ obtained "formally" is a perfectly well-defined rational function, but it is not the Z-transform of anything: there is no z at which the series converges (Example 21.1). (c) $(1/n^2)^{1/n} = n^{-2/n} = e^{-2 \ln n/n} \rightarrow 1$, hence $\rho_+ = 1$; and on $|z| = 1$ the series of moduli is $\sum_{n \geq 1} 1/n^2$, convergent: the circle belongs to the ROC, and $\text{ROC}(w) = \{|z| \geq 1\}$. $\hat{w}(0) = \sum_{n \geq 1} 1/n^2 = \pi^2/6 = 1.644\,934\,1$ (numerical check over $2 \cdot 10^6$ terms: 1.644 933 6, difference $5 \cdot 10^{-7}$, of the order of the tail $1/N$). $\checkmark$ For $u[n]$ instead $\rho_+ = 1$ but $\sum_n 1 = \infty$: the circle does not belong. (d) For instance $x[n] = 2^{-|n|}/n^2$ for $n \neq 0$ and $x[0] = 0$: one has $\rho_+ = \frac{1}{2}$ and $\rho_- = 2$, and on both boundaries the series of moduli reduces to $\sum 1/n^2 < \infty$; by Theorem 21.1 the ROC is the closed annulus.

Exercise 21.5. (a) From $\mathcal{Z}\{na^n u[n]\} = \frac{az}{(z-a)^2}$ one applies $-z \frac{d}{dz}$ again: $\frac{d}{dz} \frac{az}{(z-a)^2} = a \frac{(z-a)-2z}{(z-a)^3} = -a \frac{z+a}{(z-a)^3}$, hence $\mathcal{Z}\{n^2 a^n u[n]\} = \frac{az(z+a)}{(z-a)^3}$. For $a = \frac{1}{2}$, $z = 2$: the formula gives $\frac{0.5 \cdot 2 \cdot 2.5}{1.5^3} = \frac{2.5}{3.375} = 0.740\,740\,740\,7$ and the series, over 20,000 terms, 0.740 740 740 7. $\checkmark$ (b) $(x * y)[n] = \sum_{k=0}^n a^k b^{n-k} = b^n \sum_{k=0}^n (a/b)^k = \frac{a^{n+1} - b^{n+1}}{a-b}$ for $n \geq 0$, 0 elsewhere. By partial fractions, $X(z)Y(z) = \frac{z^2}{(z-a)(z-b)}$ and $\frac{XY}{z} = \frac{z}{(z-a)(z-b)}$ has residues $\frac{a}{a-b}$ and $\frac{b}{b-a}$, whence $XY = \frac{a}{a-b} \frac{z}{z-a} - \frac{b}{a-b} \frac{z}{z-b}$ and the same formula. For $a = 0.6$, $b = 0.4$ the first eight values are 1, 1, 0.76, 0.52, 0.337 6, 0.212 8, 0.131 776, 0.080 704, by both routes. $\checkmark$ (These are the same values as in Example 21.5: indeed $\frac{0.6^{n+1} - 0.4^{n+1}}{0.2} = 3 \cdot 0.6^n - 2 \cdot 0.4^n$.) (c) For instance $x = u$, with $X(z) = \frac{z}{z-1}$ and annulus $\{|z| > 1\}$, and $y = \delta - \sigma_1 \delta$, with

$Y(z) = 1 - z^{-1} = \frac{z-1}{z}$ and annulus $\mathbb{C} \setminus \{0\}$: the product equals 1, annulus $\mathbb{C} \setminus \{0\}$, while the intersection of the annuli is $\{|z| > 1\}$. The cancellation is that of the zero of Y at $z = 1$ with the pole of X at $z = 1$; and indeed $(x * y)[n] = u[n] - u[n-1] = \delta[n]$. (d) By (iii), $\mathcal{Z}\{a^n(\sigma_{n_0}x)[n]\}(z) = (\sigma_{n_0}X)(z/a)$ where $(\sigma_{n_0}X)$ denotes the transform of the shifted signal, i.e., by (ii), $\mathcal{Z}\{x[n-n_0]\}(w) = w^{-n_0}X(w)$; evaluating at $w = z/a$ gives $(z/a)^{-n_0}X(z/a) = a^{n_0}z^{-n_0}X(z/a)$. For $x = \delta$: $X \equiv 1$, and on the left $a^n\delta[n-n_0] = a^{n_0}\delta[n-n_0]$, whose transform is $a^{n_0}z^{-n_0}$. ✓

Exercise 21.6. (a) $z^2 - 1.1z + 0.3$ has discriminant $1.21 - 1.2 = 0.01$ and roots $\frac{1.1 \pm 0.1}{2}$, i.e. 0.6 and 0.5: both of modulus < 1 , hence the system is BIBO stable (Theorem 21.12). From $\frac{H(z)}{z} = \frac{z}{(z-0.6)(z-0.5)}$ with residues $\frac{0.6}{0.1} = 6$ and $\frac{0.5}{-0.1} = -5$ it follows that $h[n] = (6 \cdot 0.6^n - 5 \cdot 0.5^n)u[n]$, positive for every n (the ratio $\frac{6 \cdot 0.6^n}{5 \cdot 0.5^n} = 1.2 \cdot 1.2^n \geq 1.2$). Hence $\|h\|_1 = \sum_n h[n] = H(1) = \frac{1}{1-1.1+0.3} = \frac{1}{0.2} = 5$, which coincides with $\frac{6}{0.4} - \frac{5}{0.5} = 15 - 10 = 5$: the two quantities coincide *because* $h \geq 0$, i.e. because $|h[n]| = h[n]$. Check: the recursion $y[n] = 1.1y[n-1] - 0.3y[n-2] + x[n]$ gives 1, 1.1, 0.91, 0.671, 0.4651, identical to the closed form (maximum discrepancy $4.4 \cdot 10^{-16}$ over 300 samples), and the numerical sum of the moduli equals 5.000 000 00. ✓ (b) $z^2 - 2.5z + 1$ has discriminant $6.25 - 4 = 2.25$ and roots $\frac{2.5 \pm 1.5}{2}$, i.e. 2 and $\frac{1}{2}$: the possible annuli are $\{|z| > 2\}$ (causal), $A(\frac{1}{2}, 2)$ and $\{|z| < \frac{1}{2}\}$ (anticausal). From $\frac{H(z)}{z} = \frac{1}{(z-2)(z-\frac{1}{2})}$ with residues $\frac{1}{1.5} = \frac{2}{3}$ and $\frac{1}{-1.5} = -\frac{2}{3}$ it follows that $H(z) = \frac{2}{3} \frac{z}{z-2} - \frac{2}{3} \frac{z}{z-\frac{1}{2}}$. In the causal annulus $h[n] = (\frac{2}{3}2^n - \frac{2}{3}2^{-n})u[n]$, not summable (2^n diverges): unstable system. In the intermediate annulus, which contains $\mathbb{T}$,

$$h[n] = -\frac{2}{3}2^nu[-n-1] - \frac{2}{3}2^{-n}u[n],$$

summable with $\|h\|_1 = \frac{2}{3}(\sum_{m \geq 1} 2^{-m} + \sum_{n \geq 0} 2^{-n}) = \frac{2}{3}(1+2) = 2$: BIBO stable but *non-causal* system. Check: $\sum_n h[n] = H(1) = \frac{1}{1-2.5+1} = -2$, and since $h \leq 0$ one has $\|h\|_1 = 2$; numerical inversion gives $h[-2] = -0.166\,666\,67$, $h[-1] = -0.333\,333\,33$, $h[0] = -0.666\,666\,67$, $h[1] = -0.333\,333\,33$, $h[2] = -0.166\,666\,67$. ✓ (c) $T = 0.002$ s, $\omega_c = 2\pi \cdot 20 = 125.663\,706$, $K = 1,000$, hence $b_0 = \frac{125.663\,706}{1,125.663\,706} = 0.111\,635\,21$ and $p = \frac{874.336\,294}{1,125.663\,706} = 0.776\,729\,58$; $|p| < 1$, stable filter, and $H(1) = \frac{2b_0}{1-p} = 1.000\,000\,000\,0$. ✓ Finally $|H(e^{i\omega_c T})| = 0.705\,236\,41$, not $1/\sqrt{2} = 0.707\,106\,78$: the difference is the warping of Corollary 21.5, because $\Omega_c = \omega_c T = 0.251\,327\,4$ is not negligible; pre-warping (Exercise 21.9) would correct it exactly. (d) $\sum_n |h[n]|^2 = \frac{4}{9}(\sum_{m \geq 1} 4^{-m} + \sum_{n \geq 0} 4^{-n}) = \frac{4}{9}(\frac{1}{3} + \frac{4}{3}) = \frac{20}{27} = 0.740\,740\,740\,7$; and $\frac{1}{2\pi} \int_{-\pi}^{\pi} |H(e^{i\Omega})|^2 d\Omega$, evaluated with 200,000 points, equals 0.740 740 740 7: the two routes coincide, as Theorem 21.9 requires. ✓

21.13. Formulary of the chapter

Definitions and annulus.

$$X(z) = \sum_{n \in \mathbb{Z}} x[n]z^{-n}, \quad \text{ROC}(x) = \left\{ z \neq 0 : \sum_n |x[n]| |z|^{-n} < \infty \right\}.$$

$$\rho_+ = \limsup_{n \rightarrow +\infty} |x[n]|^{1/n}, \quad \rho_- = \left(\limsup_{m \rightarrow +\infty} |x[-m]|^{1/m} \right)^{-1}, \quad A(\rho_+, \rho_-) \subseteq \text{ROC}(x) \subseteq \overline{A}.$$

Causal $\Rightarrow \rho_- = \infty$ (exterior of a circle); anticausal $\Rightarrow \rho_+ = 0$ (disk); $\rho_- < \rho_+ \Rightarrow$ empty annulus.

Inversion, uniqueness, holomorphy.

$$x[n] = \frac{1}{2\pi i} \oint_{|z|=r} X(z) z^{n-1} dz = \frac{1}{2\pi} \int_0^{2\pi} X(re^{i\theta}) r^n e^{in\theta} d\theta, \quad \rho_+ < r < \rho_-.$$

X is holomorphic on $A(\rho_+, \rho_-)$ and $\sum_n x[n]z^{-n}$ is its Laurent series; expression *and* annulus determine x , the expression alone does not:

$$\frac{z}{z-a} \longleftrightarrow \begin{cases} a^n u[n], & |z| > |a|, \\ -a^n u[-n-1], & |z| < |a|. \end{cases}$$

The five properties.

$$\alpha x + \beta y \mapsto \alpha X + \beta Y; \quad x[n-n_0] \mapsto z^{-n_0} X(z); \quad a^n x[n] \mapsto X(z/a);$$

$$n x[n] \mapsto -z X'(z); \quad (x * y)[n] = \sum_k x[k]y[n-k] \mapsto X(z)Y(z),$$

with $\text{ROC} \supseteq \mathcal{R}_x \cap \mathcal{R}_y$ in cases (i) and (v), $\mathcal{R}$ unchanged in (ii) and (iv), $|a|\mathcal{R}_x$ in (iii).

Table of notable Z-transforms (causal signals).

$$\delta[n] \mapsto 1 \ (\mathbb{C} \setminus \{0\}); \quad u[n] \mapsto \frac{z}{z-1} \ (|z| > 1); \quad a^n u[n] \mapsto \frac{z}{z-a} \ (|z| > |a|);$$

$$n a^n u[n] \mapsto \frac{az}{(z-a)^2}; \quad n^2 a^n u[n] \mapsto \frac{az(z+a)}{(z-a)^3}; \quad \frac{1}{(z-p)^j} \mapsto \binom{n-1}{j-1} p^{n-j} u[n-j];$$

$$\cos(\Omega_0 n) u[n] \mapsto \frac{z^2 - z \cos \Omega_0}{z^2 - 2z \cos \Omega_0 + 1}, \quad \sin(\Omega_0 n) u[n] \mapsto \frac{z \sin \Omega_0}{z^2 - 2z \cos \Omega_0 + 1} \quad (|z| > 1).$$

DTFT.

$$\hat{x}(\Omega) = \sum_n x[n] e^{-in\Omega} = X(e^{i\Omega}), \quad \hat{x}(\Omega + 2\pi) = \hat{x}(\Omega), \quad \|\hat{x}\|_\infty \leq \|x\|_1;$$

$$x[n] = \frac{1}{2\pi} \int_{-\pi}^{\pi} \hat{x}(\Omega) e^{in\Omega} d\Omega; \quad \sum_n x[n] \overline{y[n]} = \frac{1}{2\pi} \int_{-\pi}^{\pi} \hat{x} \bar{\hat{y}} d\Omega.$$

$$\mathbb{T} \subseteq \text{ROC}(x) \iff x \in \ell^1(\mathbb{Z}).$$

Stability.

$$\text{BIBO} \iff \|h\|_1 = \sum_n |h[n]| < \infty \iff \mathbb{T} \subseteq \text{ROC}(h),$$

$$\text{and in the causal rational case} \quad \text{BIBO} \iff \max_\ell |p_\ell| < 1,$$

with optimal constant $M = \|h\|_1$ and, for a causal rational system, $\text{ROC}(h) = \{|z| > \max_\ell |p_\ell|\}$ exactly.

The three planes, sampling and the bilinear map.

$$z = e^{sT} : \quad |e^{sT}| = e^{T \text{Re } s}, \quad e^{sT} = e^{s'T} \iff s - s' \in \frac{2\pi i}{T} \mathbb{Z} \text{ (aliasing);}$$

$$\beta(s) = \frac{1 + \frac{T}{2}s}{1 - \frac{T}{2}s}, \quad s = \frac{2}{T} \cdot \frac{z-1}{z+1}, \quad |\beta(s)|^2 - 1 = \frac{2T \text{Re}(s)}{|1 - \frac{T}{2}s|^2},$$

$$\Omega = 2 \arctan \frac{\omega T}{2}, \quad \omega = \frac{2}{T} \tan \frac{\Omega}{2} \quad (\text{pre-warping}).$$

First-order bilinear low-pass filter, and the numbers of the chapter.

$$H(s) = \frac{\omega_c}{s + \omega_c} \longrightarrow H(z) = b_0 \frac{1 + z^{-1}}{1 - pz^{-1}}, \quad b_0 = \frac{\omega_c}{K + \omega_c}, \quad p = \frac{K - \omega_c}{K + \omega_c}, \quad K = \frac{2}{T},$$

$$y[n] = p y[n-1] + b_0(x[n] + x[n-1]), \quad H(1) = \frac{2b_0}{1-p} = 1.$$

f_s (Hz)	1,000	200	500	1,000 (pre-warp)
f_c (Hz)	10	5	20	200
b_0	0.030 459 0	0.072 820 5	0.111 635 2	0.420 807 8
p	0.939 081 9	0.854 359 0	0.776 729 6	0.158 384 4

Sources and bibliography

- [1] A. V. Oppenheim, R. W. Schaffer, *Discrete-Time Signal Processing*, 3rd edition, Pearson, Upper Saddle River (New Jersey), 2010, 1108 pages, ISBN 978-0-13-198842-2. Chapter 2, on discrete-time signals and systems (convolution, LTI systems, stability, the discrete-time Fourier transform: source of Definition 21.2, of Proposition 21.1, of Theorem 21.10 and of Definition 21.5); and Chapter 3, on the Z-transform (region of convergence, inversion, properties, rational systems: source of Theorem 21.1, of Theorem 21.3 and of Theorem 21.5). Bibliographic data (title, edition, publisher, year, pagination, ISBN) verified on the Open Library record for ISBN 9780131988422; the role of Chapters 2 and 3 as the site of the elementary treatment of the Z-transform and the DTFT is confirmed by the syllabus of MIT 6.341 *Discrete-Time Signal Processing* (MIT OpenCourseWare, Fall 2005), which lists them among the prerequisites — verified on 6 September 2026.
- [2] A. V. Oppenheim, A. S. Willsky, S. H. Nawab, *Signals & Systems*, 2nd edition, Prentice-Hall Signal Processing Series, Prentice Hall, Upper Saddle River (New Jersey), 1997, 957 pages, ISBN 0-13-814757-4. Chapter 10, *The z-Transform*, sections 10.1–10.10: definition of the transform, region of convergence and its properties, inversion, operational properties, rational transfer functions and stability of LTI systems. It is the primary source of the pedagogical approach of Section 21.2 and Section 21.5. Bibliographic data verified on the Open Library record for ISBN 0138147574; the assignment of sections 10.1–10.10 to the treatment of the Z-transform is verified on the *Readings* page of MIT 6.003 *Signals and Systems* (MIT OpenCourseWare, Fall 2011), which adopts this text (listed there as "2nd ed., Prentice Hall, 1996", the copyright year of the edition whose printing Open Library records as 1997) — verified on 6 September 2026.
- [3] S. K. Mitra, *Digital Signal Processing: A Computer-Based Approach*, 4th edition, McGraw-Hill, New York, 2011, 992 pages, ISBN 978-0-07-338049-0. It is the reference text for the implementation-oriented material: the tables of notable Z-transforms (Example 21.3 and Appendix C, Â§3) and the design of IIR filters by the bilinear transform, with and without pre-warping (Section 21.7 and Exercise 21.9). The bibliographic data were verified on the Open Library record for ISBN 9780073380490 — verified on 6 September 2026.
- [4] W. Rudin, *Real and Complex Analysis*, 3rd edition, McGraw-Hill, New York, 1987, xiv+416 pages, ISBN 0-07-054234-1. Chapter 3, *L^p-spaces*: it is the source of the only result **imported** into this chapter, the completeness of $L^2(\mathbb{T})$ (the Riesz–Fischer theorem), declared in Remark 21.7 and needed to extend Theorem 21.9 from $\ell^1(\mathbb{Z})$ to $\ell^2(\mathbb{Z})$.

Bibliographic data verified on the Open Library record for ISBN 0070542341 — verified on 6 September 2026.

- [5] For the results of the treatise recalled with \ref: the lemma on the integral of powers on the circle, the Laurent series expansion theorem with uniqueness of the coefficients, the identity principle and the fundamental theorem of algebra are proved in Chapter 15; L^2 convergence and the completeness of the trigonometric system in Chapter 17; the covering $\mathbb{R} \rightarrow \mathbb{T}$ and the winding number in Chapter 12; Möbius transformations and polar form in Chapter 6; the Laplace transform, its region of convergence and its restriction to the imaginary axis in Chapter 20. Definition 21.3, Theorem 21.6, Theorem 21.12, Remark 21.8, Remark 21.11, Section 21.7 with the listing FB_LOWPASS1 and Section 21.8 come from Volume II, Chapter 4, §11 and §12, and from Appendix A, §3, and are reproduced in full according to the Executive Plan, §3.4, row 21.
- [6] **Open point.** The reference, inherited from Volume II and kept in Remark 21.11, to a 2025 work on the optimal choice of the parameter α of the generalized bilinear transform (attributed to "Chen, Li, Cui et al.") **has not been verified**: the entry does not appear in the bibliography of Volume III and it was not possible to ascertain its authors, title and venue. It is flagged as such in the warning that follows that remark and is not used in any statement, computation or proof in the chapter.

The discrete Fourier transform

A signal observed by a computer is a finite sequence of numbers: N samples, and nothing more. The discrete Fourier transform is the only change of basis that turns that finite vector into “a sum of sinusoids” with no approximation at all, because the N discrete exponentials $n \mapsto e^{-2\pi i kn/N}$ are exactly N pairwise orthogonal vectors of $\mathbb{C}^N$: not one more, not one less. The whole chapter follows from this single fact, which is the orthogonality of the N -th roots of unity already proved in Chapter 6 (Theorem 6.5), read again as a statement of linear algebra in $\mathbb{C}^N$.

The path is linear. We fix the convention (Definition 22.1) and prove the orthogonality of the discrete exponential vectors (Theorem 22.1), treating separately the case in which the denominator of the geometric sum vanishes (Lemma 22.1). From there comes the inversion formula (Theorem 22.2), proved twice — directly and by a matrix argument —, the unitarity of the normalized matrix (Theorem 22.3), its Vandermonde structure (Proposition 22.3) together with its determinant (Corollary 22.3), and the order-four periodicity $F_N^4 = I$ (Corollary 22.4) that confines the eigenvalues of the DFT to the four fourth roots of unity (Corollary 22.5). Next come circular convolution together with the discrete convolution theorem (Theorem 22.5), Parseval’s identity (Theorem 22.6), the conjugate symmetry of real signals (Theorem 22.7) and the diagonalization of circulant matrices (Theorem 22.8), which is the algebraic reason why a filter is applied by multiplying spectra. The final part is applied in nature and just as fully proved: the DFT as sampling of the DTFT (Theorem 22.9), zero-padding as spectral interpolation with the Dirichlet kernel (Theorem 22.11), leakage, and the rectangular, Hann and Hamming windows, for which the coherent gain (Proposition 22.6), the equivalent noise bandwidth (Proposition 22.7) and the main-lobe width (Proposition 22.8) are all computed in closed form.

The material that the Execution Plan moved here from Volume II — Section 8 of Chapter 3 and the first part of Section 13 of Chapter 4, with the butterfly network, the `FB_FFT8` block in SCL and the discussion of leakage, plus Appendix B “Eight-point DFT” — is preserved in full and is found in Sections 22.10, 22.10.3 and 22.12, followed by the inherited exercises, quiz and formulary (Section 22.13). What was there stated or used without proof — orthogonality in the degenerate case, inversion, Parseval, Hermitian symmetry, the role of windows — is here proved, and the eight-point example is worked out symbolically, inverted on all eight samples, and cross-checked with an executed script.

INFO

Level and prerequisites. Level **B–C**: the theory (Sections 22.1–22.9) requires only linear algebra in $\mathbb{C}^N$ and is level **B**; the part on windows and spectral analysis (Section 22.10.3) and the diagonalization of circulants are level **C**.

Internal prerequisites. n -th roots of unity and their orthogonality (Chapter 6, Definition 6.2, Theorem 6.2, Theorem 6.4, Theorem 6.5); the Zeta transform and the DTFT (Chapter 21, Definition 21.3, Theorem 21.6); Fourier series and the Gibbs phenomenon (Chapter 17). The characters of the cyclic group $\mathbb{Z}/N\mathbb{Z}$ and their orthogonality are treated in Volume II, Chapter 7: that chapter proves that the N maps $\chi_k(n) = e^{2\pi i kn/N}$ are exactly all the homomorphisms of $\mathbb{Z}/N\mathbb{Z}$ into $\mathbb{T}$, and that the orthogonality relation used here is the orthogonality

relation of the characters of a finite abelian group. In the present chapter that fact is not assumed: the one identity that is needed is proved again from scratch in Lemma 22.1.

External prerequisites, assumed and not reproved:

- linear algebra over $\mathbb{C}$: the Hermitian inner product, unitary matrices, the determinant and its elementary properties (multilinearity in the columns, invariance under adding a multiple of one column to another, Laplace expansion), the minimal polynomial and the criterion “annihilating polynomial with simple roots $\Rightarrow$ diagonalizability”;
- the sum of a geometric progression and its telescoping identity (recalled and used, in any case, in the form proved in Theorem 6.4);
- elementary trigonometry: Euler’s formulas, product-to-sum identities, and the values $\cos(\pi/4) = \sin(\pi/4) = \sqrt{2}/2$, $\cos(\pi/8)$, $\sin(\pi/8)$.

Everything else is proved here.

What is learned. Writing the DFT as a matrix-vector product and recognizing its Vandermonde structure; proving inversion in two independent ways; using unitarity to obtain Parseval without computation; computing a circular convolution both directly and via spectra; diagonalizing a circulant matrix and solving its linear system in $O(N \log N)$; predicting what a spectrum shows when the tone does not fall on a bin, and choosing the window accordingly, knowing what is gained and what is lost.

Warning. Conventions of the chapter.

- $N \geq 1$ is an integer, and we fix once and for all

$$\omega_N = e^{-2\pi i/N},$$

so that $\omega_N^{-1} = \overline{\omega_N} = e^{2\pi i/N} = \zeta_N$ is the primitive N -th root of unity of Chapter 6 (Definition 6.2). The negative sign in the exponent is the convention of signal engineering, and is the one used by Oppenheim and Schaffer and by Briggs and Henson.

- The indices n (time) and k (frequency) run over $\{0, 1, \dots, N-1\}$; whenever they appear outside this range they are meant **modulo** N , which is always legitimate by Proposition 22.1. The notation $\langle m \rangle_N$ denotes the remainder of m on division by N , i.e. the unique integer of $\{0, \dots, N-1\}$ congruent to m modulo N .
- The Hermitian inner product on $\mathbb{C}^N$ is $\langle u, v \rangle = \sum_{n=0}^{N-1} u_n \overline{v_n}$, linear in the first variable; $\|u\|^2 = \langle u, u \rangle$. For a matrix A , $A^* = \overline{A}^T$.
- In Sections 22.10 and 22.10.3, inherited from Volume II, the symbol ζ_N appears with the *local* convention $\zeta_N = e^{-2\pi i/N}$ declared in Theorem 22.13: there, ζ_N is thus our ω_N . The original text is preserved; this note only serves to avoid ambiguity with $\zeta_N = e^{+2\pi i/N}$ of Chapter 6.
- Numerical values are rounded to the fifth decimal place unless stated otherwise, and each one is obtained twice by independent routes: a closed formula and an executed script. The symbol $\checkmark$ marks agreement between the two routes.
- “Bin” is the current name for the index k read as a frequency: bin k corresponds to the frequency $k f_s / N$, where $f_s = 1/T$ is the sampling frequency.

22.1. Definition, convention, first properties

Definition 22.1: Discrete Fourier transform. Let $x = (x[0], x[1], \dots, x[N-1]) \in \mathbb{C}^N$. Its **discrete Fourier transform** (DFT) is the vector $X = (X[0], \dots, X[N-1]) \in \mathbb{C}^N$ defined by

$$X[k] = \sum_{n=0}^{N-1} x[n] \omega_N^{kn} = \sum_{n=0}^{N-1} x[n] e^{-2\pi i kn/N}, \quad k = 0, 1, \dots, N-1,$$

where $\omega_N = e^{-2\pi i/N}$. One writes $X = \mathcal{F}_N x$, or $X = \text{DFT}_N\{x\}$.

Definition 22.2: Inverse discrete Fourier transform. Let $X \in \mathbb{C}^N$. Its **inverse discrete Fourier transform** (IDFT) is the vector with components

$$(\mathcal{F}_N^{-1} X)[n] = \frac{1}{N} \sum_{k=0}^{N-1} X[k] \omega_N^{-kn} = \frac{1}{N} \sum_{k=0}^{N-1} X[k] e^{+2\pi i kn/N}, \quad n = 0, 1, \dots, N-1.$$

That this map is indeed the inverse of $\mathcal{F}_N$ is not part of the definition: it is the content of Theorem 22.2, and until that point the notation $\mathcal{F}_N^{-1}$ should be read as a mere name.

Definition 22.3: DFT matrix and normalized matrix. The **DFT matrix** and the **normalized matrix** of order N are the matrices $W_N, F_N \in \mathbb{C}^{N \times N}$ with entries

$$(W_N)_{kn} = \omega_N^{kn}, \quad (F_N)_{kn} = \frac{1}{\sqrt{N}} \omega_N^{kn}, \quad k, n = 0, \dots, N-1,$$

i.e. $F_N = N^{-1/2} W_N$. With this notation, Definition 22.1 reads as the matrix-vector product $X = W_N x$.

Remark 22.1: The competing conventions, and why the choice is not innocent. Three conventions circulate in the literature: the one adopted here (factor 1 forward, $1/N$ backward, sign $-$ in the forward exponent), used by Oppenheim and Schaffer and implemented by `numpy.fft`; the symmetric one (factor $1/\sqrt{N}$ both ways), which makes the transform unitary already at the level of the definition; and the one with sign $+$ in the forward exponent, common in crystallography. The three differ by multiplicative constants and by a conjugation, and every formula of the chapter changes accordingly: Parseval's identity, for instance, carries the factor $1/N$ in our convention (Theorem 22.6) and no factor at all in the symmetric one. Stating the convention before writing any formula is not pedantry: it is the first thing to check when two FFT implementations disagree.

Proposition 22.1: Periodicity of the two indices. Extend the formulas of Definition 22.1 and Definition 22.2 to every integer, setting $X[k] = \sum_{n=0}^{N-1} x[n] \omega_N^{kn}$ for $k \in \mathbb{Z}$ and $\tilde{x}[n] = \frac{1}{N} \sum_{k=0}^{N-1} X[k] \omega_N^{-kn}$ for $n \in \mathbb{Z}$. Then

$$X[k+N] = X[k] \quad \text{for every } k \in \mathbb{Z}, \quad \tilde{x}[n+N] = \tilde{x}[n] \quad \text{for every } n \in \mathbb{Z}.$$

In particular $X[k] = X[\langle k \rangle_N]$: writing an index outside $\{0, \dots, N-1\}$ is always legitimate, and means writing it modulo N .

Proof. Since $\omega_N^N = e^{-2\pi i} = 1$, for every $n \in \mathbb{Z}$ one has $\omega_N^{(k+N)n} = \omega_N^{kn} \omega_N^{Nn} = \omega_N^{kn} (\omega_N^N)^n = \omega_N^{kn} \cdot 1^n = \omega_N^{kn}$. Substituting term by term in the sum defining $X[k+N]$ gives exactly the sum

defining $X[k]$, hence $X[k+N] = X[k]$. The computation for $\tilde{x}$ is identical with ω_N^{-1} in place of ω_N : $\omega_N^{-k(n+N)} = \omega_N^{-kn}(\omega_N^{-N})^k = \omega_N^{-kn}$, and the constant $1/N$ plays no role. Finally, given $k \in \mathbb{Z}$ there is $q \in \mathbb{Z}$ with $k = \langle k \rangle_N + qN$; iterating the equality just proved q times (forward if $q > 0$, backward if $q < 0$) gives $X[k] = X[\langle k \rangle_N]$. $\square$

Proposition 22.2: Linearity. *The map $\mathcal{F}_N : \mathbb{C}^N \rightarrow \mathbb{C}^N$ of Definition 22.1 is $\mathbb{C}$ -linear: for all $x, y \in \mathbb{C}^N$ and all $\alpha, \beta \in \mathbb{C}$, $\mathcal{F}_N(\alpha x + \beta y) = \alpha \mathcal{F}_N x + \beta \mathcal{F}_N y$.*

Proof. For each fixed k ,

$$\sum_{n=0}^{N-1} (\alpha x[n] + \beta y[n]) \omega_N^{kn} = \alpha \sum_{n=0}^{N-1} x[n] \omega_N^{kn} + \beta \sum_{n=0}^{N-1} y[n] \omega_N^{kn},$$

by distributivity of multiplication over addition and because a finite number of terms in $\mathbb{C}$ can be reordered. The left-hand side is $(\mathcal{F}_N(\alpha x + \beta y))[k]$, the right-hand side is $\alpha X[k] + \beta Y[k]$; since this holds for every $k = 0, \dots, N-1$, the two vectors coincide. Equivalently: $\mathcal{F}_N$ is multiplication by the matrix W_N of Definition 22.3, and matrix-vector multiplication is linear. $\square$

22.2. Orthogonality of the discrete exponential vectors

The whole theory rests on a single identity, the sum of a geometric progression whose ratio is a root of unity. The delicate point — the only one — is that the closed formula for the geometric sum *does not apply* when the ratio equals 1: that case must be isolated and summed by hand. This is done here explicitly.

Lemma 22.1: Sum of the powers of a root of unity. *Let $N \geq 1$ and $j \in \mathbb{Z}$. Then*

$$\sum_{n=0}^{N-1} \omega_N^{jn} = \begin{cases} N, & \text{if } N \mid j, \\ 0, & \text{if } N \nmid j. \end{cases}$$

Proof. Set $q = \omega_N^j = e^{-2\pi i j/N}$, so that $\sum_{n=0}^{N-1} \omega_N^{jn} = \sum_{n=0}^{N-1} q^n$. Two cases are distinguished, which are exactly the case of vanishing denominator and that of nonvanishing denominator in the geometric-sum formula.

Case 1: $N \mid j$ (vanishing denominator). Then $j/N \in \mathbb{Z}$, hence $q = e^{-2\pi i(j/N)} = 1$, because $e^{-2\pi i m} = 1$ for every integer m . The closed formula $\sum_{n=0}^{N-1} q^n = \frac{q^N - 1}{q - 1}$ **cannot be used**: the denominator $q - 1$ vanishes (and so does the numerator, so the quotient would be the indeterminate form $0/0$). One sums directly instead: all N terms equal $1^n = 1$, so

$$\sum_{n=0}^{N-1} q^n = \underbrace{1 + 1 + \dots + 1}_{N \text{ times}} = N.$$

Case 2: $N \nmid j$ (nonvanishing denominator). One first shows $q \neq 1$. Indeed $q = e^{-2\pi i j/N} = 1$ is equivalent to $-2\pi j/N \in 2\pi\mathbb{Z}$, i.e. to $j/N \in \mathbb{Z}$, i.e. to $N \mid j$: excluded by hypothesis. For every $q \in \mathbb{C}$ the telescoping identity already proved in Theorem 6.4 (Step 1) holds,

$$(q - 1) \sum_{n=0}^{N-1} q^n = q^N - 1,$$

and now, since $q - 1 \neq 0$, it is legitimate to divide: $\sum_{n=0}^{N-1} q^n = \frac{q^N - 1}{q - 1}$. Finally $q^N = (e^{-2\pi i j/N})^N = e^{-2\pi i j} = 1$ because j is an integer: the numerator vanishes, the denominator does not, and the sum equals 0. $\square$

Remark 22.2: The same statement, three times in the treatise. Lemma 22.1 is Theorem 6.5 of Chapter 6 written with $\omega_N = \zeta_N^{-1}$ in place of ζ_N : since $N \mid j$ if and only if $N \mid (-j)$, the two statements coincide term by term, and the proof has been repeated here only because the degenerate case $N \mid j$ is the most frequent source of error in an implementation. The same fact appears a third time in Volume II, Chapter 7, where it is the orthogonality relation of the characters of the cyclic group $\mathbb{Z}/N\mathbb{Z}$: the vectors $\chi_k = (\omega_N^{kn})_{n=0}^{N-1}$ are the restrictions to $\{0, \dots, N-1\}$ of the homomorphisms $\mathbb{Z}/N\mathbb{Z} \rightarrow \mathbb{T}$, and the sum of the lemma is the integral of the character χ_j over the group, which vanishes for every nontrivial character. Geometry (roots of unity), algebra (characters) and numerical analysis (the DFT) are here the same identity.

Theorem 22.1: Orthogonality of the discrete exponential vectors. For $k = 0, 1, \dots, N-1$ set

$$e_k = \left(\omega_N^{-kn} \right)_{n=0}^{N-1} = (1, e^{2\pi i k/N}, e^{4\pi i k/N}, \dots, e^{2\pi i k(N-1)/N}) \in \mathbb{C}^N.$$

Then, with respect to the Hermitian inner product $\langle u, v \rangle = \sum_n u_n \overline{v_n}$,

$$\langle e_k, e_\ell \rangle = N \delta_{k\ell} = \begin{cases} N, & k = \ell, \\ 0, & k \neq \ell, \end{cases} \quad k, \ell \in \{0, \dots, N-1\}.$$

In particular every e_k has norm $\|e_k\| = \sqrt{N}$, and the vectors $e_0, \dots, e_{N-1}$ are pairwise orthogonal.

Proof. Since $|\omega_N| = |e^{-2\pi i/N}| = 1$, for every integer m one has $\overline{\omega_N^m} = \omega_N^{-m}$. Hence

$$\langle e_k, e_\ell \rangle = \sum_{n=0}^{N-1} \omega_N^{-kn} \overline{\omega_N^{-\ell n}} = \sum_{n=0}^{N-1} \omega_N^{-kn} \omega_N^{\ell n} = \sum_{n=0}^{N-1} \omega_N^{(\ell-k)n}.$$

Lemma 22.1 is now applied with $j = \ell - k$. Since $k, \ell \in \{0, \dots, N-1\}$, one has $|\ell - k| \leq N-1 < N$, and hence $N \mid (\ell - k)$ if and only if $\ell - k = 0$, i.e. $\ell = k$. In the first case the sum equals N , in the second 0: this is the claim. The norm follows by setting $\ell = k$: $\|e_k\|^2 = N$, hence $\|e_k\| = \sqrt{N}$ (arithmetic root, $N > 0$). $\square$

Corollary 22.1: The exponential vectors are an orthogonal basis of $\mathbb{C}^N$. The vectors $e_0, \dots, e_{N-1}$ of Theorem 22.1 form an orthogonal basis of $\mathbb{C}^N$, and $(N^{-1/2}e_k)_{k=0}^{N-1}$ is an orthonormal basis of it. Consequently every $x \in \mathbb{C}^N$ is written in a unique way as $x = \sum_{k=0}^{N-1} c_k e_k$ with $c_k \in \mathbb{C}$.

Proof. Let $c_0, \dots, c_{N-1} \in \mathbb{C}$ satisfy $\sum_k c_k e_k = 0$. Fixing ℓ , take the Hermitian inner product of both sides with e_ℓ : by linearity in the first variable and by Theorem 22.1,

$$0 = \left\langle \sum_k c_k e_k, e_\ell \right\rangle = \sum_k c_k \langle e_k, e_\ell \rangle = c_\ell N.$$

Since $N \neq 0$ one gets $c_\ell = 0$ for every ℓ : the vectors are linearly independent. They are N independent vectors in a space of dimension N , hence a basis. Normalization is immediate since $\|N^{-1/2}e_k\| = N^{-1/2}\sqrt{N} = 1$, and orthogonality is unchanged under multiplication by nonzero scalars. Uniqueness of the coefficients is the uniqueness of the representation with respect to a basis. $\square$

22.3. Inversion, proved twice

Theorem 22.2: DFT inversion formula. Let $x \in \mathbb{C}^N$ and let $X = \mathcal{F}_N x$ be its DFT (Definition 22.1). Then, for every $n = 0, 1, \dots, N-1$,

$$x[n] = \frac{1}{N} \sum_{k=0}^{N-1} X[k] \omega_N^{-kn} = \frac{1}{N} \sum_{k=0}^{N-1} X[k] e^{2\pi i kn/N}.$$

In other words $\mathcal{F}_N$ is bijective and its inverse is the map of Definition 22.2.

Proof. The right-hand side is computed directly. Fixing $n \in \{0, \dots, N-1\}$, substitute the definition of $X[k]$, taking care to rename m the internal dummy index so as not to confuse it with n :

$$\frac{1}{N} \sum_{k=0}^{N-1} X[k] \omega_N^{-kn} = \frac{1}{N} \sum_{k=0}^{N-1} \left(\sum_{m=0}^{N-1} x[m] \omega_N^{km} \right) \omega_N^{-kn}.$$

The sums are finite (exactly N^2 terms), so exchanging the order of summation is legitimate without any convergence hypothesis: it is the associative and commutative property of addition in $\mathbb{C}$ applied to a finite number of terms. Collecting $x[m]$:

$$= \frac{1}{N} \sum_{m=0}^{N-1} x[m] \sum_{k=0}^{N-1} \omega_N^{k(m-n)}.$$

The inner sum is the one of Lemma 22.1 with $j = m - n$. Since $m, n \in \{0, \dots, N-1\}$ one has $|m - n| \leq N - 1 < N$, hence $N \mid (m - n)$ if and only if $m = n$; the inner sum equals N for $m = n$ and 0 for $m \neq n$. A single term survives:

$$\frac{1}{N} \sum_{m=0}^{N-1} x[m] \cdot N \delta_{mn} = \frac{1}{N} \cdot N x[n] = x[n],$$

which is the claim. It follows that $\mathcal{F}_N$ is injective (if $\mathcal{F}_N x = 0$, the formula just proved gives $x[n] = 0$ for every n) and, being an injective endomorphism of a finite-dimensional space, is bijective; the map of Definition 22.2 is a left inverse of it, hence its inverse. $\square$

Second proof: by a matrix argument. We work with the matrices of Definition 22.3. The (k, n) entry of W_N is ω_N^{kn} ; since $|\omega_N| = 1$, the (n, k) entry of $W_N^* = \overline{W_N}^T$ is $\overline{(W_N)_{kn}} = \overline{\omega_N^{kn}} = \omega_N^{-kn}$. The product $W_N^* W_N$ is now computed; its (n, m) entry is

$$(W_N^* W_N)_{nm} = \sum_{k=0}^{N-1} (W_N^*)_{nk} (W_N)_{km} = \sum_{k=0}^{N-1} \omega_N^{-kn} \omega_N^{km} = \sum_{k=0}^{N-1} \omega_N^{k(m-n)}.$$

By Lemma 22.1, with $|m - n| \leq N - 1 < N$, this sum equals N if $m = n$ and 0 otherwise; hence

$$W_N^* W_N = N I_N.$$

Since $\det(NI_N) = N^N \neq 0$, the matrix W_N is invertible and, multiplying the identity $W_N^* W_N = NI_N$ on the right by W_N^{-1} , one obtains

$$W_N^{-1} = \frac{1}{N} W_N^*.$$

Applying this equality to the vector $X = W_N x$ gives $x = W_N^{-1} X = \frac{1}{N} W_N^* X$, which componentwise is $x[n] = \frac{1}{N} \sum_k \omega_N^{-kn} X[k]$: the same formula. The matrix route has the extra advantage of delivering, as a by-product, the identity $W_N^* W_N = NI_N$, i.e. the unitarity of $F_N = N^{-1/2} W_N$ (Theorem 22.3). $\square$

Corollary 22.2: Uniqueness of the spectrum and reconstruction. *Two vectors of $\mathbb{C}^N$ with the same DFT coincide. Moreover, for every $x \in \mathbb{C}^N$ the expansion*

$$x = \frac{1}{N} \sum_{k=0}^{N-1} X[k] e_k$$

holds, with e_k the vectors of Theorem 22.1: that is, $X[k]/N$ are the coefficients of x in the orthogonal basis (e_k) , and $X[k] = \langle x, e_k \rangle$.

Proof. If $\mathcal{F}_N x = \mathcal{F}_N y$ then $\mathcal{F}_N(x - y) = 0$ by Proposition 22.2, and Theorem 22.2 applied to $x - y$ gives $(x - y)[n] = 0$ for every n , i.e. $x = y$.

For the expansion: the n -th component of $\frac{1}{N} \sum_k X[k] e_k$ is $\frac{1}{N} \sum_k X[k] \omega_N^{-kn}$, which by Theorem 22.2 equals $x[n]$; holding for every n , the two vectors coincide. Finally

$$\langle x, e_k \rangle = \sum_{n=0}^{N-1} x[n] \overline{\omega_N^{-kn}} = \sum_{n=0}^{N-1} x[n] \omega_N^{kn} = X[k],$$

again because $|\omega_N| = 1$. Note the consistency with the formula for the coefficients with respect to an orthogonal basis: $x = \sum_k \frac{\langle x, e_k \rangle}{\|e_k\|^2} e_k = \sum_k \frac{X[k]}{N} e_k$. $\square$

22.4. The DFT matrix: Vandermonde, unitarity, determinant, eigenvalues

Proposition 22.3: W_N is a Vandermonde matrix. *Set $z_k = \omega_N^k$ for $k = 0, \dots, N-1$. Then the matrix W_N of Definition 22.3 is the Vandermonde matrix of the nodes $z_0, \dots, z_{N-1}$:*

$$W_N = (z_k^n)_{k,n=0}^{N-1} = \begin{pmatrix} 1 & 1 & 1 & \cdots & 1 \\ 1 & z_1 & z_1^2 & \cdots & z_1^{N-1} \\ 1 & z_2 & z_2^2 & \cdots & z_2^{N-1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & z_{N-1} & z_{N-1}^2 & \cdots & z_{N-1}^{N-1} \end{pmatrix},$$

and the nodes $z_0, \dots, z_{N-1}$ are pairwise distinct.

Proof. By definition $(W_N)_{kn} = \omega_N^{kn} = (\omega_N^k)^n = z_k^n$, which is the required form: the k -th row is the sequence of powers $0, 1, \dots, N-1$ of the node z_k . The nodes are distinct: if $z_k = z_\ell$ with $k, \ell \in \{0, \dots, N-1\}$ then $\omega_N^{k-\ell} = 1$, i.e. $e^{-2\pi i(k-\ell)/N} = 1$, i.e. $N \mid (k-\ell)$; but $|k-\ell| \leq N-1 < N$, hence $k = \ell$. (This is the same argument by which Theorem 6.2 counts

Figure 22.1: The points $\omega_8^{-k} = e^{2\pi i k/8}$, $k = 0, \dots, 7$, at which the eight-point DFT evaluates the polynomial $\sum_n x[n]z^{-n}$ (Theorem 22.12). The coordinates are $(\cos(2\pi k/8), \sin(2\pi k/8))$: $(\pm 1, 0)$, $(0, \pm 1)$, and the four points with coordinates $\pm\sqrt{2}/2 = \pm 0.70711$, computed by hand from $\cos(\pi/4) = \sin(\pi/4) = \sqrt{2}/2$ and cross-checked numerically.

exactly N N -th roots of unity.) □

Lemma 22.2: Vandermonde determinant. Let $z_0, \dots, z_{m-1} \in \mathbb{C}$ and $V = (z_k^n)_{k,n=0}^{m-1}$. Then

$$\det V = \prod_{0 \leq k < \ell \leq m-1} (z_\ell - z_k).$$

(For $m = 1$ the product is empty and equals 1.)

Proof. By induction on m .

Base case $m = 1$. $V = (1)$, $\det V = 1$, and the product over an empty set of pairs equals 1: the equality holds.

Inductive step. Let $m \geq 2$ and suppose the statement true for $m - 1$ nodes. Perform on V the sequence of elementary column operations

$$C_n \leftarrow C_n - z_0 C_{n-1}, \quad n = m-1, m-2, \dots, 1,$$

carried out in this order, i.e. starting from the last column. Each of them adds to one column a multiple of another column and hence *does not change the determinant*; moreover, being carried out from last to first, each operation uses a column C_{n-1} not yet modified. The new (k, n) entry, for $n \geq 1$, is

$$z_k^n - z_0 z_k^{n-1} = z_k^{n-1} (z_k - z_0),$$

while column $n = 0$ remains all 1's. Row $k = 0$ therefore becomes $(1, 0, 0, \dots, 0)$, because for $k = 0$ one has $z_0^{n-1}(z_0 - z_0) = 0$. Expanding the determinant along the first row (Laplace expansion) leaves only the minor obtained by deleting row 0 and column 0:

$$\det V = \det \left(z_k^{n-1} (z_k - z_0) \right)_{k=1, \dots, m-1; n=1, \dots, m-1}.$$

In this $(m-1) \times (m-1)$ matrix, row k has the common factor $(z_k - z_0)$; by multilinearity of the determinant in the rows it is factored out, one row at a time:

$$\det V = \left(\prod_{k=1}^{m-1} (z_k - z_0) \right) \cdot \det (z_k^{n-1})_{k,n=1}^{m-1}.$$

The last matrix is, up to the relabeling $k' = k - 1$, $n' = n - 1$, the Vandermonde matrix of the nodes $z_1, \dots, z_{m-1}$. By the inductive hypothesis its determinant equals $\prod_{1 \leq k < \ell \leq m-1} (z_\ell - z_k)$, and hence

$$\det V = \prod_{k=1}^{m-1} (z_k - z_0) \cdot \prod_{1 \leq k < \ell \leq m-1} (z_\ell - z_k) = \prod_{0 \leq k < \ell \leq m-1} (z_\ell - z_k),$$

because the first product collects exactly the pairs with $k = 0$ and the second all the others. The induction is complete. $\square$

Theorem 22.3: Unitarity of the normalized matrix. The matrix $F_N = N^{-1/2}W_N$ of Definition 22.3 is unitary:

$$F_N^* F_N = F_N F_N^* = I_N, \quad \text{equivalently} \quad W_N^* W_N = W_N W_N^* = N I_N.$$

In particular $F_N^{-1} = F_N^*$ and $\|F_N x\| = \|x\|$ for every $x \in \mathbb{C}^N$.

Proof. The identity $W_N^* W_N = N I_N$ was proved in the computation of the Matrix variant of the proof of Theorem 22.2: the (n, m) entry of the product is $\sum_k \omega_N^{k(m-n)}$, which equals $N \delta_{nm}$ by Lemma 22.1. Dividing by N gives $F_N^* F_N = I_N$, i.e. F_N^* is a left inverse of F_N . A square matrix with a left inverse is invertible and that left inverse is the inverse: indeed $F_N^* F_N = I$ implies $\det(F_N^*) \det(F_N) = 1$, hence $\det F_N \neq 0$, and multiplying $F_N^* F_N = I$ on the right by F_N^{-1} gives $F_N^* = F_N^{-1}$; consequently also $F_N F_N^* = I$.

Norm preservation follows: for every x ,

$$\|F_N x\|^2 = \langle F_N x, F_N x \rangle = (F_N x)^* (F_N x) = x^* F_N^* F_N x = x^* x = \|x\|^2,$$

and norms are nonnegative.

Note on symmetry. W_N is symmetric ($W_N^T = W_N$, because $\omega_N^{kn} = \omega_N^{nk}$), so $W_N^* = \overline{W_N}$ and the identity also reads $\overline{W_N} W_N = N I_N$. $\square$

Corollary 22.3: Modulus of the determinant. $|\det F_N| = 1$ and $|\det W_N| = N^{N/2}$. Moreover, in explicit form,

$$\det W_N = \prod_{0 \leq k < \ell \leq N-1} (\omega_N^\ell - \omega_N^k).$$

Proof. From unitarity (Theorem 22.3) one has $F_N^* F_N = I$, hence $\det(F_N^*) \det(F_N) = 1$. But $\det(F_N^*) = \overline{\det F_N}$ (the determinant of the transpose coincides with that of the matrix, and conjugation factors out of the determinant, being a sum of products of entries), hence $\overline{\det F_N} \cdot \det F_N = |\det F_N|^2 = 1$, i.e. $|\det F_N| = 1$. Since $W_N = \sqrt{N} F_N$ and $\det(\lambda A) = \lambda^N \det A$ for an $N \times N$ matrix,

$$|\det W_N| = (\sqrt{N})^N |\det F_N| = N^{N/2}.$$

The explicit form is Lemma 22.2 applied to the nodes $z_k = \omega_N^k$ of Proposition 22.3. $\square$

Example 22.1: The determinants for $N = 4$ and $N = 8$, computed two ways. Case $N = 4$. Here $\omega_4 = e^{-i\pi/2} = -i$, and the nodes are $z_0 = 1$, $z_1 = -i$, $z_2 = -1$, $z_3 = i$. Corollary 22.3 gives the product of the six differences $z_\ell - z_k$ with $k < \ell$:

$$\begin{aligned} & (z_1 - z_0)(z_2 - z_0)(z_3 - z_0)(z_2 - z_1)(z_3 - z_1)(z_3 - z_2) \\ &= (-i - 1)(-1 - 1)(i - 1)(-1 + i)(i + i)(i + 1). \end{aligned}$$

Group the terms: $(-i-1)(i-1) = -(1+i)(i-1) = -(i-1+i^2-i) = -(-2) = 2$; then $(-1-1) = -2$; then $(-1+i)(2i) = -2i+2i^2 = -2-2i$; finally $(i+1)$. The product is therefore

$$2 \cdot (-2) \cdot (-2-2i) \cdot (1+i) = (-4) \cdot (-2-2i)(1+i) = (-4) \cdot (-2-2i-2i-2i^2) = (-4)(-4i) = 16i.$$

The modulus is $16 = 4^{4/2} = 4^2 \checkmark$, in agreement with Corollary 22.3.

Case $N = 8$. The product of the $\binom{8}{2} = 28$ differences is not conveniently written by hand; Corollary 22.3 nonetheless predicts $|\det W_8| = 8^{8/2} = 8^4 = 4096$. The explicit computation (Vandermonde product and, entirely independently, LU factorization of the 8×8 matrix) gives

$$\det W_8 = -4096i,$$

whose modulus is $4096 \checkmark$.

Executed check. The script of Section 22.12.1 computes, for $N = 4$ and $N = 8$, the determinant of W_N with `numpy.linalg.det` and, separately, the Vandermonde product $\prod_{k < \ell} (\omega_N^\ell - \omega_N^k)$: the two values agree to within 10^{-11} , and equal $16i$ and $-4096i$ respectively; the moduli are 16 and 4096 $\checkmark$.

Theorem 22.4: The square of the normalized DFT is time reversal. Let $P \in \mathbb{C}^{N \times N}$ be the matrix of the permutation $n \mapsto \langle -n \rangle_N$, i.e. $P_{mn} = 1$ if $m+n \equiv 0 \pmod{N}$ and $P_{mn} = 0$ otherwise. Then

$$F_N^2 = P.$$

Equivalently: if $X = \mathcal{F}_N x$ and $Y = \mathcal{F}_N X$, then $Y[n] = N x[\langle -n \rangle_N]$ for every n .

Proof. The (m, n) entry of W_N^2 is computed:

$$(W_N^2)_{mn} = \sum_{k=0}^{N-1} \omega_N^{mk} \omega_N^{kn} = \sum_{k=0}^{N-1} \omega_N^{k(m+n)}.$$

By Lemma 22.1 with $j = m+n$, this sum equals N if $N \mid (m+n)$ and 0 otherwise; that is, $(W_N^2)_{mn} = N P_{mn}$, i.e. $W_N^2 = NP$. Dividing by N (since $F_N^2 = N^{-1}W_N^2$) gives $F_N^2 = P$. For the reformulation: $Y = W_N X = W_N^2 x = NPx$, and the n -th component of Px is $\sum_m P_{nm} x[m] = x[m_0]$ where m_0 is the unique index in $\{0, \dots, N-1\}$ with $n+m_0 \equiv 0$, i.e. $m_0 = \langle -n \rangle_N$.

Note that P is well defined: for every n there is one and only one $m \in \{0, \dots, N-1\}$ with $m \equiv -n$, and it is $m = 0$ if $n = 0$ and $m = N-n$ otherwise. Hence P fixes the index 0 and swaps n with $N-n$. $\square$

Corollary 22.4: Order-four periodicity. $F_N^4 = I_N$, and hence $W_N^4 = N^2 I_N$. The normalized DFT is thus a unitary operator of finite order: applied four times it returns the original signal.

Proof. By Theorem 22.4, $F_N^4 = (F_N^2)^2 = P^2$. Now P^2 is the matrix of the composed permutation $n \mapsto \langle -n \rangle_N \mapsto \langle -(-n) \rangle_N = \langle n \rangle_N = n$, i.e. of the identity: $P^2 = I_N$. Alternatively, by a direct matrix computation,

$$(P^2)_{mn} = \sum_{r=0}^{N-1} P_{mr} P_{rn},$$

and the only r for which $P_{mr} \neq 0$ is $r = \langle -m \rangle_N$, for which $P_{rn} \neq 0$ if and only if $r+n \equiv 0$, i.e. $n \equiv m$: hence $(P^2)_{mn} = \delta_{mn}$. Finally $W_N^4 = (\sqrt{N})^4 F_N^4 = N^2 I_N$. $\square$

Corollary 22.5: The eigenvalues of the DFT. Every eigenvalue λ of F_N satisfies $\lambda^4 = 1$, i.e. $\lambda \in \{1, i, -1, -i\}$: the eigenvalues of the normalized DFT are fourth roots of unity. Moreover F_N is diagonalizable, and $\mathbb{C}^N$ is the direct sum of the four (possibly zero) eigenspaces associated with $1, i, -1, -i$.

Proof. Let λ be an eigenvalue of F_N and $v \neq 0$ an eigenvector, $F_N v = \lambda v$. Applying F_N three more times, $F_N^4 v = \lambda^4 v$; by Corollary 22.4 the left-hand side is v , hence $(\lambda^4 - 1)v = 0$ and, since $v \neq 0$, $\lambda^4 = 1$. The solutions of $\lambda^4 = 1$ are the four fourth roots of unity $1, i, -1, -i$ (Theorem 6.2 with $n = 4$).

For diagonalizability: the polynomial $p(t) = t^4 - 1$ annihilates F_N and is a product of distinct linear factors, $p(t) = (t - 1)(t - i)(t + 1)(t + i)$. An annihilating polynomial with all simple roots implies that the minimal polynomial of F_N has simple roots, a necessary and sufficient condition for diagonalizability over $\mathbb{C}$; and the eigenspace decomposition is the associated primary decomposition. (Alternatively: F_N is unitary by Theorem 22.3, and every unitary matrix is diagonalizable by the spectral theorem.) $\square$

Remark 22.3: The multiplicities of the four eigenvalues: what remains imported. Corollary 22.5 says which the eigenvalues are, not with what multiplicity they occur; and this second question is not proved here. The exact count of the multiplicities of the eigenvalues $1, -i, -1, i$ of the matrix F_N is the content of a theorem of J. H. McClellan and T. W. Parks (1972): it is here **imported**, i.e. used as information rather than derived. What is missing, precisely: the proof requires constructing an explicit basis of eigenvectors (or computing the trace of F_N, F_N^2, F_N^3 , which leads to the quadratic Gauss sums $\sum_n e^{-2\pi i n^2/N}$, not treated in the treatise). The direct computation of the eigenvalues for $N = 4, \dots, 12$, carried out in the script of Section 22.12.1, gives the multiplicities

N	$\lambda = 1$	$\lambda = -i$	$\lambda = -1$	$\lambda = i$
4	2	1	1	0
5	2	1	1	1
6	2	1	2	1
7	2	2	2	1
8	3	2	2	1
12	4	3	3	2

consistent with the McClellan–Parks statement; the sum of each row is N ✓. Nothing in the rest of the chapter depends on this table.

Remark 22.4: Why order four is not a coincidence. Corollary 22.4 is the exact discrete analogue of a known fact of the continuous Fourier transform (Chapter 19): transforming twice is the same as reflecting, transforming four times is the same as doing nothing. The reason is the same in both cases and is Theorem 22.4: the kernel ω_N^{kn} is symmetric in k and n , so composing the transform with itself produces $\sum_k \omega_N^{k(m+n)}$, i.e. again the orthogonality identity, but with $m+n$ in place of $m-n$ — and it is this sign change that produces the reflection. It also follows that the DFT admits a natural square root (the discrete fractional Fourier transform), an object not treated in Volume III.

22.5. Circular convolution and the discrete convolution theorem

Definition 22.4: Circular convolution. Let $x, y \in \mathbb{C}^N$. Their **circular convolution** $x \circledast y \in \mathbb{C}^N$ is defined by

$$(x \circledast y)[n] = \sum_{m=0}^{N-1} x[m] y[\langle n - m \rangle_N], \quad n = 0, 1, \dots, N-1,$$

where $\langle n - m \rangle_N$ is, as stated in the conventions of the chapter, the unique integer of $\{0, \dots, N-1\}$ congruent to $n - m$ modulo N . Writing out the first indices in full, for $N = 4$:

$$\begin{aligned} (x \circledast y)[0] &= x[0]y[0] + x[1]y[3] + x[2]y[2] + x[3]y[1], \\ (x \circledast y)[1] &= x[0]y[1] + x[1]y[0] + x[2]y[3] + x[3]y[2], \\ (x \circledast y)[2] &= x[0]y[2] + x[1]y[1] + x[2]y[0] + x[3]y[3], \\ (x \circledast y)[3] &= x[0]y[3] + x[1]y[2] + x[2]y[1] + x[3]y[0]. \end{aligned}$$

The adjective “circular” recalls that the index of the second factor *wraps around*: when $n - m$ becomes negative, one restarts from the end, as on a circle of N positions.

Proposition 22.4: Circular shift and modulation. Let $x \in \mathbb{C}^N$, $X = \mathcal{F}_N x$, and let $n_0 \in \mathbb{Z}$. Set $x_{n_0}[n] = x[\langle n - n_0 \rangle_N]$ (circular shift by n_0 positions). Then

$$(\mathcal{F}_N x_{n_0})[k] = \omega_N^{kn_0} X[k], \quad k = 0, \dots, N-1.$$

Dually, if $y[n] = \omega_N^{-k_0 n} x[n]$ then $(\mathcal{F}_N y)[k] = X[\langle k - k_0 \rangle_N]$.

Proof. Compute $(\mathcal{F}_N x_{n_0})[k] = \sum_{n=0}^{N-1} x[\langle n - n_0 \rangle_N] \omega_N^{kn}$ and substitute $r = \langle n - n_0 \rangle_N$. As n ranges over $\{0, \dots, N-1\}$, the index r runs *exactly once* over the whole of $\{0, \dots, N-1\}$: the map $n \mapsto \langle n - n_0 \rangle_N$ is indeed a bijection of $\{0, \dots, N-1\}$ onto itself, with inverse $r \mapsto \langle r + n_0 \rangle_N$. Moreover $n \equiv r + n_0 \pmod{N}$, and since $\omega_N^N = 1$ one has $\omega_N^{kn} = \omega_N^{k(r+n_0)}$ (powers of ω_N depend on the exponent only modulo N). Hence

$$\sum_{n=0}^{N-1} x[\langle n - n_0 \rangle_N] \omega_N^{kn} = \sum_{r=0}^{N-1} x[r] \omega_N^{k(r+n_0)} = \omega_N^{kn_0} \sum_{r=0}^{N-1} x[r] \omega_N^{kr} = \omega_N^{kn_0} X[k].$$

For the dual statement: $(\mathcal{F}_N y)[k] = \sum_n \omega_N^{-k_0 n} x[n] \omega_N^{kn} = \sum_n x[n] \omega_N^{(k-k_0)n} = X[k - k_0]$, which by Proposition 22.1 equals $X[\langle k - k_0 \rangle_N]$. $\square$

Theorem 22.5: Discrete convolution theorem. Let $x, y \in \mathbb{C}^N$ with DFTs X and Y . Then

$$\mathcal{F}_N(x \circledast y)[k] = X[k] Y[k], \quad k = 0, 1, \dots, N-1:$$

the DFT turns circular convolution into componentwise multiplication. Equivalently,

$$x \circledast y = \mathcal{F}_N^{-1}(X \cdot Y), \quad (x \circledast y)[n] = \frac{1}{N} \sum_{k=0}^{N-1} X[k] Y[k] \omega_N^{-kn}.$$

Proof. Start from the definition and exchange the order of the two finite sums (legitimate, as in the proof of Theorem 22.2, because the terms are finite in number):

$$\mathcal{F}_N(x \circledast y)[k] = \sum_{n=0}^{N-1} \left(\sum_{m=0}^{N-1} x[m] y[\langle n - m \rangle_N] \right) \omega_N^{kn} = \sum_{m=0}^{N-1} x[m] \underbrace{\sum_{n=0}^{N-1} y[\langle n - m \rangle_N] \omega_N^{kn}}_{=: S_m}.$$

The inner sum S_m is, by Proposition 22.4 applied to the vector y with $n_0 = m$, exactly $\omega_N^{km} Y[k]$. For clarity the step is repeated here explicitly: setting $r = \langle n - m \rangle_N$, as n ranges over $\{0, \dots, N-1\}$ so too does r range once over $\{0, \dots, N-1\}$, and $n \equiv r + m \pmod{N}$, so $\omega_N^{kn} = \omega_N^{k(r+m)}$ because $\omega_N^N = 1$; hence

$$S_m = \sum_{r=0}^{N-1} y[r] \omega_N^{k(r+m)} = \omega_N^{km} \sum_{r=0}^{N-1} y[r] \omega_N^{kr} = \omega_N^{km} Y[k].$$

Substituting,

$$\mathcal{F}_N(x \circledast y)[k] = \sum_{m=0}^{N-1} x[m] \omega_N^{km} Y[k] = Y[k] \sum_{m=0}^{N-1} x[m] \omega_N^{km} = X[k] Y[k].$$

The last formula of the statement is obtained by applying the inverse to both sides, legitimate by Theorem 22.2. $\square$

Corollary 22.6: The dual: product in time, convolution in frequency. Let $x, y \in \mathbb{C}^N$ and let $z[n] = x[n]y[n]$ be the componentwise product. Then

$$Z[k] = \frac{1}{N} (X \circledast Y)[k] = \frac{1}{N} \sum_{j=0}^{N-1} X[j] Y[\langle k - j \rangle_N].$$

Proof. Substitute for $x[n]$ and $y[n]$ their respective inversion formulas (Theorem 22.2), using distinct dummy indices j and ℓ :

$$Z[k] = \sum_{n=0}^{N-1} \left(\frac{1}{N} \sum_{j=0}^{N-1} X[j] \omega_N^{-jn} \right) \left(\frac{1}{N} \sum_{\ell=0}^{N-1} Y[\ell] \omega_N^{-\ell n} \right) \omega_N^{kn}.$$

Factoring out the finite sums over j and ℓ :

$$Z[k] = \frac{1}{N^2} \sum_{j=0}^{N-1} \sum_{\ell=0}^{N-1} X[j] Y[\ell] \sum_{n=0}^{N-1} \omega_N^{n(k-j-\ell)}.$$

By Lemma 22.1 the sum over n equals N if $N \mid (k - j - \ell)$, i.e. if $\ell \equiv k - j \pmod{N}$, and 0 otherwise. For each fixed j there is exactly one $\ell \in \{0, \dots, N-1\}$ with this property, namely $\ell = \langle k - j \rangle_N$. Hence only N terms survive:

$$Z[k] = \frac{1}{N^2} \sum_{j=0}^{N-1} X[j] Y[\langle k - j \rangle_N] \cdot N = \frac{1}{N} (X \circledast Y)[k].$$

$\square$

Example 22.2: A circular convolution computed two ways. Let $N = 4$, $a = (1, 2, 3, 4)$ and $b = (1, 0, -1, 0)$.

First route: the definition. Using the four rows written in full in Definition 22.4 with $x = a$, $y = b$:

$$\begin{aligned}(a \otimes b)[0] &= 1 \cdot 1 + 2 \cdot 0 + 3 \cdot (-1) + 4 \cdot 0 = 1 - 3 = -2, \\(a \otimes b)[1] &= 1 \cdot 0 + 2 \cdot 1 + 3 \cdot 0 + 4 \cdot (-1) = 2 - 4 = -2, \\(a \otimes b)[2] &= 1 \cdot (-1) + 2 \cdot 0 + 3 \cdot 1 + 4 \cdot 0 = -1 + 3 = 2, \\(a \otimes b)[3] &= 1 \cdot 0 + 2 \cdot (-1) + 3 \cdot 0 + 4 \cdot 1 = -2 + 4 = 2.\end{aligned}$$

Hence $a \otimes b = (-2, -2, 2, 2)$.

Second route: Theorem 22.5. With $\omega_4 = -i$,

$$A = \mathcal{F}_4 a = (10, -2 + 2i, -2, -2 - 2i), \quad B = \mathcal{F}_4 b = (0, 2, 0, 2).$$

(For A : $A[0] = 1 + 2 + 3 + 4 = 10$; $A[1] = 1 + 2(-i) + 3(-1) + 4(i) = 1 - 2i - 3 + 4i = -2 + 2i$; $A[2] = 1 - 2 + 3 - 4 = -2$; $A[3] = \overline{A[1]} = -2 - 2i$ by Theorem 22.7, since a is real. For B : $B[k] = 1 - (-i)^{2k} = 1 - (-1)^k$, which equals 0 for even k and 2 for odd k .) The componentwise product is $A \cdot B = (0, -4 + 4i, 0, -4 - 4i)$, and the inverse transform gives

$$(\mathcal{F}_4^{-1}(A \cdot B))[n] = \frac{1}{4} \left((-4 + 4i) i^n + (-4 - 4i) i^{3n} \right) = \frac{1}{4} \cdot 2 \operatorname{Re}((-4 + 4i) i^n),$$

having used $\omega_4^{-kn} = i^{kn}$ and the fact that the two terms are conjugates. For $n = 0$: $\frac{1}{2} \operatorname{Re}(-4 + 4i) = -2$; for $n = 1$: $\frac{1}{2} \operatorname{Re}((-4 + 4i)i) = \frac{1}{2} \operatorname{Re}(-4i - 4) = -2$; for $n = 2$: $\frac{1}{2} \operatorname{Re}(4 - 4i) = 2$; for $n = 3$: $\frac{1}{2} \operatorname{Re}((-4 + 4i)(-i)) = \frac{1}{2} \operatorname{Re}(4i + 4) = 2$. We recover $(-2, -2, 2, 2)$ ✓.

Executed check. The script of Section 22.12.1 computes the circular convolution from the definition and as `ifft(ffft(a)*ffft(b))`: both return $(-2, -2, 2, 2)$ ✓.

22.6. Discrete Parseval identity

Theorem 22.6: Discrete Parseval and Plancherel identities. For all $x, y \in \mathbb{C}^N$, with $X = \mathcal{F}_N x$ and $Y = \mathcal{F}_N y$,

$$\sum_{n=0}^{N-1} x[n] \overline{y[n]} = \frac{1}{N} \sum_{k=0}^{N-1} X[k] \overline{Y[k]} \quad (\text{Parseval}).$$

In particular, setting $y = x$,

$$\sum_{n=0}^{N-1} |x[n]|^2 = \frac{1}{N} \sum_{k=0}^{N-1} |X[k]|^2 \quad (\text{Plancherel, or energy conservation}).$$

Proof. First route (from unitarity). By Theorem 22.3 the matrix $F_N = N^{-1/2} W_N$ is unitary, and a unitary map preserves the Hermitian inner product:

$$\langle F_N x, F_N y \rangle = (F_N y)^* (F_N x) = y^* F_N^* F_N x = y^* x = \langle x, y \rangle.$$

But $F_N x = N^{-1/2} X$ and $F_N y = N^{-1/2} Y$, hence $\langle F_N x, F_N y \rangle = \frac{1}{N} \langle X, Y \rangle$, which is the claim.

Second route (direct computation). Substitute for $x[n]$ and $\overline{y[n]}$ the inversion formula (Theorem 22.2), with dummy indices j and ℓ ; note that $\overline{y[n]} = \frac{1}{N} \sum_{\ell} \overline{Y[\ell]} \omega_N^{\ell n}$ because $\overline{\omega_N^{\ell n}} =$

$\omega_N^{\ell n}$. Then

$$\sum_{n=0}^{N-1} x[n] \overline{y[n]} = \frac{1}{N^2} \sum_{j=0}^{N-1} \sum_{\ell=0}^{N-1} X[j] \overline{Y[\ell]} \sum_{n=0}^{N-1} \omega_N^{n(\ell-j)}.$$

By Lemma 22.1 the inner sum equals N if $j = \ell$ (the indices lie in $\{0, \dots, N-1\}$, so $N \mid (\ell-j)$ is equivalent to $\ell = j$) and 0 otherwise. N terms survive:

$$= \frac{1}{N^2} \sum_{j=0}^{N-1} X[j] \overline{Y[j]} \cdot N = \frac{1}{N} \sum_{j=0}^{N-1} X[j] \overline{Y[j]}.$$

The two routes agree. $\square$

Corollary 22.7: The numerical check that exposes normalization errors. If an implementation of the DFT returns $\tilde{X} = cX$ with $c > 0$ a constant, then $\frac{1}{N} \sum_k |\tilde{X}[k]|^2 = c^2 \sum_n |x[n]|^2$: the ratio between the two sides of the Plancherel identity equals c^2 and immediately reveals the wrong normalization factor. If, on the other hand, the error is a wrong sign in the exponent, i.e. $\tilde{X} = \mathcal{F}_N \bar{x}$ conjugated, the Plancherel identity remains true and reveals nothing: one then needs the check on conjugate symmetry (Theorem 22.7) or on inversion.

Proof. For the first claim, $\frac{1}{N} \sum_k |cX[k]|^2 = \frac{c^2}{N} \sum_k |X[k]|^2 = c^2 \sum_n |x[n]|^2$ by Theorem 22.6, and the ratio with $\sum_n |x[n]|^2$ equals c^2 (the denominator is nonzero if $x \neq 0$). For the second: if $\tilde{X}[k] = \sum_n x[n] \omega_N^{kn}$, then $\tilde{X}[k] = \sum_n x[n] \omega_N^{-kn} = \overline{X[\langle -k \rangle_N]}$ by Proposition 22.1; hence $|\tilde{X}[k]| = |X[\langle -k \rangle_N]|$ and, since $k \mapsto \langle -k \rangle_N$ is a bijection of $\{0, \dots, N-1\}$ onto itself, $\sum_k |\tilde{X}[k]|^2 = \sum_k |X[k]|^2$: the Plancherel identity is satisfied by $\tilde{X}$ exactly as by X . $\square$

22.7. Conjugate symmetry of real signals

Theorem 22.7: Hermitian symmetry. Let $x \in \mathbb{C}^N$ with DFT X . Then

$$x[n] \in \mathbb{R} \text{ for every } n \quad \Longleftrightarrow \quad X[\langle -k \rangle_N] = \overline{X[k]} \text{ for every } k,$$

that is, in terms of indices in $\{0, \dots, N-1\}$: $X[N-k] = \overline{X[k]}$ for $k = 1, \dots, N-1$, and $X[0] = \overline{X[0]}$.

Proof. ($\Rightarrow$) Let x be real, i.e. $\overline{x[n]} = x[n]$ for every n . Then

$$\overline{X[k]} = \overline{\sum_{n=0}^{N-1} x[n] \omega_N^{kn}} = \sum_{n=0}^{N-1} \overline{x[n]} \overline{\omega_N^{kn}} = \sum_{n=0}^{N-1} x[n] \omega_N^{-kn} = \sum_{n=0}^{N-1} x[n] \omega_N^{(-k)n} = X[-k],$$

where $\overline{\omega_N^m} = \omega_N^{-m}$ was used (valid since $|\omega_N| = 1$) and, in the last step, the extension to every integer of Proposition 22.1, by which $X[-k] = X[\langle -k \rangle_N]$.

($\Leftarrow$) Suppose $X[\langle -k \rangle_N] = \overline{X[k]}$ for every k . By the inversion formula (Theorem 22.2),

$$\overline{x[n]} = \frac{1}{N} \sum_{k=0}^{N-1} \overline{X[k] \omega_N^{kn}} = \frac{1}{N} \sum_{k=0}^{N-1} \overline{X[k]} \omega_N^{kn} = \frac{1}{N} \sum_{k=0}^{N-1} X[\langle -k \rangle_N] \omega_N^{kn}.$$

Set $j = \langle -k \rangle_N$: as k ranges over $\{0, \dots, N-1\}$ so too does j range once over $\{0, \dots, N-1\}$ (it is the involutive permutation P of Theorem 22.4), and $k \equiv -j \pmod{N}$, hence $\omega_N^{kn} = \omega_N^{-jn}$.

Therefore

$$\overline{x[n]} = \frac{1}{N} \sum_{j=0}^{N-1} X[j] \omega_N^{-jn} = x[n],$$

again by Theorem 22.2: $x[n]$ is real for every n . $\square$

Corollary 22.8: Real bins and counting the information. Let $x \in \mathbb{R}^N$. Then:

- (i) $X[0] = \sum_n x[n]$ is real;
- (ii) if N is even, $X[N/2] = \sum_n (-1)^n x[n]$ is real (the Nyquist bin);
- (iii) $|X[N-k]| = |X[k]|$ and $\arg X[N-k] = -\arg X[k]$ for $k = 1, \dots, N-1$: the modulus of the spectrum is even, the phase odd;
- (iv) the spectrum contains exactly N independent real numbers: for N even, the two real values $X[0]$ and $X[N/2]$ together with the $\frac{N}{2} - 1$ complex numbers $X[1], \dots, X[N/2 - 1]$; for N odd, the real value $X[0]$ together with the $\frac{N-1}{2}$ complex numbers $X[1], \dots, X[\frac{N-1}{2}]$.

Proof. (i) Setting $k = 0$ in Definition 22.1 gives $X[0] = \sum_n x[n] \omega_N^0 = \sum_n x[n]$, a sum of real numbers. Alternatively, from Theorem 22.7 with $k = 0$: $\langle -0 \rangle_N = 0$, hence $X[0] = \overline{X[0]}$.

(ii) Let $N = 2M$. Then $\omega_N^{Mn} = e^{-2\pi i Mn/(2M)} = e^{-i\pi n} = (-1)^n$, so $X[M] = \sum_n (-1)^n x[n]$, a sum of real numbers. Alternatively, from Theorem 22.7 with $k = M$: $\langle -M \rangle_{2M} = M$, hence $X[M] = \overline{X[M]}$.

(iii) From $X[N-k] = \overline{X[k]}$ it follows that $|X[N-k]| = |\overline{X[k]}| = |X[k]|$ and $\arg X[N-k] = \arg \overline{X[k]} = -\arg X[k]$ (for $X[k] \neq 0$; if $X[k] = 0$ then also $X[N-k] = 0$ and the phase is undefined for either one).

(iv) For $N = 2M$ even: the values $X[0]$ and $X[M]$ are real by (i) and (ii), and the values $X[M+1], \dots, X[N-1]$ are determined by $X[1], \dots, X[M-1]$ via $X[N-k] = \overline{X[k]}$. The count of real parameters is therefore $1 + 1 + 2(M-1) = 2M = N$. For $N = 2M+1$ odd: only $X[0]$ is real, and $X[M+1], \dots, X[N-1]$ are the conjugates of $X[M], \dots, X[1]$; the count is $1 + 2M = N$. In both cases the number of independent real parameters coincides with the real dimension of $\mathbb{R}^N$, as it must, since $\mathcal{F}_N$ is bijective (Theorem 22.2) and $\mathbb{R}^N$ is a real subspace of $\mathbb{C}^N$ of real dimension N . $\square$

22.8. Circulant matrices diagonalized by the DFT

Definition 22.5: Circulant matrix. Given $c = (c[0], \dots, c[N-1]) \in \mathbb{C}^N$, the **circulant matrix** $C = \text{circ}(c)$ is the $N \times N$ matrix with entries

$$C_{nm} = c[\langle n - m \rangle_N], \quad n, m = 0, \dots, N-1,$$

that is,

$$C = \begin{pmatrix} c[0] & c[N-1] & c[N-2] & \cdots & c[1] \\ c[1] & c[0] & c[N-1] & \cdots & c[2] \\ c[2] & c[1] & c[0] & \cdots & c[3] \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ c[N-1] & c[N-2] & c[N-3] & \cdots & c[0] \end{pmatrix};$$

each row is the previous one shifted one position to the right, with circular wraparound. The first column is c .

Proposition 22.5: Circulant-vector product and convolution. For every $x \in \mathbb{C}^N$, $\text{circ}(c)x = c \circledast x$.

Proof. The n -th component of the matrix-vector product is

$$(Cx)[n] = \sum_{m=0}^{N-1} C_{nm} x[m] = \sum_{m=0}^{N-1} c[\langle n-m \rangle_N] x[m],$$

which is Definition 22.4 with the roles of c and x swapped relative to the writing adopted there. That the two ways of writing the convolution coincide is seen by substituting $r = \langle n-m \rangle_N$: as m ranges over $\{0, \dots, N-1\}$ so too does r range once over $\{0, \dots, N-1\}$, and $m \equiv n-r$, hence $\sum_m c[\langle n-m \rangle_N] x[m] = \sum_r c[r] x[\langle n-r \rangle_N] = (c \circledast x)[n]$. In particular circular convolution is commutative. $\square$

Theorem 22.8: Circulants are all diagonalized by the DFT. Let $C = \text{circ}(c)$ and let $\lambda = \mathcal{F}_N c$ be the DFT of its generator. Then, with F_N the unitary matrix of Definition 22.3,

$$F_N C F_N^* = \text{diag}(\lambda[0], \lambda[1], \dots, \lambda[N-1]), \quad \text{i.e.} \quad C = F_N^* \text{diag}(\lambda) F_N.$$

In particular: the eigenvalues of C are the values $\lambda[k] = \sum_m c[m] \omega_N^{km}$ of the DFT of c , and an eigenvector for $\lambda[k]$ is the vector $e_k = (\omega_N^{-kn})_{n=0}^{N-1}$ of Theorem 22.1, i.e. the k -th column of $\sqrt{N} F_N^*$. The basis that diagonalizes all circulants of order N is thus a single one and does not depend on c .

Proof. Step 1: e_k is an eigenvector. By Proposition 22.5, $Ce_k = c \circledast e_k$, whose n -th component is

$$\sum_{m=0}^{N-1} c[m] e_k[\langle n-m \rangle_N] = \sum_{m=0}^{N-1} c[m] \omega_N^{-k\langle n-m \rangle_N} = \sum_{m=0}^{N-1} c[m] \omega_N^{-k(n-m)},$$

where the last step is legitimate because $\langle n-m \rangle_N \equiv n-m \pmod{N}$ and powers of ω_N depend on the exponent only modulo N (since $\omega_N^N = 1$). Collecting ω_N^{-kn} :

$$(Ce_k)[n] = \omega_N^{-kn} \sum_{m=0}^{N-1} c[m] \omega_N^{km} = \lambda[k] e_k[n].$$

Holding for every n , this gives $Ce_k = \lambda[k] e_k$.

Step 2: from the basis to the operators. The vectors $e_0, \dots, e_{N-1}$ form an orthogonal basis of $\mathbb{C}^N$ (Corollary 22.1) and $u_k = N^{-1/2} e_k$ is the corresponding orthonormal basis. Let U be the matrix with $u_0, \dots, u_{N-1}$ as columns: U is unitary (the columns are orthonormal) and, by Step 1, $CU = U \text{diag}(\lambda)$, i.e. $U^*CU = \text{diag}(\lambda)$. It remains to recognize U : the (n, k) entry of U is $N^{-1/2} \omega_N^{-kn}$, which is the conjugate of $(F_N)_{kn} = N^{-1/2} \omega_N^{kn}$; hence $U = \overline{F_N}^T = F_N^*$. Substituting, $F_N C F_N^* = \text{diag}(\lambda)$, and multiplying on the left by F_N^* and on the right by F_N gives $C = F_N^* \text{diag}(\lambda) F_N$.

Step 3: consistency with the convolution theorem. The statement is Theorem 22.5 rewritten in matrix form: applying C to x means convolving, i.e. (up to normalizations) transforming, multiplying componentwise by λ , and transforming back. In formulas: $Cx = c \circledast x = \mathcal{F}_N^{-1}(\lambda \cdot \mathcal{F}_N x) = \frac{1}{N} W_N^* \text{diag}(\lambda) W_N x = F_N^* \text{diag}(\lambda) F_N x$. $\square$

Corollary 22.9: The algebra of circulants. Let $B = \text{circ}(b)$ and $C = \text{circ}(c)$ be of order N . Then:

- (i) $BC = CB$, and $BC = \text{circ}(b \otimes c)$;
- (ii) $\alpha B + \beta C = \text{circ}(\alpha b + \beta c)$ for all $\alpha, \beta \in \mathbb{C}$;
- (iii) $\det C = \prod_{k=0}^{N-1} \lambda[k]$ with $\lambda = \mathcal{F}_N c$;
- (iv) C is invertible if and only if $\lambda[k] \neq 0$ for every k , and in that case $C^{-1} = \text{circ}(d)$ with $d = \mathcal{F}_N^{-1}(1/\lambda)$, where $1/\lambda$ is the vector of components $1/\lambda[k]$.

Proof. (i) and (ii). By Theorem 22.8, $B = F_N^* \text{diag}(\beta_\lambda) F_N$ and $C = F_N^* \text{diag}(\lambda) F_N$ with $\beta_\lambda = \mathcal{F}_N b$; hence

$$BC = F_N^* \text{diag}(\beta_\lambda) F_N F_N^* \text{diag}(\lambda) F_N = F_N^* \text{diag}(\beta_\lambda) \text{diag}(\lambda) F_N,$$

having used $F_N F_N^* = I$ (Theorem 22.3). Diagonal matrices commute with each other and their product is the diagonal of the products, so $BC = CB$ and $BC = F_N^* \text{diag}(\beta_\lambda \cdot \lambda) F_N$, which by the same theorem (read backwards) is the circulant generated by the DFT vector $\beta_\lambda \cdot \lambda$, i.e., by Theorem 22.5, by $b \otimes c$. Claim (ii) is immediate from Definition 22.5, since $(\alpha B + \beta C)_{nm} = \alpha b[\langle n - m \rangle_N] + \beta c[\langle n - m \rangle_N]$.

(iii) From Theorem 22.8 and the Binet formula, $\det C = \det(F_N^*) \det(\text{diag } \lambda) \det(F_N) = \det(\text{diag } \lambda) \det(F_N^* F_N) = \prod_k \lambda[k]$.

(iv) C is invertible if and only if $\det C \neq 0$, i.e., by (iii), if and only if no $\lambda[k]$ vanishes. In that case $C^{-1} = F_N^* \text{diag}(\lambda)^{-1} F_N = F_N^* \text{diag}(1/\lambda) F_N$, which again by Theorem 22.8 is the circulant with generator $d = \mathcal{F}_N^{-1}(1/\lambda)$. $\square$

Example 22.3: A 4×4 circulant, diagonalized and solved. Let $c = (1, 2, 3, 4)$ and

$$C = \text{circ}(c) = \begin{pmatrix} 1 & 4 & 3 & 2 \\ 2 & 1 & 4 & 3 \\ 3 & 2 & 1 & 4 \\ 4 & 3 & 2 & 1 \end{pmatrix}.$$

The eigenvalues are, by Theorem 22.8, the components of $\lambda = \mathcal{F}_4 c$, computed in Example 22.2:

$$\lambda = (10, -2 + 2i, -2, -2 - 2i).$$

The determinant is therefore

$$\det C = 10 \cdot (-2 + 2i) \cdot (-2) \cdot (-2 - 2i) = 10 \cdot (-2) \cdot [(-2)^2 + 2^2] = -20 \cdot 8 = -160,$$

having used $(-2 + 2i)(-2 - 2i) = |-2 + 2i|^2 = 4 + 4 = 8$. The independent computation via LU factorization gives $\det C = -160.00000 \checkmark$ (the discrepancy from the exact value is of order 10^{-13} , i.e. the double-precision rounding error).

Solving $Cy = b$ without inverting the matrix. Let $b = (5, 3, 5, 7)$. Since $\omega_4 = -i$ one has $\omega_4^n = (-i)^n$, so

$$\begin{aligned} B[0] &= 5 + 3 + 5 + 7 = 20, & B[1] &= 5 + 3(-i) + 5(-1) + 7(i) = 4i, \\ B[2] &= 5 - 3 + 5 - 7 = 0, & B[3] &= \overline{B[1]} = -4i, \end{aligned}$$

where for $B[2]$ we used $\omega_4^{2n} = (-1)^n$ and for $B[3]$ conjugate symmetry (Theorem 22.7), since b is real. By Corollary 22.9(iv) it now suffices to divide spectrum by spectrum:

$$\frac{\mathcal{F}_4 b}{\lambda} = \left(\frac{20}{10}, \frac{4i}{-2 + 2i}, \frac{0}{-2}, \frac{-4i}{-2 - 2i} \right) = (2, 1 - i, 0, 1 + i),$$

since $\frac{4i}{-2+2i} = \frac{4i(-2-2i)}{(-2)^2+2^2} = \frac{-8i-8i^2}{8} = \frac{8-8i}{8} = 1-i$, and the $k=3$ component is its conjugate. Transforming back, with $\omega_4^{-kn} = i^{kn}$ and grouping the two conjugate terms $k=1$ and $k=3$,

$$y[n] = \frac{1}{4} \left(2 + (1-i)i^n + 0 + (1+i)i^{3n} \right) = \frac{1}{4} \left(2 + 2 \operatorname{Re}((1-i)i^n) \right),$$

whence $y[0] = \frac{1}{4}(2+2 \cdot 1) = 1$; $y[1] = \frac{1}{4}(2+2 \operatorname{Re}(1+i)) = 1$ since $(1-i)i = 1+i$; $y[2] = \frac{1}{4}(2+2 \operatorname{Re}(-1+i)) = 0$; $y[3] = \frac{1}{4}(2+2 \operatorname{Re}(-1-i)) = 0$. Hence $y = (1, 1, 0, 0)$, and the direct check is immediate: Cy is the sum of the first two columns of C , i.e. $(1+4, 2+1, 3+2, 4+3) = (5, 3, 5, 7) = b$ ✓. The script of Section 22.12.1 recomputes y as `ifft(fft(b)/fft(c))` and obtains $(1, 1, 0, 0)$ to within 10^{-15} ✓.

Remark 22.5: Why this theorem is the heart of digital filtering. A shift-invariant linear filter, applied to a block of N samples with periodic boundary conditions, is multiplication by a circulant matrix: the n -th row contains the impulse response read backwards and wrapped around. Theorem 22.8 then says that all such filters are simultaneously diagonalized by the same basis, that of the discrete exponentials: this is why “filtering” in frequency reduces to multiplying each bin by a number, and why the cost of filtering drops from $O(N^2)$ (matrix-vector product) to $O(N \log N)$ (two FFTs and N multiplications) — see Section 22.10 and Chapter 23. The price is the implicit periodicity of the block: the sample $x[N-1]$ is “close” to $x[0]$, and it is exactly this fiction that produces the leakage of Section 22.10.3 when the signal is not periodic with period N .

22.9. The DFT and the DTFT: spectrum sampling and zero-padding

Definition 22.6: Discrete Dirichlet kernel. For $N \geq 1$, the **discrete Dirichlet kernel** is the function $D_N : \mathbb{R} \rightarrow \mathbb{C}$,

$$D_N(\Omega) = \sum_{n=0}^{N-1} e^{-in\Omega}.$$

Lemma 22.3: Closed form of the discrete Dirichlet kernel. For every $\Omega \in \mathbb{R}$,

$$D_N(\Omega) = \begin{cases} \frac{\sin(N\Omega/2)}{\sin(\Omega/2)} e^{-i(N-1)\Omega/2}, & \Omega \notin 2\pi\mathbb{Z}, \\ N, & \Omega \in 2\pi\mathbb{Z}. \end{cases}$$

In particular $|D_N(\Omega)| = |\sin(N\Omega/2)/\sin(\Omega/2)|$ outside multiples of 2π , and $D_N(\Omega) = 0$ if and only if $N\Omega/2 \in \pi\mathbb{Z}$ but $\Omega/2 \notin \pi\mathbb{Z}$, i.e. if and only if $\Omega = 2\pi m/N$ with $m \in \mathbb{Z}$ and $N \nmid m$.

Proof. This is the geometric sum with ratio $q = e^{-i\Omega}$, and once again the case of vanishing denominator must be distinguished.

Case $\Omega \in 2\pi\mathbb{Z}$. Then $q = e^{-i\Omega} = 1$ and the sum has N terms all equal to 1: $D_N(\Omega) = N$. (The closed formula does not apply: the denominator $\sin(\Omega/2)$ vanishes.)

Case $\Omega \notin 2\pi\mathbb{Z}$. Then $q \neq 1$: indeed $e^{-i\Omega} = 1$ is equivalent to $\Omega \in 2\pi\mathbb{Z}$. By the telescoping identity of Theorem 6.4 (Step 1), $(q-1) \sum_{n<N} q^n = q^N - 1$, and dividing by $q-1 \neq 0$,

$$D_N(\Omega) = \frac{e^{-iN\Omega} - 1}{e^{-i\Omega} - 1}.$$

The “half angles” are now collected, in numerator and denominator: for every $\varphi \in \mathbb{R}$,

$$e^{-i\varphi} - 1 = e^{-i\varphi/2}(e^{-i\varphi/2} - e^{i\varphi/2}) = e^{-i\varphi/2}(-2i \sin(\varphi/2)),$$

having used $e^{i\theta} - e^{-i\theta} = 2i \sin \theta$. Applying the identity with $\varphi = N\Omega$ and with $\varphi = \Omega$ and simplifying the factor $-2i$:

$$D_N(\Omega) = \frac{e^{-iN\Omega/2}(-2i) \sin(N\Omega/2)}{e^{-i\Omega/2}(-2i) \sin(\Omega/2)} = e^{-i(N-1)\Omega/2} \frac{\sin(N\Omega/2)}{\sin(\Omega/2)},$$

since $-N\Omega/2 + \Omega/2 = -(N-1)\Omega/2$, and the denominator $\sin(\Omega/2)$ is nonzero precisely because $\Omega \notin 2\pi\mathbb{Z}$.

The modulus follows from $|e^{-i(N-1)\Omega/2}| = 1$. The zeros: outside $2\pi\mathbb{Z}$ the exponential factor never vanishes and the denominator is nonzero, so $D_N(\Omega) = 0$ if and only if $\sin(N\Omega/2) = 0$, i.e. $N\Omega/2 = \pi m$ with $m \in \mathbb{Z}$, i.e. $\Omega = 2\pi m/N$; and the condition $\Omega \notin 2\pi\mathbb{Z}$ is $N \nmid m$. $\square$

Theorem 22.9: The DFT samples the DTFT. Let $x \in \mathbb{C}^N$ and consider the sequence $x[n]$ extended by zeros outside $\{0, \dots, N-1\}$. Its DTFT (Chapter 21, Theorem 21.6) is the 2π -periodic function

$$\hat{X}(\Omega) = \sum_{n=0}^{N-1} x[n] e^{-in\Omega}, \quad \Omega \in \mathbb{R}.$$

Then, for every $k = 0, 1, \dots, N-1$,

$$X[k] = \hat{X}\left(\frac{2\pi k}{N}\right):$$

the DFT is the DTFT sampled at N equally spaced points of the unit circle. Moreover $\hat{X}$ is determined by X : it is, in $\mathbb{C}$, the polynomial $\hat{X}(\Omega) = \sum_n x[n] e^{-in\Omega}$ whose coefficients $x[n]$ are reconstructed from X by Theorem 22.2.

Proof. Substitute $\Omega = 2\pi k/N$ into the definition of $\hat{X}$:

$$\hat{X}\left(\frac{2\pi k}{N}\right) = \sum_{n=0}^{N-1} x[n] e^{-2\pi i kn/N} = \sum_{n=0}^{N-1} x[n] \omega_N^{kn} = X[k]$$

by Definition 22.1. That the sum is restricted to $n = 0, \dots, N-1$ is a consequence of the zero extension: the other terms vanish. For the second claim: once X is known, Theorem 22.2 returns $x[0], \dots, x[N-1]$, and these are by definition the coefficients of $\hat{X}$; hence two sequences of length N with the same DFT have the same DTFT, and conversely. $\square$

Remark 22.6: The link with the Zeta transform and with aliasing. Theorem 22.9 and Theorem 22.12 are the same statement read on two domains: $\hat{X}(\Omega) = X(z)$ for $z = e^{i\Omega}$, i.e. the DTFT is the restriction of the Zeta transform to the unit circle (Theorem 21.6), and the points $\Omega = 2\pi k/N$ correspond to the N -th roots of unity. A third phenomenon must be kept distinct: when the samples $x[n]$ come from sampling a continuous periodic function, the DFT does not return the Fourier coefficients of that function but their sum over all

frequencies congruent modulo N . This is the aliasing formula, proved in full in the solution of the inherited exercise 22.5, and connected with the error of the periodic trapezoidal rule.

Theorem 22.10: Zero-padding: the long DFT samples the same DTFT more finely. Let $x \in \mathbb{C}^N$, let $M \geq N$ and let $x^{(M)} \in \mathbb{C}^M$ be the vector obtained by extending x with zeros:

$$x^{(M)}[n] = \begin{cases} x[n], & 0 \leq n \leq N-1, \\ 0, & N \leq n \leq M-1. \end{cases}$$

Then, denoting by $X_M = \mathcal{F}_M x^{(M)}$ the M -point DFT,

$$X_M[k] = \hat{X}\left(\frac{2\pi k}{M}\right), \quad k = 0, 1, \dots, M-1,$$

with $\hat{X}$ the DTFT of Theorem 22.9. In particular, if $M = rN$ with $r \in \mathbb{N}$, then $X_M[rk] = X[k]$ for $k = 0, \dots, N-1$: the samples of the short DFT are all found among those of the long DFT.

Proof. By definition,

$$X_M[k] = \sum_{n=0}^{M-1} x^{(M)}[n] e^{-2\pi i kn/M} = \sum_{n=0}^{N-1} x[n] e^{-2\pi i kn/M},$$

since the terms with $n \geq N$ vanish. The last sum is exactly $\hat{X}(\Omega)$ evaluated at $\Omega = 2\pi k/M$.

For the last claim, with $M = rN$: $\frac{2\pi(rk)}{M} = \frac{2\pi rk}{rN} = \frac{2\pi k}{N}$, hence $X_M[rk] = \hat{X}(2\pi k/N) = X[k]$ by Theorem 22.9. $\square$

Theorem 22.11: Zero-padding is interpolation with the Dirichlet kernel. Under the hypotheses of Theorem 22.10, for every $k = 0, \dots, M-1$,

$$X_M[k] = \frac{1}{N} \sum_{j=0}^{N-1} X[j] D_N\left(2\pi\left(\frac{k}{M} - \frac{j}{N}\right)\right),$$

with D_N the discrete Dirichlet kernel of Definition 22.6. Zero-padding therefore adds no information whatsoever: the new spectrum samples are linear combinations of the old ones, with weights fixed once and for all by the kernel D_N .

Proof. Start from the formula of Theorem 22.10 and substitute for $x[n]$ the inversion formula (Theorem 22.2), with dummy index j :

$$X_M[k] = \sum_{n=0}^{N-1} \left(\frac{1}{N} \sum_{j=0}^{N-1} X[j] e^{2\pi i j n/N} \right) e^{-2\pi i kn/M}.$$

The sums are finite: exchange the order and collect $X[j]$:

$$X_M[k] = \frac{1}{N} \sum_{j=0}^{N-1} X[j] \sum_{n=0}^{N-1} e^{2\pi i n \left(\frac{j}{N} - \frac{k}{M} \right)}.$$

Now set

$$\Omega_{kj} = 2\pi \left(\frac{k}{M} - \frac{j}{N} \right),$$

so that the exponent of the inner sum is $2\pi in(\frac{j}{N} - \frac{k}{M}) = -in\Omega_{kj}$. The inner sum is thus, literally, the kernel of Definition 22.6 evaluated at Ω_{kj} :

$$\sum_{n=0}^{N-1} e^{2\pi in(\frac{j}{N} - \frac{k}{M})} = \sum_{n=0}^{N-1} e^{-in\Omega_{kj}} = D_N(\Omega_{kj}).$$

Substituting gives exactly the identity of the statement. Note that the order of the two terms in the argument is not immaterial: $D_N(-\Omega) = \overline{D_N(\Omega)}$, so writing $2\pi(\frac{j}{N} - \frac{k}{M})$ in place of Ω_{kj} would replace the kernel with its conjugate and the formula would be false (except at points where D_N is real).

Check. That the formula is correct is verified on a case where the result is known: if $M = N$ and $k = j_0$, then $\frac{k}{M} - \frac{j}{N} = \frac{j_0 - j}{N}$ and, by Lemma 22.3, $D_N(2\pi(j_0 - j)/N)$ equals N if $N \mid (j_0 - j)$, i.e. $j = j_0$, and 0 otherwise; the sum reduces to $\frac{1}{N}X[j_0] \cdot N = X[j_0] \checkmark$, as it must. The general numerical check is in Section 22.12.1: for $N = 8$, $M = 32$ and $x = (1, 1, 1, 1, 0, 0, 0, 0)$ the maximum discrepancy between the 32 values $X_M[k]$ computed with the FFT and those computed with the interpolation formula is $1.03 \cdot 10^{-14} \checkmark$. $\square$

Example 22.4: Zero-padding from 8 to 32 points, with a value computed by hand.

Let $x = (1, 1, 1, 1, 0, 0, 0, 0)$, the rectangular window of Section 22.12, and let $M = 32$. By Theorem 22.10, $X_{32}[k] = \widehat{X}(2\pi k/32)$, and since $x[n] = 1$ exactly for $n = 0, 1, 2, 3$,

$$X_{32}[k] = \sum_{n=0}^3 w^n = 1 + w + w^2 + w^3 = \frac{1 - w^4}{1 - w}, \quad w = e^{-2\pi ik/32} = e^{-i\pi k/16} \quad (w \neq 1).$$

For $k = 2$ one has $w = e^{-i\pi/8}$ and $w^4 = e^{-i\pi/2} = -i$, hence

$$X_{32}[2] = \frac{1 + i}{1 - e^{-i\pi/8}}.$$

With $\cos(\pi/8) = 0.92388$ and $\sin(\pi/8) = 0.38268$, the denominator is $1 - 0.92388 + 0.38268i = 0.07612 + 0.38268i$, with squared modulus $0.07612^2 + 0.38268^2 = 0.00579 + 0.14645 = 0.15224$. Multiplying numerator and denominator by the conjugate of the denominator:

$$X_{32}[2] = \frac{(1 + i)(0.07612 - 0.38268i)}{0.15224} = \frac{0.45880 - 0.30656i}{0.15224} = 3.01367 - 2.01367i.$$

The modulus is computed more quickly in closed form: by Lemma 22.3,

$$|X_{32}[2]| = \frac{|1 - w^4|}{|1 - w|} = \frac{|1 + i|}{2 \sin(\pi/16)} = \frac{\sqrt{2}}{2 \cdot 0.19509} = 3.62451,$$

having used $|1 - e^{-i\varphi}| = 2|\sin(\varphi/2)|$. Check: $\sqrt{3.01367^2 + 2.01367^2} = \sqrt{9.08222 + 4.05487} = \sqrt{13.13709} = 3.62451 \checkmark$. The script of Section 22.12.1 obtains $X_{32}[2] = 3.01367 - 2.01367i \checkmark$.

What was gained. Nothing, in terms of information: by Theorem 22.11 the value $X_{32}[2]$ is a fixed combination of the eight values $X[0], \dots, X[7]$ of the short DFT. What was gained is only readability of the plot: between bins 0 and 1 of the eight-point DFT, where before there was nothing, three more points of the same continuous curve $|\widehat{X}(\Omega)|$ are now visible. Zero-padding does *not* improve the frequency resolution, which remains f_s/N and depends on the duration of the observation, not on the number of points at which the spectrum is sampled (Proposition 22.8 and Remark 22.12).

22.10. The Discrete Fourier Transform and the FFT algorithm

We now return to the DFT matrix of Chapter 3 (Section 3.3) with the tools of the Zeta transform just introduced, to then arrive at the algorithm that made these computations practical on any microcontroller or PLC: the *Fast Fourier Transform* (FFT).

Theorem 22.12: The DFT as sampling of the Zeta transform on the roots of unity. Let $x[0], \dots, x[N-1]$ be a finite sequence and let $X(z) = \sum_{n=0}^{N-1} x[n]z^{-n}$ be its Zeta transform (a polynomial in z^{-1} , hence defined on all of $\mathbb{C} \setminus \{0\}$). The discrete Fourier transform (DFT) of $x[n]$,

$$X[k] = \sum_{n=0}^{N-1} x[n] e^{-2\pi i k n / N}, \quad k = 0, \dots, N-1,$$

coincides with the evaluation of $X(z)$ at the points $z = \zeta_N^{-k} = e^{2\pi i k / N}$, i.e. exactly at the N N -th roots of unity of Definition 3.2 of Chapter 3: $X[k] = X(\zeta_N^{-k})$, where $\zeta_N = e^{-2\pi i / N}$ is the local convention of this section (convention note at the beginning of the chapter and Theorem 22.13).

Proof. By definition $X(z) = \sum_{n=0}^{N-1} x[n]z^{-n}$. Setting $z = \zeta_N^{-k} = e^{2\pi i k / N}$ gives $z^{-n} = e^{-2\pi i k n / N}$, hence

$$X(\zeta_N^{-k}) = \sum_{n=0}^{N-1} x[n] e^{-2\pi i k n / N} = X[k].$$

This is precisely the matrix-vector product $W_N x$ of Definition 3.3, row by row: the k -th row of W_N contains exactly the samples $\zeta_N^{kn} = e^{-2\pi i k n / N}$ (again with the local convention $\zeta_N = e^{-2\pi i / N}$). $\square$

Remark 22.7: Why it matters. Theorem 22.12 closes the circle (in the true sense of the word) among three objects that in the text have been presented separately: the roots of unity (Chapter 3, geometry), the Zeta transform (this chapter, discrete control systems) and the DFT (numerical frequency analysis). They are the same algebraic construction seen from three different applied angles.

22.10.1 The Cooley-Tukey algorithm

Computing $X[k]$ directly from the definition requires, for each of the N values of k , a sum of N terms: overall $O(N^2)$ complex multiplications. For $N = 1024$ samples (typical in vibration or audio analysis) this means over one million operations. The FFT (*Fast Fourier Transform*) algorithm, in the form published by Cooley and Tukey in 1965¹, reduces the cost to $O(N \log_2 N)$ by exploiting the symmetry of the roots of unity.

Theorem 22.13: Decimation in time, radix-2. Let $N = 2^m$ be even. Separate the even and odd indices of $x[n]$: $e[r] = x[2r]$, $o[r] = x[2r+1]$, for $r = 0, \dots, N/2 - 1$. Then

$$X[k] = E[k] + \zeta_N^k O[k], \quad X[k + N/2] = E[k] - \zeta_N^k O[k], \quad k = 0, \dots, \frac{N}{2} - 1,$$

where $E[k]$ and $O[k]$ are the $N/2$ -point DFTs of $e[r]$ and $o[r]$ respectively, and $\zeta_N = e^{-2\pi i / N}$.

¹The algorithm was in fact already known, in a different form, to Carl Friedrich Gauss in 1805, for interpolating asteroid orbits: a manuscript that remained unpublished until 1866 and was rediscovered only in the 1980s (Heideman, Johnson, Burrus, 1985).

Proof. Separating the sum over even and odd indices:

$$\begin{aligned} X[k] &= \sum_{r=0}^{N/2-1} x[2r] \zeta_N^{2rk} + \sum_{r=0}^{N/2-1} x[2r+1] \zeta_N^{(2r+1)k} \\ &= \sum_{r=0}^{N/2-1} e[r] \zeta_{N/2}^{rk} + \zeta_N^k \sum_{r=0}^{N/2-1} o[r] \zeta_{N/2}^{rk} = E[k] + \zeta_N^k O[k], \end{aligned}$$

using $\zeta_N^2 = \zeta_{N/2}$ (Corollary 3.2 of Chapter 3, a property of roots of unity). For the index $k + N/2$, since E and O are periodic with period $N/2$ (they are $N/2$ -point DFTs: $E[k + N/2] = E[k]$, $O[k + N/2] = O[k]$) and $\zeta_N^{k+N/2} = \zeta_N^k \zeta_N^{N/2} = -\zeta_N^k$ (because $\zeta_N^{N/2} = e^{-i\pi} = -1$), one obtains $X[k + N/2] = E[k] - \zeta_N^k O[k]$. $\square$

Figure 22.2: Butterfly network of the radix-2 FFT algorithm (decimation in time) for $N = 8$: input in bit-reversed order (left), $\log_2 8 = 3$ stages of butterflies (the diagonal lines carry the twiddle factor ζ_N^k), output in natural order (right) — the same structure implemented iteratively in Listing 4.3 (FB_FFT8) and underlying the exam question on the $O(N \log N)$ complexity (Theorem 22.14).

Remark 22.8: The “butterfly” and the $O(N \log N)$ complexity. The pair of formulas of Theorem 22.13 is called a butterfly: from two complex numbers $E[k]$, $O[k]$ and a single twiddle factor ζ_N^k , two outputs $X[k]$, $X[k + N/2]$ are obtained with a single complex multiplication (the product $\zeta_N^k O[k]$ is computed once and used twice, with opposite sign). Applying the same decomposition recursively to E and O (each an $N/2$ -point problem) gives the recurrence

$$T(N) = 2T(N/2) + cN,$$

whose solution is $T(N) = O(N \log_2 N)$ (full proof in Theorem 22.14 below), against $O(N^2)$ for the direct computation. For $N = 1024 = 2^{10}$: $N^2 = 1\,048\,576$ against $N \log_2 N = 1024 \times 10 = 10\,240$, a saving factor of ≈ 100 ; for $N = 1\,048\,576 = 2^{20}$ (one second of audio at about 1 MHz) the saving factor exceeds 50 000. This is why the FFT has been called by some “the most important algorithm of the twentieth century” (Strang, 1994) and underlies every spectrum analyzer, every audio/video codec, and much of the digital signal processing used in industrial systems (vibration analysis on motors, bearing diagnostics, acoustic quality

control).

Theorem 22.14: Complexity of the FFT: solution of the recurrence. Let $T(N)$ be the number of complex arithmetic operations performed by the radix-2 FFT algorithm (Theorem 22.13) on an input of length $N = 2^m$, $m \in \mathbb{N}$. Then $T(N)$ satisfies the recurrence

$$T(N) = 2T(N/2) + cN, \quad T(1) = c_0,$$

for suitable constants $c, c_0 > 0$ independent of N , and its solution is

$$T(N) = \Theta(N \log_2 N).$$

Proof. First observe that the recurrence correctly describes the cost of the algorithm: each call on a vector of length N separates the even/odd indices in time $O(N)$, makes two recursive calls on subproblems of length $N/2$, and finally combines the results with $N/2$ butterflies, each of cost $O(1)$ (one complex multiplication and two sums/differences), for a total of $O(N)$ combination operations; hence the term cN in the recurrence, with base case $T(1) = c_0$ (no operations: the single sample is returned).

We give two independent proofs that $T(N) = \Theta(N \log_2 N)$, following the practice of this treatise of reporting several proof routes when available in the literature.

First proof (substitution method, by induction). We prove by induction on m (with $N = 2^m$) that $T(N) \leq CN \log_2 N + c_0 N$ for a constant $C \geq c$ to be fixed.

Base case ($m = 0$, $N = 1$): $T(1) = c_0 \leq C \cdot 1 \cdot \log_2 1 + c_0 \cdot 1 = c_0$, true with equality for every C (since $\log_2 1 = 0$).

Inductive step: suppose the inductive hypothesis holds for $N/2 = 2^{m-1}$, i.e. $T(N/2) \leq C \cdot \frac{N}{2} \log_2 \frac{N}{2} + c_0 \frac{N}{2}$. Then

$$\begin{aligned} T(N) &= 2T(N/2) + cN \leq 2 \left(C \cdot \frac{N}{2} \log_2 \frac{N}{2} + c_0 \frac{N}{2} \right) + cN \\ &= CN \log_2 \frac{N}{2} + c_0 N + cN = CN(\log_2 N - 1) + c_0 N + cN = CN \log_2 N - CN + c_0 N + cN = CN \log_2 N + c_0 N - (C - c)N \end{aligned}$$

Choosing $C \geq c$, the last term $-(C - c)N$ is ≤ 0 , hence $T(N) \leq CN \log_2 N + c_0 N$, closing the induction. This proves $T(N) = O(N \log_2 N)$. The opposite inequality $T(N) = \Omega(N \log_2 N)$ is obtained by an identical argument, reversing all inequalities (the combination cost is *at least* cN , not merely at most cN , and one proves by induction $T(N) \geq cN \log_2 N$); together, $T(N) = \Theta(N \log_2 N)$.

Second proof (recursion tree). Represent the recursion as a binary tree in which the root node (depth $k = 0$) corresponds to the problem of size N , with combination cost cN (excluding the subproblems). Its two children, at depth $k = 1$, are the two subproblems of size $N/2$, each with combination cost $c \cdot (N/2)$: the total cost at that level is $2 \cdot c(N/2) = cN$. In general, at depth k there are 2^k subproblems, each of size $N/2^k$ and combination cost $c \cdot N/2^k$; the total cost at level k is thus

$$2^k \cdot c \frac{N}{2^k} = cN,$$

independent of k . The recursion ends when $N/2^k = 1$, i.e. at depth $k = \log_2 N$: the tree has exactly $\log_2 N + 1$ levels (from $k = 0$ to $k = \log_2 N$), the last of which contains N leaves of base cost $O(1)$ each, for a total contribution $O(N)$. Summing the cost cN over each of the $\log_2 N$ internal levels, plus the leaf level, gives

$$T(N) = \underbrace{cN + cN + \cdots + cN}_{\log_2 N \text{ internal levels}} + \Theta(N) = cN \log_2 N + \Theta(N) = \Theta(N \log_2 N).$$

Remark 22.9: Scope of the result. The two proofs are the canonical methods for solving divide-and-conquer recurrences of the form $T(N) = aT(N/b) + f(N)$: inductive substitution and the recursion tree (equivalent, and underlying the general proof of the so-called “master” theorem); here they are carried out in full, rather than merely invoked, precisely because the FFT recurrence — the case $a = b = 2$, $f(N) = \Theta(N)$ — is the most cited example in algorithms and data structures exams. The same proof scheme applies, with the obvious modifications, to the recurrence of merge sort ($T(N) = 2T(N/2) + \Theta(N)$, identical) and to that of integer/polynomial multiplication with Karatsuba’s algorithm ($T(N) = 3T(N/2) + \Theta(N)$, which instead solves to $\Theta(N^{\log_2 3})$).

Recursive FFT algorithm (radix-2, decimation in time)

1. If $N = 1$: return $x[0]$ (base case).
2. Otherwise split x into $e[r] = x[2r]$ and $o[r] = x[2r + 1]$, $r = 0, \dots, N/2 - 1$.
3. Recursively compute $E = \text{FFT}(e)$ and $O = \text{FFT}(o)$ (each on $N/2$ points).
4. For $k = 0, \dots, N/2 - 1$, compute the twiddle $\zeta_N^k = e^{-2\pi i k/N}$ and combine: $X[k] = E[k] + \zeta_N^k O[k]$, $X[k + N/2] = E[k] - \zeta_N^k O[k]$. □

Listing 22.1: Recursive radix-2 FFT in Python (for teaching purposes; for real use, use `numpy.fft.fft`, which is optimized and not restricted to N a power of 2).

```
import numpy as np

def fft_radix2(x):
    """Recursive FFT, decimation in time. len(x) must be a power of
    2."""
    N = len(x)
    if N == 1:
        return x
    if N % 2 != 0:
        raise ValueError("N must be a power of 2")
    E = fft_radix2(x[0::2]) # sub-problem on even indices
    O = fft_radix2(x[1::2]) # sub-problem on odd indices
    twiddles = np.exp(-2j * np.pi * np.arange(N // 2) / N)
    butterfly = twiddles * O
    return np.concatenate([E + butterfly, E - butterfly])

# Check against numpy.fft.fft
x = np.array([1, -1, 1, -1, 1, -1, 1, -1], dtype=complex)
X_mine = fft_radix2(x)
X_numpy = np.fft.fft(x)
print(np.allclose(X_mine, X_numpy)) # True
print(np.round(X_mine, 6))
# [ 0.+0.j  0.+0.j  0.+0.j  0.+0.j  8.-0.j  0.+0.j  0.+0.j  0.+0.j ]
```

22.10.2 An SCL implementation for PLC

In industrial automation the DFT/FFT is used directly in vibration analysis, predictive diagnostics of pumps and motors, filtering of noisy analog signals before PID computation, and harmonic analysis of electrical networks (detection of THD, *total harmonic distortion*, in plants with inverter drives — relevant also in water treatment, where the frequency inverters of lift pumps are a common source of harmonic distortion). Unlike Python, a Siemens PLC (SCL, *Structured Control Language*, an IEC 61131-3 dialect of Structured Text) has no native complex

numbers nor convenient recursion: the FFT must therefore be written in *iterative* form, with real and imaginary parts kept in two separate arrays.

Adapting Cooley-Tukey to iterative form 1. Bit-reversal: the iterative version operates in place, but requires the input samples to be reordered according to the *bit-reversal* permutation of the binary index (e.g. for $N = 8$: index $1 = 001_2$ is swapped with $4 = 100_2$, $3 = 011_2$ with $6 = 110_2$, etc.) — a direct consequence of how the recurrence of Theorem 22.13 separates even/odd at each level.

2. Stages (butterflies) instead of recursion: for $N = 2^m$, m stages are executed; at stage s ($s = 1, \dots, m$) the butterflies operate on blocks of size 2^s , with base angle $\pi/2^{s-1}$ between one twiddle and the next.

3. Recursive twiddles: instead of calling cos/sin for every butterfly (expensive on a PLC), the twiddle is updated multiplicatively, $w \leftarrow w \cdot w_m$, where $w_m = e^{-2\pi i/2^s}$ is precomputed per stage. $\square$

Listing 22.2: FB_FFT8: iterative radix-2 FFT, $N = 8$ fixed points, in SCL for a Siemens PLC (TIA Portal).

```

        wRe := wReNext;
        wIm := wImNext;
    END_FOR;
END_FOR;
END_FUNCTION_BLOCK

```

Worked example: FB_FFT8 on a wave at half the sampling frequency. Take as input $x = [1, -1, 1, -1, 1, -1, 1, -1]$ (zero imaginary part), a signal that oscillates every sample: the highest frequency representable with $N = 8$ samples, i.e. exactly the Nyquist frequency (Section 4.12, $k = N/2 = 4$). Computing by hand from the definition,

$$X[4] = \sum_{n=0}^7 x[n]e^{-2\pi i \cdot 4n/8} = \sum_{n=0}^7 x[n](-1)^n = \sum_{n=0}^7 (-1)^n(-1)^n = \sum_{n=0}^7 1 = 8,$$

while for $k \neq 4$ the sum vanishes by the orthogonality of the roots of unity (Corollary 3.2, Chapter 3): the signal is a pure sinusoid at frequency $k = 4$, so all the energy is concentrated in that bin. Running FB_FFT8 on this input indeed gives

$$\text{reArr} = [0, 0, 0, 0, 8, 0, 0, 0], \quad \text{imArr} = [0, 0, 0, 0, 0, 0, 0, 0],$$

in exact agreement with the direct computation and with the Python output of the previous example — a useful cross-check when porting an algorithm from a development environment to a production PLC.

Remark 22.10: Why not use recursion directly on a PLC. IEC 61131-3 languages (SCL included) in theory allow recursive functions, but the cyclic execution of a PLC (scan cycle) and the static memory management of function blocks make recursion inadvisable in practice: every recursive call consumes task stack, whose size is limited and configured beforehand, and a deep recursive FFT can exceed it under unforeseen conditions (violating the real-time determinism constraints required by a control cycle). The iterative form of FB_FFT8, with a fixed number of iterations known in advance ($N \log_2 N/2$ butterflies), has a deterministic execution time: a property indispensable for a block called cyclically in an automation OB.

22.10.3 Windows and spectral leakage

The FFT of Section 4.11 implicitly assumes that the samples $x[0], \dots, x[N-1]$ constitute *exactly* one period (or an integer number of periods) of the signal. In practice a real signal is observed for a finite window of duration $T_{\text{fin}} = NT$ chosen by the operator, almost never in phase with the period of the signal: the DFT then implicitly sees the signal periodized with a **discontinuity** at the edges of the window — exactly the situation of Remark 17.3 (Gibbs), applied this time to a sampled signal instead of a square wave.

Definition 22.7: Windowing. Given a sequence $x[n]$, $n = 0, \dots, N-1$, and a window function $w[n] \geq 0$, the windowed signal is $x_w[n] = x[n]w[n]$ and its DFT $X_w[k] = \text{DFT}\{x_w[n]\}$ approximates the true spectrum of x .

Remark 22.11: Leakage: energy scattered into neighboring bins. If $x[n] = \cos(2\pi f_0 nT)$ and f_0 falls exactly on a bin (i.e. $f_0 = k_0 f_s/N$ for some integer k_0), the implicit rectangular window ($w[n] \equiv 1$) gives a spectrum perfectly concentrated at k_0 (and at its mirror $N - k_0$), consistently with the Theorem (Volume II, Chapter 4). But if f_0 falls between two bins, the energy scatters (leakage) over all neighboring bins with a slow decay: the rectangular window has side lobes that decay by only ≈ 6 dB per octave, the slowest among the windows used in practice.

Definition 22.8: Hann window. The Hann window gradually tapers the samples toward the edges of the window, eliminating the implicit discontinuity:

$$w_{\text{Hann}}[n] = \frac{1}{2} \left(1 - \cos \frac{2\pi n}{N-1} \right), \quad n = 0, \dots, N-1.$$

Worked example — rectangular/Hann numerical comparison. Let $N = 64$, $f_s = 100$ Hz (bins spaced by $f_s/N \approx 1.56$ Hz). For a tone exactly on bin 8 ($f_0 = 12.5$ Hz), the DFT with a rectangular window is perfectly concentrated: all neighboring bins are at -240 dB from the peak (numerical zero). Moving the tone halfway between two bins ($f_0 = 13.28$ Hz, i.e. 8.5 cycles in the window), the same rectangular window shows marked leakage: the adjacent bin (bin 7) is only -9.1 dB below the peak, and distant bins such as bin 4 remain at only -17.0 dB. Applying instead the Hann window to the same misaligned signal: the main lobe widens (bins 8 and 9 are now nearly matched, both close to 0 dB), but the distant lobes decay much faster (-30.5 dB at bin 6, -46.9 dB at bin 4, against -13.1 dB and -17.0 dB respectively with the rectangular window). This is the classic trade-off: the Hann window sacrifices resolution (wider main lobe) to gain suppression of distant leakage (lower side lobes).

Listing 22.3: Rectangular/Hann numerical comparison (Python, NumPy).

```
import numpy as np

N, fs = 64, 100.0
n = np.arange(N)
f0 = 8.5 * fs / N          # 8.5 cycles in the window: not aligned
                           # to a bin

x = np.sin(2*np.pi*f0*n/fs)
rect = np.ones(N)
hann = 0.5 - 0.5*np.cos(2*np.pi*n/(N-1))  # identical to numpy.hanning(N)

def spectrum_db(x, w):
```

```

X = np.fft.fft(x*w)
mag = np.abs(X[:N//2])
return 20*np.log10(mag/np.max(mag))

db_rect = spectrum_db(x, rect)
db_hann = spectrum_db(x, hann)
print(db_rect[6:11])    # compare with library numpy.hanning(N)
print(db_hann[6:11])

```

Remark 22.12: Frequency resolution and practical consequences. Regardless of the window chosen, the spacing between bins is always $\Delta f = f_s/N$: distinguishing two nearby tones requires a long enough window (large N), not a different window — the window fights leakage, it does not improve resolution. In industrial vibration analysis (bearing diagnostics, misalignment, imbalance) the choice of window is anything but academic: uncontrolled leakage can mask a weak fault component under the lobe of a nearby strong component (for example the fundamental rotation frequency), exactly the situation of Remark 22.11.

22.11. Windows: coherent gain, equivalent bandwidth, resolution

Section 22.10.3 introduced windowing and showed, on a numerical example, the trade-off between main-lobe width and side-lobe height. This section proves in closed form the three quantities that quantify that trade-off — coherent gain, equivalent noise bandwidth, main-lobe width — for the three windows in common use.

Definition 22.9: The three windows, in periodic and symmetric form. Let $N \geq 3$. For $n = 0, 1, \dots, N-1$, define:

$$\begin{aligned}
\text{rectangular} \quad w_R[n] &= 1, \\
\text{Hann} \quad w_H[n] &= \frac{1}{2} - \frac{1}{2} \cos \frac{2\pi n}{N}, \quad (\text{periodic form}) \\
\text{Hamming} \quad w_M[n] &= 0.54 - 0.46 \cos \frac{2\pi n}{N}, \quad (\text{periodic form}).
\end{aligned}$$

The corresponding *symmetric forms* are obtained by substituting $N-1$ for N in the denominator of the cosine argument; this is the convention of Definition 22.8 and that of `numpy.hanning`. All three have the common form

$$w[n] = a_0 - a_1 \cos \frac{2\pi n}{N} \quad \text{with} \quad (a_0, a_1) = (1, 0), \left(\frac{1}{2}, \frac{1}{2}\right), \left(\frac{27}{50}, \frac{23}{50}\right),$$

since $0.54 = 27/50$ and $0.46 = 23/50$.

Definition 22.10: Coherent gain and equivalent noise bandwidth. Given a window $w \in \mathbb{R}^N$ with $\sum_n w[n] \neq 0$, define

$$\begin{aligned}
\text{CG}(w) &= \frac{1}{N} \sum_{n=0}^{N-1} w[n] \quad (\text{coherent gain}), \\
\text{ENBW}(w) &= \frac{N \sum_{n=0}^{N-1} w[n]^2}{\left(\sum_{n=0}^{N-1} w[n]\right)^2} \quad (\text{equivalent noise bandwidth, in bins}).
\end{aligned}$$

The first is the factor by which the peak of the windowed spectrum must be divided to recover the true amplitude of a tone aligned to a bin; the second is the width, measured in bins, of the ideal rectangular filter that would let through the same white-noise power as the filter realized by the window.

Lemma 22.4: *Two exact trigonometric sums. Let $N \geq 3$. Then*

$$\sum_{n=0}^{N-1} \cos \frac{2\pi n}{N} = 0, \quad \sum_{n=0}^{N-1} \cos^2 \frac{2\pi n}{N} = \frac{N}{2}, \quad \sum_{n=0}^{N-1} \cos \frac{4\pi n}{N} = 0.$$

If moreover $N \geq 4$, $\sum_{n=0}^{N-1} \cos \frac{2\pi n}{N-1} = 1$.

Proof. By Euler's formula, $\cos \theta = \frac{1}{2}(e^{i\theta} + e^{-i\theta})$, hence

$$\sum_{n=0}^{N-1} \cos \frac{2\pi n}{N} = \frac{1}{2} \sum_{n=0}^{N-1} \omega_N^{-n} + \frac{1}{2} \sum_{n=0}^{N-1} \omega_N^n.$$

By Lemma 22.1 with $j = -1$ and with $j = 1$: since $N \geq 3 > 1$, one has $N \nmid 1$ and $N \nmid (-1)$, so both sums vanish and the total is 0.

For the third sum, the same lemma is applied with $j = \pm 2$: since $N \geq 3$, one has $N \mid 2$ only for $N = 2$, excluded, so both sums vanish.

The second follows from the double-angle formula $\cos^2 \theta = \frac{1+\cos 2\theta}{2}$:

$$\sum_{n=0}^{N-1} \cos^2 \frac{2\pi n}{N} = \frac{1}{2} \sum_{n=0}^{N-1} 1 + \frac{1}{2} \sum_{n=0}^{N-1} \cos \frac{4\pi n}{N} = \frac{N}{2} + 0 = \frac{N}{2}.$$

For the last: split the sum into the first $N-1$ terms (indices $n = 0, \dots, N-2$) and the last one. The first $N-1$ terms are $\sum_{n=0}^{(N-1)-1} \cos \frac{2\pi n}{N-1}$, i.e. the first sum of the statement with $N-1$ in place of N : it equals 0 because $N-1 \geq 3$. The last term is $\cos \frac{2\pi(N-1)}{N-1} = \cos 2\pi = 1$. The total is 1. $\square$

Proposition 22.6: *Coherent gain of the three windows. Let $N \geq 3$ and let $w[n] = a_0 - a_1 \cos(2\pi n/N)$ be a window in periodic form. Then*

$$\sum_{n=0}^{N-1} w[n] = a_0 N, \quad \text{CG}(w) = a_0.$$

In particular: $\text{CG}(w_R) = 1$, $\text{CG}(w_H) = \frac{1}{2}$, $\text{CG}(w_M) = 0.54$. If instead the window is in symmetric form, $w[n] = a_0 - a_1 \cos(2\pi n/(N-1))$ with $N \geq 4$, then

$$\sum_{n=0}^{N-1} w[n] = a_0 N - a_1, \quad \text{CG}(w) = a_0 - \frac{a_1}{N}.$$

Proof. In the periodic case, by linearity of the sum and by Lemma 22.4,

$$\sum_{n=0}^{N-1} w[n] = a_0 \sum_{n=0}^{N-1} 1 - a_1 \sum_{n=0}^{N-1} \cos \frac{2\pi n}{N} = a_0 N - a_1 \cdot 0 = a_0 N,$$

and $\text{CG} = \frac{1}{N} \cdot a_0 N = a_0$ by Definition 22.10. In the symmetric case, with the fourth identity of Lemma 22.4, $\sum_n w[n] = a_0 N - a_1 \cdot 1 = a_0 N - a_1$, and one divides by N .

Numerical check. For $N = 64$: periodic Hann form, $\sum w = 32$ and $\text{CG} = 0.50000$; symmetric form, $\sum w = a_0 N - a_1 = 32 - 0.5 = 31.5$ and $\text{CG} = 31.5/64 = 0.49219 = 63/128$. For symmetric Hamming, $\sum w = 0.54 \cdot 64 - 0.46 = 34.56 - 0.46 = 34.10$ and $\text{CG} = 0.53281 = 0.54 - 0.46/64$. The script of Section 22.12.1 returns 32, 31.5, 34.56, 34.10 and the gains 0.50000, 0.49219, 0.54000, 0.53281 ✓. $\square$

Proposition 22.7: Equivalent noise bandwidth of the three windows. Let $N \geq 3$ and let $w[n] = a_0 - a_1 \cos(2\pi n/N)$ be a window in periodic form with $a_0 \neq 0$. Then

$$\sum_{n=0}^{N-1} w[n]^2 = N \left(a_0^2 + \frac{a_1^2}{2} \right), \quad \text{ENBW}(w) = 1 + \frac{a_1^2}{2a_0^2}.$$

In particular

$$\text{ENBW}(w_R) = 1, \quad \text{ENBW}(w_H) = \frac{3}{2} = 1.5, \quad \text{ENBW}(w_M) = \frac{1987}{1458} = 1.36283.$$

Proof. Expanding the square and using the first three identities of Lemma 22.4:

$$\begin{aligned} \sum_{n=0}^{N-1} \left(a_0 - a_1 \cos \frac{2\pi n}{N} \right)^2 &= a_0^2 \sum_n 1 - 2a_0 a_1 \sum_n \cos \frac{2\pi n}{N} + a_1^2 \sum_n \cos^2 \frac{2\pi n}{N} \\ &= a_0^2 N - 0 + a_1^2 \cdot \frac{N}{2} = N \left(a_0^2 + \frac{a_1^2}{2} \right). \end{aligned}$$

By Proposition 22.6 one has $\sum_n w[n] = a_0 N$, hence

$$\text{ENBW}(w) = \frac{N \cdot N \left(a_0^2 + \frac{a_1^2}{2} \right)}{(a_0 N)^2} = \frac{a_0^2 + \frac{a_1^2}{2}}{a_0^2} = 1 + \frac{a_1^2}{2a_0^2}.$$

The three values follow by substitution. For the rectangular window, $a_1 = 0$ gives 1. For Hann, $a_1^2/(2a_0^2) = \frac{1/4}{2 \cdot 1/4} = \frac{1}{2}$, hence $\frac{3}{2}$. For Hamming, with $a_0 = 27/50$ and $a_1 = 23/50$,

$$\text{ENBW} = 1 + \frac{(23/50)^2}{2(27/50)^2} = 1 + \frac{529}{2 \cdot 729} = 1 + \frac{529}{1458} = \frac{1987}{1458},$$

and the division gives $1987/1458 = 1.362825\dots$, i.e. 1.36283 to five decimal places.

Numerical check. For $N = 64$ and $N = 1024$ the script of Section 22.12.1 computes ENBW from the definition and obtains 1.00000 (rectangular), 1.50000 (periodic Hann) and 1.36283 (periodic Hamming), independently of N as predicted by the formula ✓. For the symmetric forms the values depend on N and equal 1.52381 and 1.37832 for $N = 64$, approaching the periodic values as N grows (1.50147 and 1.36378 for $N = 1024$), consistently with the fact that the difference between the two forms is a single sample out of N . $\square$

Theorem 22.15: The DTFT of a two-term window. Let $w[n] = a_0 - a_1 \cos(2\pi n/N)$, $n = 0, \dots, N-1$, and let $\hat{w}(\Omega) = \sum_{n=0}^{N-1} w[n]e^{-in\Omega}$ be its DTFT. Then

$$\hat{w}(\Omega) = a_0 D_N(\Omega) - \frac{a_1}{2} D_N\left(\Omega - \frac{2\pi}{N}\right) - \frac{a_1}{2} D_N\left(\Omega + \frac{2\pi}{N}\right),$$

with D_N the discrete Dirichlet kernel (Definition 22.6). In particular, for the rectangular window ($a_1 = 0$) one has $\hat{w}_R = D_N$.

Proof. By Euler's formula, $\cos \frac{2\pi n}{N} = \frac{1}{2}(e^{2\pi in/N} + e^{-2\pi in/N})$, hence

$$w[n] = a_0 - \frac{a_1}{2}e^{2\pi in/N} - \frac{a_1}{2}e^{-2\pi in/N}.$$

Multiplying by $e^{-in\Omega}$ and summing over $n = 0, \dots, N-1$ (a finite sum, the three pieces separate):

$$\hat{w}(\Omega) = a_0 \sum_{n=0}^{N-1} e^{-in\Omega} - \frac{a_1}{2} \sum_{n=0}^{N-1} e^{-in(\Omega - \frac{2\pi}{N})} - \frac{a_1}{2} \sum_{n=0}^{N-1} e^{-in(\Omega + \frac{2\pi}{N})},$$

having used $e^{2\pi in/N} e^{-in\Omega} = e^{-in(\Omega - 2\pi/N)}$ and similarly for the other term. The three sums are, by Definition 22.6, $D_N(\Omega)$, $D_N(\Omega - 2\pi/N)$ and $D_N(\Omega + 2\pi/N)$. $\square$

Proposition 22.8: Main-lobe width. Let $N \geq 5$ and measure frequency in bins, setting $\Omega = 2\pi f/N$. Then:

- (i) for the rectangular window, $\hat{w}_R(2\pi m/N) = 0$ for every integer m with $1 \leq |m| \leq N-1$: the first zero falls at ± 1 bin from the center and the main lobe is 2 bins wide between the two zeros;
- (ii) for a two-term window with $a_1 \neq 0$ (Hann and Hamming), $\hat{w}(2\pi m/N) = 0$ for every integer m with $2 \leq |m| \leq N-2$, while $\hat{w}(\pm 2\pi/N) = -\frac{a_1}{2}N \neq 0$: the first zero falls at ± 2 bins from the center and the main lobe is 4 bins wide;
- (iii) in every case the spacing between bins remains $\Delta f = f_s/N$, and does not depend on the window.

Proof. Evaluate the formula of Theorem 22.15 at $\Omega = 2\pi m/N$ with $m \in \mathbb{Z}$. The three arguments of the kernel become $\frac{2\pi m}{N}$, $\frac{2\pi(m-1)}{N}$ and $\frac{2\pi(m+1)}{N}$, and by Lemma 22.3 one has $D_N(2\pi r/N) = N$ if $N \mid r$ and 0 otherwise. Hence

$$\hat{w}\left(\frac{2\pi m}{N}\right) = a_0 N [N \mid m] - \frac{a_1}{2} N [N \mid (m-1)] - \frac{a_1}{2} N [N \mid (m+1)],$$

where $[\cdot]$ equals 1 if the condition holds and 0 otherwise.

(i) With $a_1 = 0$ only the first term survives: $\hat{w}_R(2\pi m/N) = 0$ for every m not a multiple of N , in particular for $1 \leq |m| \leq N-1$. The central value is $\hat{w}_R(0) = N \neq 0$, so the zeros closest to the center are $m = \pm 1$ and the main lobe, understood as the interval between the two zeros adjacent to the maximum, is $(-1, 1)$ in bins, of width 2.

(ii) Let $2 \leq |m| \leq N-2$. Then m is not a multiple of N (since $0 < |m| < N$); neither is $m-1$, because $1 \leq m-1 \leq N-3$ if $m > 0$, and $-N+1 \leq m-1 \leq -3$ if $m < 0$, in both cases $0 < |m-1| < N$; similarly $m+1$ is not a multiple of N . All three indicators vanish, hence $\hat{w}(2\pi m/N) = 0$. For $m = 1$ only the term with $N \mid (m-1)$ survives, i.e. $N \mid 0$, true: $\hat{w}(2\pi/N) = -\frac{a_1}{2}N$, nonzero because $a_1 \neq 0$. Symmetrically for $m = -1$. The central value is $\hat{w}(0) = a_0 N \neq 0$. The zeros closest to the maximum are thus $m = \pm 2$, and the main lobe is 4 bins wide.

(iii) The spacing between bins is, by Theorem 22.9, the distance between two consecutive sampling points of the DTFT, i.e. $\Delta\Omega = 2\pi/N$; in frequency units, with $f = \Omega f_s/(2\pi)$, this is $\Delta f = f_s/N$. The computation does not involve w in any way.

Numerical check. Evaluating the DTFT of the three windows with $N = 64$ on 2^{16} points (zero-padding), the first zero falls at 1.0010 bins for the rectangular window and at 2.0010 bins for periodic Hann and Hamming, where the discrepancy from 1 and from 2 is exactly the resolution of the grid used ($64/2^{16} = 0.0010$ bin) $\checkmark$. $\square$

Figure 22.3: Normalized modulus of the DTFT of the rectangular and (periodic) Hann windows, for $N = 8$, as a function of frequency measured in bins. The ordinates are $|D_8(2\pi f/8)|/8$ and the analogous expression for Hann, computed with the closed form of Lemma 22.3 and with the three-kernel decomposition of Theorem 22.15: the two routes agree to within $2.5 \cdot 10^{-16}$. The zeros predicted by Proposition 22.8 are visible: at every nonzero integer for the rectangular window, only from $|f| \geq 2$ for Hann, whose main lobe is thus twice as wide; in exchange, at $f = 2.5$ the rectangular window equals 0.15030 and Hann 0.02236, i.e. about seven times less.

Remark 22.13: Side lobes: computed values, and what remains imported. The height of the highest side lobe, relative to the maximum, is computed by evaluating $|\hat{w}|$ on a fine grid: with $N = 64$ and 2^{16} points one obtains

window	side-lobe peak	width at -3 dB
rectangular	-13.25 dB	0.88 bin
Hann (periodic)	-31.47 dB	1.44 bin
Hamming (periodic)	-42.45 dB	1.30 bin

These values are computed, not cited, and are consistent with the ordering and the orders of magnitude of Harris's (1978) comparative table of windows, which remains the standard reference for systematic comparison.

What remains imported. The asymptotic law of decay of the far side lobes — about -6 dB per octave for rectangular and for Hamming, about -18 dB per octave for Hann — is here **imported** from Harris (1978) and not proved. What is missing, precisely: one would need an asymptotic expansion of $|\hat{w}(\Omega)|$ for Ω far from the origin, showing how in the three-kernel combination of Theorem 22.15 the terms of order $1/\Omega$ and $1/\Omega^2$ cancel for Hann (thanks to $a_0 = 2 \cdot \frac{a_1}{2}$) but not for Hamming; the computation is elementary but long, and nothing in the chapter relies on it. The three quantities actually used — coherent gain (Proposition 22.6), equivalent bandwidth (Proposition 22.7) and main-lobe width (Proposition 22.8) — are instead proved in closed and exact form.

Best practice. Choosing the window. In order of priority: **(1)** if the signal is periodic and an integer number of periods can be acquired, use the rectangular window: there is no leakage and the resolution is the best possible. **(2)** If an *amplitude* is being measured and the tone is not aligned to a bin, use Hann and divide the peak by $\text{CG} = 0.5$ (Proposition 22.6); the residual *scallop* error remains regardless, and canceling it requires interpolating between bins. **(3)** If a weak component must be found near a strong one, use Hamming or a window with even lower lobes: resolution is lost but one gains the 29 dB difference between the side-lobe peaks of rectangular and Hamming. **(4)** If *noise power* is being measured, divide by ENBW (Proposition 22.7): 1.5 for Hann, 1.36283 for Hamming. **(5)** In every

case, doubling the resolution requires doubling N , i.e. the observation time: no window and no zero-padding can replace it (Theorem 22.11).

22.12. An eight-point DFT by hand

Algorithm. $X_k = \sum_{n=0}^{N-1} x_n e^{-2\pi i k n / N}$, with $N = 8$.

Given. The rectangular window $x = (1, 1, 1, 1, 0, 0, 0, 0)$.

Computation. Since $x_n = 1$ only for $n \leq 3$, each X_k is a geometric sum with ratio $w = e^{-2\pi i k / 8}$:

$$X_k = 1 + w + w^2 + w^3 = \frac{1 - w^4}{1 - w} \quad (w \neq 1), \quad X_0 = 4.$$

Since $w^4 = e^{-i\pi k} = (-1)^k$, the numerator equals 0 for even k and 2 for odd k : hence $X_2 = X_4 = X_6 = 0$ with no computation at all. For odd k :

k	X_k	$\Re X_k$	$\Im X_k$	$ X_k $
0	4	4	0	4.00000
1	$1 - 2.41421 i$	1	-2.41421	2.61313
2	0	0	0	0
3	$1 - 0.41421 i$	1	-0.41421	1.08239
4	0	0	0	0
5	$1 + 0.41421 i$	1	$+0.41421$	1.08239
6	0	0	0	0
7	$1 + 2.41421 i$	1	$+2.41421$	2.61313

For example $X_1 = 1 + e^{-i\pi/4} + e^{-i\pi/2} + e^{-i3\pi/4}$, and summing the real and imaginary parts: $\Re = 1 + 0.70711 + 0 - 0.70711 = 1$, $\Im = 0 - 0.70711 - 1 - 0.70711 = -2.41421$. Note the Hermitian symmetry $X_{8-k} = \overline{X_k}$, due to the fact that x is real.

Independent check (Parseval).

$$\sum_k |X_k|^2 = 16 + 6.82843 + 0 + 1.17157 + 0 + 1.17157 + 0 + 6.82843 = 32,$$

while $N \sum_n |x_n|^2 = 8 \cdot 4 = 32 \checkmark$. Parseval's identity is the most effective check of an FFT implementation: it catches any normalization error or sign error in the exponent.

22.12.1 The eight-point example, worked in full

The computation just given is now taken up again and carried through: all the X_k are obtained in exact symbolic form, inversion is checked on *all eight* samples, Hermitian symmetry and Parseval are checked, and the executed script is reported together with its output.

Step 1 — exact values, symbolically. With $N = 8$ and $\omega_8 = e^{-i\pi/4}$ one has, for fixed k , $w = \omega_8^k$ and

$$X_k = \sum_{n=0}^3 w^n = 1 + w + w^2 + w^3.$$

If $k = 0$ then $w = 1$ and the closed formula does not apply (vanishing denominator, Lemma 22.1): one sums directly, $X_0 = 4$. If $k \neq 0$ then $w \neq 1$ (the powers ω_8^k , $k = 0, \dots, 7$, are distinct by Proposition 22.3) and

$$X_k = \frac{1 - w^4}{1 - w}, \quad w^4 = \omega_8^{4k} = e^{-i\pi k} = (-1)^k.$$

For even k the numerator is $1 - 1 = 0$, hence $X_2 = X_4 = X_6 = 0$ with no computation at all. For odd k the numerator equals 2 and $X_k = 2/(1 - \omega_8^k)$ remains. Now $1 - e^{-i\varphi} = e^{-i\varphi/2}(e^{i\varphi/2} - e^{-i\varphi/2}) = 2i \sin(\varphi/2) e^{-i\varphi/2}$, hence with $\varphi = \pi k/4$:

$$X_k = \frac{2}{2i \sin(\pi k/8) e^{-i\pi k/8}} = \frac{e^{i\pi k/8}}{i \sin(\pi k/8)} = \frac{\cos(\pi k/8) + i \sin(\pi k/8)}{i \sin(\pi k/8)} = 1 - i \cot \frac{\pi k}{8}.$$

The real part of every X_k with k odd is thus *exactly* 1, and the imaginary part is $-\cot(\pi k/8)$:

k	$\cot(\pi k/8)$	X_k
1	$\cot(\pi/8) = 1 + \sqrt{2}$	$1 - (1 + \sqrt{2})i$
3	$\cot(3\pi/8) = \sqrt{2} - 1$	$1 - (\sqrt{2} - 1)i$
5	$\cot(5\pi/8) = -(\sqrt{2} - 1)$	$1 + (\sqrt{2} - 1)i$
7	$\cot(7\pi/8) = -(1 + \sqrt{2})$	$1 + (1 + \sqrt{2})i$

The two cotangent values are obtained from the bisection formula $\cot \frac{\theta}{2} = \frac{1+\cos\theta}{\sin\theta}$: for $\theta = \pi/4$, $\cot(\pi/8) = \frac{1+\sqrt{2}/2}{\sqrt{2}/2} = \frac{2+\sqrt{2}}{\sqrt{2}} = \sqrt{2} + 1$; for $\theta = 3\pi/4$, $\cot(3\pi/8) = \frac{1-\sqrt{2}/2}{\sqrt{2}/2} = \frac{2-\sqrt{2}}{\sqrt{2}} = \sqrt{2} - 1$. The two rows with $k = 5, 7$ follow from Hermitian symmetry (Theorem 22.7), since x is real: $X_5 = \overline{X_3}$ and $X_7 = \overline{X_1}$. Numerically $1 + \sqrt{2} = 2.41421$ and $\sqrt{2} - 1 = 0.41421$, in agreement with the table of Section 22.12 ✓.

Step 2 — the moduli. $|X_0| = 4$; $|X_1|^2 = 1 + (1 + \sqrt{2})^2 = 1 + 3 + 2\sqrt{2} = 4 + 2\sqrt{2} = 6.82843$, hence $|X_1| = |X_7| = \sqrt{4 + 2\sqrt{2}} = 2.61313$; similarly $|X_3|^2 = 1 + (\sqrt{2} - 1)^2 = 1 + 3 - 2\sqrt{2} = 4 - 2\sqrt{2} = 1.17157$ and $|X_3| = |X_5| = 1.08239$. The script below returns (4.00000; 2.61313; 0; 1.08239; 0; 1.08239; 0; 2.61313) ✓.

Figure 22.4: Modulus of the spectrum of $x = (1, 1, 1, 1, 0, 0, 0, 0)$. The heights are the exact values 4, $\sqrt{4 + 2\sqrt{2}} = 2.61313$, 0, $\sqrt{4 - 2\sqrt{2}} = 1.08239$, 0, 1.08239, 0, 2.61313, computed by hand in Step 2 and cross-checked with the script. The symmetry about bin 4 (Nyquist frequency) is that of Corollary 22.8(iii): $|X_{8-k}| = |X_k|$.

Step 3 — inversion, checked on all eight samples. Since $X_2 = X_4 = X_6 = 0$, $X_5 = \overline{X_3}$ and $X_7 = \overline{X_1}$, and since $\omega_8^{-7n} = \overline{\omega_8^{-n}}$ and $\omega_8^{-5n} = \overline{\omega_8^{-3n}}$ (powers depend on the exponent modulo 8 and $|\omega_8| = 1$), the inversion formula of Theorem 22.2 reduces to

$$x[n] = \frac{1}{8} \left(4 + 2 \operatorname{Re} (X_1 e^{i\pi n/4}) + 2 \operatorname{Re} (X_3 e^{3i\pi n/4}) \right).$$

Writing $X_1 = 1 - (1 + \sqrt{2})i$ and using $\operatorname{Re}((a + bi)e^{i\theta}) = a \cos \theta - b \sin \theta$ with $\cos(\pi/4) =$

$\sin(\pi/4) = \sqrt{2}/2$, one obtains the exact values

n	0	1	2	3	4	5	6	7
$2 \operatorname{Re}(X_1 e^{i\pi n/4})$	2	$2(1+\sqrt{2})$	$2(1+\sqrt{2})$	2	-2	$-2(1+\sqrt{2})$	$-2(1+\sqrt{2})$	-2
$2 \operatorname{Re}(X_3 e^{3i\pi n/4})$	2	$-2(\sqrt{2}-1)$	$-2(\sqrt{2}-1)$	2	-2	$2(\sqrt{2}-1)$	$2(\sqrt{2}-1)$	-2
sum + 4	8	8	8	8	0	0	0	0
$x[n] = \text{sum}/8$	1	1	1	1	0	0	0	0

Let us check two columns in full. For $n = 1$: $\operatorname{Re}(X_1 e^{i\pi/4}) = 1 \cdot \frac{\sqrt{2}}{2} + (1 + \sqrt{2}) \frac{\sqrt{2}}{2} = \frac{\sqrt{2}}{2}(2 + \sqrt{2}) = \sqrt{2} + 1$, hence the first term is $2(1 + \sqrt{2})$; and $\operatorname{Re}(X_3 e^{3i\pi/4}) = 1 \cdot (-\frac{\sqrt{2}}{2}) + (\sqrt{2} - 1) \frac{\sqrt{2}}{2} = \frac{\sqrt{2}}{2}(\sqrt{2} - 2) = 1 - \sqrt{2}$, hence the second term is $-2(\sqrt{2} - 1)$. The sum of the two is $2(1 + \sqrt{2}) - 2(\sqrt{2} - 1) = 2 + 2\sqrt{2} - 2\sqrt{2} + 2 = 4$; with the 4 of the constant term this makes 8, and dividing by 8 gives $x[1] = 1 \checkmark$. For $n = 5$ the arguments are $5\pi/4$ and $15\pi/4 \equiv 7\pi/4 \pmod{2\pi}$, with $\cos(5\pi/4) = \sin(5\pi/4) = -\frac{\sqrt{2}}{2}$ and $\cos(7\pi/4) = -\sin(7\pi/4) = \frac{\sqrt{2}}{2}$; hence

$$\operatorname{Re}(X_1 e^{5i\pi/4}) = -\frac{\sqrt{2}}{2} - (1 + \sqrt{2}) \frac{\sqrt{2}}{2} = -\frac{\sqrt{2}}{2}(2 + \sqrt{2}) = -(1 + \sqrt{2}),$$

$$\operatorname{Re}(X_3 e^{15i\pi/4}) = \frac{\sqrt{2}}{2} - (\sqrt{2} - 1) \frac{\sqrt{2}}{2} = \frac{\sqrt{2}}{2}(2 - \sqrt{2}) = \sqrt{2} - 1,$$

whose doubles are $-2(1 + \sqrt{2})$ and $2(\sqrt{2} - 1)$; their sum is -4 , which with the constant 4 gives 0, hence $x[5] = 0 \checkmark$. The other six columns are obtained in the same way and are given in the table: *all eight* samples are reconstructed exactly.

Step 4 — Parseval, again. The check of Section 22.12 is now a case of Theorem 22.6:

$$\sum_{k=0}^7 |X_k|^2 = 16 + 2(4 + 2\sqrt{2}) + 2(4 - 2\sqrt{2}) = 16 + 8 + 8 = 32,$$

where the terms in $\sqrt{2}$ cancel in pairs, and $N \sum_n |x_n|^2 = 8 \cdot 4 = 32 \checkmark$. Note that the identity holds *exactly*, with no rounding.

Step 5 — the executed script. The listing that follows is the script actually executed for the chapter; the lines after each group of statements give its literal output.

Listing 22.4: Numerical checks of Chapter 22 (Python 3 with NumPy). Executed; the output is reported at the end of the listing.

```

Remark 22.14: What the comparison actually checked. Every numerical value of the chapter appears twice: once as a proved closed formula, once as the output of the script. In particular the following were verified: the values X_k and the moduli of the eight-point exam-

ple (Steps 1–2); inversion on all eight samples (Step 3, symbolically, and the $\text{IDFT}(X)$ line of the script); Parseval (Step 4); unitarity and $F_N^4 = I$ for $N = 4, 8$ (Theorem 22.3, Corollary 22.4); the determinants $16i$ and $-4096i$ computed both by factorization and with the Vandermonde product (Example 22.1); circular convolution by two routes (Example 22.2); the eigenvalues and the determinant of the circulant and the solution of the system $Cy = b$ (Example 22.3); the Dirichlet interpolation of zero-padding, with discrepancy $1.03 \cdot 10^{-14}$ over 32 values (Theorem 22.11); coherent gain and equivalent bandwidth for two values of N and for the periodic and symmetric forms (Propositions 22.6 and 22.7); the position of the first zero and the side-lobe peak (Proposition 22.8 and Remark 22.13); the multiplicities of the four eigenvalues of F_N for $N = 4, 5, 6, 7, 8, 12$ (Remark 22.3), whose sum is N each time. The discrepancies between the two routes are in every case of the order of the double-precision rounding error, i.e. $\leq 10^{-14}$.

22.13. Exercises inherited from Volume II

The exercises that follow come from Volume II, Chapter 4, and concern the topics of this chapter. They are reproduced in full, with their solutions, which follow in the same order as the exercises.

Exercises

Exercise 22.1. Using Theorem 22.12, compute the 4-point DFT of $x = [1, 0, -1, 0]$ by evaluating $X(z) = \sum_n x[n]z^{-n}$ directly at the 4 fourth roots of unity, and compare the result with the direct computation from the definition of the DFT.

Exercise 22.2. A vibration analyzer acquires $N = 4096$ samples per window. Compare the number of complex operations required by the direct computation of the DFT ($O(N^2)$) with those required by the radix-2 FFT ($O(N \log_2 N)$), and compute the speedup factor.

Exercise 22.3. Trace by hand, for $N = 8$, the bit-reversal permutation used in `FB_FFT8`: write the index i in 3-bit binary, reverse the order of the bits, and check that the result matches the `bitRev` array of the listing. Then carry out by hand the first stage ($m = 2$) of butterflies on the already permuted array for the input of the Worked example (input $[1, -1, 1, -1, 1, -1, 1, -1]$), checking that the intermediate result is consistent with the decomposition of Theorem 22.13.

Exercise 22.4. (Leakage) — A signal at $f_0 = 15$ Hz is sampled at $f_s = 100$ Hz with $N = 50$ samples. Check whether f_0 falls exactly on a DFT bin (i.e. whether $f_0 N / f_s$ is an integer) and, if not, explain qualitatively what the spectrum with a rectangular window would show compared to a Hann window, using Remark 22.11.

Exercise 22.5: S10 — From series to DFT: the aliasing formula. Let f be continuous on $\mathbb{T}$ with $\sum_n |\hat{f}(n)| < \infty$, and let $x_k = f(2\pi k/N)$, $k = 0, \dots, N-1$, be its samples. Prove the **aliasing formula**

$$\frac{1}{N} X_j = \sum_{m \in \mathbb{Z}} \hat{f}(j + mN), \quad X_j = \sum_{k=0}^{N-1} x_k e^{-2\pi i j k / N},$$

and interpret it: the DFT does not see the individual Fourier coefficients, but their sum over all frequencies congruent modulo N . Connect this with the Theorem (Volume II, Chapter 2)

Solutions

Solution. The associated polynomial is $X(z) = \sum_{n=0}^3 x[n]z^{-n} = 1 + 0 \cdot z^{-1} - z^{-2} + 0 \cdot z^{-3} = 1 - z^{-2}$. The 4 fourth roots of unity (Chapter 3) are $\zeta_4^k = e^{2\pi i k/4} = i^k$, $k = 0, 1, 2, 3$, i.e. $1, i, -1, -i$. Evaluating (with the convention $z = \zeta_4^k$, $z^{-2} = \zeta_4^{-2k} = (-1)^{-k} = (-1)^k$):

$$X[0] = 1 - 1 = 0, \quad X[1] = 1 - (-1) = 2, \quad X[2] = 1 - 1 = 0, \quad X[3] = 1 - (-1) = 2.$$

From the direct definition of the DFT, $X[k] = \sum_{n=0}^3 x[n]e^{-2\pi i k n/4} = 1 - e^{-i\pi k}$ (only the terms $n = 0, 2$ contribute, since $x[1] = x[3] = 0$): for even k , $e^{-i\pi k} = 1$, hence $X[k] = 0$; for odd k , $e^{-i\pi k} = -1$, hence $X[k] = 2$. The two computations coincide exactly, as guaranteed by Theorem 22.12.

Solution. Direct computation: $N^2 = 4096^2 = 16\,777\,216$ complex operations. Radix-2 FFT: $N \log_2 N = 4096 \times 12 = 49\,152$ (since $4096 = 2^{12}$, $\log_2 4096 = 12$). The speedup factor is $16\,777\,216/49\,152 \approx 341$: the FFT requires about $1/341$ of the operations of the direct computation, a saving that makes real-time spectral analysis possible on embedded hardware even with limited computing resources.

Solution. Writing $i = 0, \dots, 7$ in 3-bit binary and reversing the order of the digits: $0 = 000 \rightarrow 000 = 0$; $1 = 001 \rightarrow 100 = 4$; $2 = 010 \rightarrow 010 = 2$; $3 = 011 \rightarrow 110 = 6$; $4 = 100 \rightarrow 001 = 1$; $5 = 101 \rightarrow 101 = 5$; $6 = 110 \rightarrow 011 = 3$; $7 = 111 \rightarrow 111 = 7$: that is, $[0, 4, 2, 6, 1, 5, 3, 7]$, exactly the `bitRev` array of the `FB_FFT8` listing.

After bit-reversal, the input $x = [1, -1, 1, -1, 1, -1, 1, -1]$ (indices 0..7) must be reordered by swapping the pairs (1, 4) and (3, 6), the only ones with `bitRev[i] > i`: position $1 \leftrightarrow 4$: $x[1] = -1$ and $x[4] = 1$ are swapped, giving $x[1] = 1$, $x[4] = -1$; position $3 \leftrightarrow 6$: $x[3] = -1$ and $x[6] = 1$ are swapped, giving $x[3] = 1$, $x[6] = -1$. The permuted vector is therefore $[1, 1, 1, 1, -1, -1, -1, -1]$ (the first four even samples grouped together, followed by the four odd ones, as expected from the even/odd recursion of Theorem 22.13).

First stage ($m = 2$, half = 1: with a single element per half-block the twiddle is always $w = 1$): for each pair $(k, k + 1) = (0, 1), (2, 3), (4, 5), (6, 7)$ one computes $x[k] \pm x[k + 1]$. For the first two pairs $x[k] = x[k + 1] = 1$: sum = 2, difference = 0. For the last two pairs $x[k] = x[k + 1] = -1$: sum = -2, difference = 0. Intermediate result after the first stage: $[2, 0, 2, 0, -2, 0, -2, 0]$ — a value also verified numerically, and consistent with the decomposition of Theorem 22.13, which at each stage combines pairs with a rotation twiddle, progressively propagating the energy toward the final bin $k = 4$ (the later stages, not required by the exercise, indeed lead to $[4, 0, 0, 0, -4, 0, 0, 0]$ after the second stage and to $[0, 0, 0, 0, 8, 0, 0, 0]$ after the third, exactly reproducing the output of `FB_FFT8` of the Worked example).

Solution. $f_0 N / f_s = 15 \times 50 / 100 = 7.5$, not an integer: f_0 falls exactly halfway between bin 7 and bin 8. By Remark 22.11, with a rectangular window the spectrum would show marked, symmetric leakage on the adjacent bins, with side lobes decaying slowly (about 6 dB per octave): energy visible even on bins far from the peak. With a Hann window the main lobe would widen (bins 7 and 8 would become almost equivalent in amplitude, both close to the peak), but the distant lobes would decay much more rapidly, making it easier to distinguish a possible weak nearby component from background noise or from leakage of

the main component — exactly the trade-off illustrated numerically in the Worked example of Section 22.10.3.

Solution. S10. *Step 1 — substituting the series into the samples.* Since $\sum_n |\hat{f}(n)| < \infty$, by Theorem 17.5(i) the Fourier series converges uniformly to f , and in particular pointwise at the nodes:

$$x_k = f\left(\frac{2\pi k}{N}\right) = \sum_{n \in \mathbb{Z}} \hat{f}(n) e^{2\pi i n k / N}.$$

Step 2 — computing the DFT. Substituting and exchanging the sums (legitimate by absolute convergence of the series and finiteness of the sum over k):

$$X_j = \sum_{k=0}^{N-1} x_k e^{-2\pi i j k / N} = \sum_{n \in \mathbb{Z}} \hat{f}(n) \sum_{k=0}^{N-1} e^{2\pi i (n-j) k / N}.$$

Step 3 — the mother identity. The inner sum is that of the Theorem (Volume II, Chapter 3) of Chapter 3: it equals N if $N \mid (n - j)$ and 0 otherwise. The surviving indices n are therefore exactly those of the form $n = j + mN$ with $m \in \mathbb{Z}$:

$$X_j = N \sum_{m \in \mathbb{Z}} \hat{f}(j + mN), \quad \text{i.e.} \quad \frac{1}{N} X_j = \sum_{m \in \mathbb{Z}} \hat{f}(j + mN).$$

Step 4 — interpretation. The DFT of the samples does not return the Fourier coefficient $\hat{f}(j)$, but the *sum* of all coefficients whose index is congruent to j modulo N . The high frequencies “fold back” onto the low ones and add to them: this is **aliasing**, and the formula is its exact statement. The error made in approximating $\hat{f}(j)$ by X_j/N is

$$\frac{X_j}{N} - \hat{f}(j) = \sum_{m \neq 0} \hat{f}(j + mN),$$

which is smaller the more rapidly the coefficients decay, i.e. the more regular f is (Remark 17.5).

Step 5 — connection with Chapter 2. For $j = 0$ the formula becomes

$$\frac{X_0}{N} = \sum_{m \in \mathbb{Z}} \hat{f}(mN) = \hat{f}(0) + \sum_{m \neq 0} \hat{f}(mN),$$

and since X_0/N is exactly the mean of the samples, i.e. $\frac{1}{2\pi} T_N[f]$ with T_N the periodic trapezoidal rule, one recovers

$$\frac{1}{2\pi} T_N[f] - \frac{1}{2\pi} I[f] = \sum_{m \neq 0} \hat{f}(mN),$$

which is precisely Step 3 of the proof of the Theorem (Volume II, Chapter 2). The aliasing formula and the periodic quadrature error are the same statement.

Inherited quiz

The items that follow come from the quiz of Volume II, Chapter 4, and are renumbered here.

1. The complexity of the FFT relative to the direct DFT is

A) $O(N^2)$ against $O(N)$

- B) $O(N \log N)$ against $O(N^2)$
 - C) $O(N)$ against $O(N \log N)$
 - D) identical
2. Spectral leakage is reduced by applying
- A) a rectangular window
 - B) a window that tapers the edges (e.g. Hann)
 - C) slower sampling
 - D) aliasing

BEST PRACTICE

Answer key.

1-B: Theorem 22.14. **2-B:** the rectangular window is the worst for leakage (Section 22.10.3).

Inherited formulary

The lines that follow come from the formulary of Volume II, Chapter 4.

Aliasing (series $\rightarrow$ DFT)

$$\frac{1}{N}X_j = \sum_{m \in \mathbb{Z}} \hat{f}(j + mN), \quad x_k = f\left(\frac{2\pi k}{N}\right)$$

22.14. Assigned exercises

Exercise 22.6: A four-point DFT, with all the checks. *Goal:* master the definition and the three standard checks. *Estimated time:* 35 minutes.

Let $x = (2, 0, -1, 3)$.

- (a) Compute $X = \mathcal{F}_4 x$ directly from Definition 22.1, with $\omega_4 = -i$.
- (b) Check the conjugate symmetry of Theorem 22.7 and state, without recomputing, which components are real and why (Corollary 22.8).
- (c) Check Parseval's identity (Theorem 22.6) by computing the two sides separately.
- (d) Reconstruct x with the inversion formula (Theorem 22.2) and check all four samples.

Exercise 22.7: Circular convolution and linear convolution. *Goal:* understand when circular convolution answers the right question. *Estimated time:* 40 minutes.

Let $a = (1, 2, 3)$ and $b = (1, -1, 0)$, both of length 3.

- (a) Compute $a \circledast b$ with $N = 3$ from Definition 22.4, and recompute it with Theorem 22.5.
- (b) Compute the *linear* convolution $c[n] = \sum_m a[m]b[n-m]$ (indices not wrapped, $b[j] = 0$ outside $\{0, 1, 2\}$), which has length $3 + 3 - 1 = 5$.
- (c) Compare the two results and identify exactly which terms of the linear convolution overlapped in the circular one.
- (d) Extend a and b with zeros up to length $N' = 5$ and check that the 5-point circular convolution reproduces the linear convolution. State the general rule (how many zeros are needed, as a function of the two lengths).

Exercise 22.8: Windows: gain, equivalent bandwidth and reading an amplitude.

Goal: use the closed-form window formulas on a measurement case. *Estimated time:* 45 minutes.

An analyzer acquires $N = 1024$ samples at $f_s = 25\,600$ Hz.

- (a) Compute $\Delta f = f_s/N$ and state to which bin a tone at 1000 Hz corresponds; is the tone aligned to a bin?
- (b) Compute, with Propositions 22.6 and 22.7, the coherent gain and the equivalent bandwidth of the periodic Hann window and of the periodic Hamming window; give the exact form, then the decimal form to five figures.
- (c) The peak of the Hann-windowed spectrum equals $|X[k_0]| = 2048$. What is the amplitude of the tone? (Recall that for a real tone the energy splits between bins k_0 and $N - k_0$, Corollary 22.8.)
- (d) With which of the two windows would a component 40 dB weaker, placed at $5\Delta f$ from the main tone, be better distinguished? Justify using Remark 22.13.

22.15. Solved exercises

Exercise 22.9: The four-point DFT of $(1, 2, 3, 4)$, with four checks. Compute $X = \mathcal{F}_4 x$ for $x = (1, 2, 3, 4)$; check conjugate symmetry, Parseval and inversion; interpret the four numbers obtained.

Solution. Strategy. With $N = 4$ the matrix W_4 has entries that are powers of $\omega_4 = e^{-i\pi/2} = -i$, which are only $1, -i, -1, i$: no trigonometric computation is needed. X is computed row by row, then the three checks are applied in the order in which they catch different errors.

Step 1 — the four sums. Since $\omega_4^{kn} = (-i)^{kn}$:

$$\begin{aligned}X[0] &= 1 + 2 + 3 + 4 = 10, \\X[1] &= 1 + 2(-i) + 3(-i)^2 + 4(-i)^3 = 1 - 2i - 3 + 4i = -2 + 2i, \\X[2] &= 1 + 2(-1) + 3(1) + 4(-1) = 1 - 2 + 3 - 4 = -2, \\X[3] &= 1 + 2(i) + 3(-1) + 4(-i) = 1 + 2i - 3 - 4i = -2 - 2i,\end{aligned}$$

having used $(-i)^2 = -1$, $(-i)^3 = i$, $(-i)^4 = 1$ and, for row $k = 2$, $\omega_4^{2n} = (-1)^n$. Hence $X = (10, -2 + 2i, -2, -2 - 2i)$.

Step 2 — symmetry check (Theorem 22.7). x is real, so $X[4 - k] = \overline{X[k]}$ must hold: indeed $X[3] = -2 - 2i = \overline{-2 + 2i} = \overline{X[1]}$ ✓. Moreover $X[0] = 10$ and $X[2] = -2$ are real, as predicted by Corollary 22.8(i) and (ii), since 4 is even and $2 = N/2$ is the Nyquist bin. This check catches sign errors in the exponent on a single row.

Step 3 — Parseval check (Theorem 22.6).

$$\sum_n |x[n]|^2 = 1 + 4 + 9 + 16 = 30; \quad \frac{1}{4} \sum_k |X[k]|^2 = \frac{100 + 8 + 4 + 8}{4} = \frac{120}{4} = 30 \quad \checkmark,$$

where $|-2 \pm 2i|^2 = 4 + 4 = 8$ and $|-2|^2 = 4$. This check catches normalization errors (Corollary 22.7).

Step 4 — inversion check (Theorem 22.2). Grouping the conjugate terms $k = 1$ and $k = 3$, and using $\omega_4^{-kn} = i^{kn}$:

$$x[n] = \frac{1}{4} \left(10 + (-2)(-1)^n + 2 \operatorname{Re}((-2 + 2i)i^n) \right).$$

For $n = 0$: $\frac{1}{4}(10 - 2 + 2(-2)) = \frac{1}{4}(10 - 2 - 4) = 1 \checkmark$. For $n = 1$: $(-2 + 2i)i = -2i - 2$, real part -2 , hence $\frac{1}{4}(10 + 2 - 4) = 2 \checkmark$. For $n = 2$: $(-2 + 2i)(-1) = 2 - 2i$, real part 2 , hence $\frac{1}{4}(10 - 2 + 4) = 3 \checkmark$. For $n = 3$: $(-2 + 2i)(-i) = 2i + 2$, real part 2 , hence $\frac{1}{4}(10 + 2 + 4) = 4 \checkmark$.

Independent check. The same DFT is obtained by observing that $x = (1, 2, 3, 4)$ is the sum of a constant $\frac{5}{2}(1, 1, 1, 1)$ and the centered ramp $(-\frac{3}{2}, -\frac{1}{2}, \frac{1}{2}, \frac{3}{2})$. The constant contributes only to $X[0]$, with $4 \cdot \frac{5}{2} = 10 \checkmark$; the centered ramp is real and antisymmetric about the center, and its DFT has $X[0] = 0$, consistent with $-\frac{3}{2} - \frac{1}{2} + \frac{1}{2} + \frac{3}{2} = 0$. Moreover the script of Section 22.12.1 prints **eigenvalues** of $\mathbf{C} = (10, -2 + 2i, -2, -2 - 2i)$, which is precisely $\mathcal{F}_4(1, 2, 3, 4) \checkmark$.

Interpretation. $X[0] = 10$ is the sum of the samples, i.e. N times the mean: the DC component. $|X[2]| = 2$ is the component at the Nyquist frequency, i.e. how much the signal “alternates” from sample to sample: here little, because the ramp is monotone. $|X[1]| = |X[3]| = 2\sqrt{2} = 2.82843$ is the component at one cycle per window, the largest after the DC term: it is the ramp, which viewed as a signal periodic with period 4 is a sawtooth, whose content is concentrated at the fundamental frequency.

Common errors. (i) Using $\omega_4 = i$ instead of $-i$: this gives the conjugate spectrum, and neither Parseval nor the moduli notice — only the symmetry check read *with the sign* or inversion reveals it. (ii) Putting the factor $1/N$ in the forward transform: Parseval fails by a factor N^2 (Corollary 22.7). (iii) Computing $X[3]$ from scratch instead of using symmetry: this is not an error, but it doubles the work and the chances of making a mistake.

Extension. Repeat with $x = (4, 3, 2, 1)$ and check, without redoing the computation, that the result is $\overline{X}$ read backwards: this is Proposition 22.4 combined with Theorem 22.4.

Exercise 22.10: Zero-padding: what appears between the bins, and why it is not new information. Let $x = (1, 1, 1, 1, 0, 0, 0, 0)$. Compute $X_{32}[k]$ for $k = 0, 2, 4$ and show that the values for k a multiple of 4 coincide with the eight-point DFT; explain why the intermediate values add no information.

Solution. Strategy. Theorem 22.10 is used to reduce everything to the same DTFT, then the geometric sum for the requested values, and finally Theorem 22.11 for the interpretation. **Step 1 — there is only one DTFT.** Since $x[n] = 1$ exactly for $n = 0, 1, 2, 3$, the DTFT is

$$\widehat{X}(\Omega) = \sum_{n=0}^3 e^{-in\Omega} = \frac{1 - e^{-4i\Omega}}{1 - e^{-i\Omega}} \quad (\Omega \notin 2\pi\mathbb{Z}), \quad \widehat{X}(0) = 4.$$

Both the eight-point DFT and the thirty-two-point DFT are samplings of this same function, at $\Omega = 2\pi k/8$ and $\Omega = 2\pi k/32$ respectively (Theorems 22.9 and 22.10).

Step 2 — $k = 0$. $\Omega = 0$: this falls into the case of vanishing denominator, and one sums directly, $X_{32}[0] = 4$. This coincides with $X[0] = 4$ of Section 22.12 $\checkmark$.

Step 3 — $k = 4$. $\Omega = 2\pi \cdot 4/32 = \pi/4$, i.e. the same point at which the eight-point DFT evaluates bin 1 ($2\pi \cdot 1/8 = \pi/4$). Hence $X_{32}[4] = X[1] = 1 - (1 + \sqrt{2})i = 1 - 2.41421i$, with no new computation at all: it is the final claim of Theorem 22.10 with $M = rN$, $r = 4$.

Step 4 — $k = 2$. This is a new point, halfway between bins 0 and 1 of the short DFT. With $w = e^{-i\pi/8}$ and $w^4 = e^{-i\pi/2} = -i$:

$$X_{32}[2] = \frac{1 - w^4}{1 - w} = \frac{1 + i}{1 - e^{-i\pi/8}}.$$

The computation is that of Example 22.4 and gives

$$X_{32}[2] = 3.01367 - 2.01367i, \quad |X_{32}[2]| = 3.62451.$$

Independent check. The modulus is recomputed in closed form without going through the real and imaginary parts: $|X_{32}[2]| = \frac{|1+i|}{|1-e^{-i\pi/8}|} = \frac{\sqrt{2}}{2\sin(\pi/16)} = \frac{1.41421}{2 \cdot 0.19509} = 3.62451 \checkmark$, and $\sqrt{3.01367^2 + 2.01367^2} = 3.62451 \checkmark$. The script of Section 22.12.1 prints $X_{32}[2] = (3.01367-2.01367j) \checkmark$.

Interpretation. The value 3.62451 is larger than $|X[1]| = 2.61313$ and much smaller than $|X[0]| = 4$: between the two bins of the short DFT the curve $|\hat{X}|$ is not at all step-monotone, and the “true” peak of the continuous spectrum lies between the bins, not on them. But it is not new information: by Theorem 22.11,

$$X_{32}[2] = \frac{1}{8} \sum_{j=0}^7 X[j] D_8\left(2\pi\left(\frac{2}{32} - \frac{j}{8}\right)\right),$$

i.e. a fixed-coefficient linear combination of the eight values already known. Zero-padding densifies the plot, not the knowledge.

Common errors. (i) Believing that zero-padding improves resolution: it does not (Proposition 22.8(iii)); two tones closer together than f_s/N remain indistinguishable no matter how many zeros are added. (ii) Adding the zeros *in the middle* instead of at the end: this gives a different signal and a different spectrum. (iii) Forgetting that the bin amplitude does not change with M in the convention adopted here (no forward factor $1/N$), whereas it would change in a normalized convention.

Extension. Compute $X_{32}[1]$ and check that $|X_{32}[1]| > |X_{32}[2]|$: the maximum of the continuous curve between bins 0 and 1 of the short DFT lies closer to 0 than to 1, as it must because $|\hat{X}|$ decreases from 4 toward the first zero.

Exercise 22.11: Measured leakage: a tone halfway between two bins. Let $N = 64$, $f_s = 100$ Hz and $x[n] = \sin(2\pi f_0 n / f_s)$ with $f_0 = 8.5 f_s / N = 13.28125$ Hz, i.e. 8.5 cycles in the window. Predict, with the Dirichlet kernel, the level of bin 7 relative to the peak for the rectangular window, and compare it with the measured value; repeat with the Hann window.

Solution. Strategy. A real sine is the difference of two complex exponentials; each exponential contributes a shifted copy of the Dirichlet kernel (Theorem 22.15 with $a_1 = 0$). One first estimates with a single term, then does the exact two-term computation and explains the difference.

Step 1 — the tone does not fall on a bin. $f_0 N / f_s = 8.5$, not an integer: the tone lies exactly halfway between bins 8 and 9. This is the situation of Remark 22.11.

Step 2 — the exact formula. From $\sin \theta = \frac{1}{2i}(e^{i\theta} - e^{-i\theta})$ and Definition 22.6,

$$X[k] = \frac{1}{2i} \left[D_N\left(\frac{2\pi(k-8.5)}{N}\right) - D_N\left(\frac{2\pi(k+8.5)}{N}\right) \right],$$

because $\sum_n e^{\pm 2\pi i \cdot 8.5 n / N} e^{-2\pi i k n / N} = \sum_n e^{-2\pi i (k \mp 8.5) n / N} = D_N(2\pi(k \mp 8.5)/N)$.

Step 3 — single-term estimate. Neglecting the second term (the “image frequency”, centered at -8.5 bins and hence 16.5 bins away from bin 8), one has, by Lemma 22.3, $|D_N(2\pi f/N)| = |\sin(\pi f)/\sin(\pi f/N)|$, and since $|\sin(\pi f)| = 1$ for f a half-integer:

$$\frac{|X[7]|}{|X[8]|} \approx \frac{1/\sin(1.5\pi/64)}{1/\sin(0.5\pi/64)} = \frac{\sin(0.5\pi/64)}{\sin(1.5\pi/64)} = \frac{0.0245412}{0.0735646} = 0.333603,$$

i.e. $20 \log_{10} 0.333603 = -9.54$ dB.

Step 4 — the measured value. The complete computation (two terms, or the FFT) gives -9.11 dB. The 0.43 dB difference from the estimate is precisely the contribution of the image frequency, which adds in phase with the main term at bin 7 but not at bin 8. That the two-term formula of Step 2 is *exact* has been verified: the maximum discrepancy between the 64 values $X[k]$ computed with it and those computed with the FFT is $3.7 \cdot 10^{-13}$ ✓.

Step 5 — the full picture, rectangular versus Hann. The measured levels, in dB relative to the peak:

bin	4	6	7	8	9	10
rectangular	-17.02	-13.06	-9.11	0.00	-0.39	-10.27
Hann (symmetric)	-46.89	-30.51	-13.41	0.00	0.00	-13.41

These are the same numbers reported in the worked example of Section 22.10.3, recomputed here.

Interpretation. With the rectangular window bins 8 and 9 are nearly matched (0.39 dB apart) and the rest of the spectrum stays high: at bin 4, i.e. four and a half bins from the tone, there is still energy at -17 dB, which would mask any weaker component. With Hann the main lobe is wider (bins 8 and 9 are now exactly equal, and bin 7 only drops to -13.41), but at bin 4 one is at -46.89 dB: almost 30 dB of gain, in line with the difference between the side-lobe peaks of the two windows (Remark 22.13: -13.25 against -31.47 dB).

Common errors. (i) Reading the tone's amplitude directly off the peak: with Hann the peak must be divided by $\text{CG} = 0.5$ (Proposition 22.6), and the *scalloping* error remains regardless because the tone is not on a bin. (ii) Attributing the leakage to measurement noise: here there is no noise, the signal is an exact sine; leakage is an effect of windowing, not of signal quality. (iii) Expecting Hann to reduce the level of bin 7: it *increases* it (from -9.11 to -13.41 is a reduction, but the main lobe is wider and bins 7 and 10 are now inside it); Hann acts on the *distant* bins.

Extension. Repeat with f_0 exactly on bin 8 ($f_0 = 12.5$ Hz): with the rectangular window all other bins drop to about -300 dB, i.e. numerical zero (this is Theorem 22.1: the signal is a combination of only two vectors e_k); with Hann, instead, bins 7 and 9 remain at -5.82 dB, because the window has *widened* a spectral line that was perfect. This is why, when an integer number of periods can be acquired, the best window is no window at all.

22.16. Self-assessment quiz

- (Definition) In the convention of this chapter the DFT of $x \in \mathbb{C}^N$ is
 - $X[k] = \frac{1}{N} \sum_n x[n] e^{-2\pi i k n / N}$
 - $X[k] = \sum_n x[n] e^{-2\pi i k n / N}$
 - $X[k] = \sum_n x[n] e^{+2\pi i k n / N}$
 - $X[k] = \frac{1}{\sqrt{N}} \sum_n x[n] e^{+2\pi i k n / N}$
- (Hypothesis) Lemma 22.1 distinguishes two cases. The case $N \mid j$ must be treated separately because
 - the sum is infinite
 - the ratio q equals 1 and the closed formula would have a vanishing denominator
 - the ratio q is zero
 - the terms are not complex numbers

-
3. (Symbolic computation) Let $x \in \mathbb{C}^N$ and $y[n] = x[\langle n - 3 \rangle_N]$. Then $Y[k]$ equals
- A) $X[k - 3]$
 - B) $3X[k]$
 - C) $\omega_N^{3k} X[k]$
 - D) $X[k] + 3$
4. (Numerical computation) For $x = (1, 1, 1, 1, 0, 0, 0, 0)$, $|X_1|$ equals
- A) 4.00000
 - B) 2.61313
 - C) 1.08239
 - D) 2.41421
5. (Proof step) In the proof of Theorem 22.2, exchanging the order of the two sums is legitimate because
- A) the series converges absolutely
 - B) the terms are finite in number
 - C) $\mathcal{F}_N$ is unitary
 - D) x is real
6. (Error diagnosis) An FFT routine passes the Parseval check but returns the signal reversed in time when applied twice forward. The most likely error is
- A) a missing factor $1/N$
 - B) no error: this is the behavior predicted by Theorem 22.4
 - C) a wrong bit-reversal
 - D) numerical overflow
7. (Transfer) To solve $Cy = b$ with C a 1024×1024 circulant, the best approach is
- A) Gaussian elimination, $O(N^3)$
 - B) inverting C once and multiplying, $O(N^2)$
 - C) dividing spectrum by spectrum with two FFTs, $O(N \log N)$
 - D) it is not possible: circulants are not invertible
8. (Source and metacognition) The comparative table of windows (gain, side lobes, equivalent bandwidth) most cited in the literature is
- A) Harris, *Proceedings of the IEEE* 66 (1978), 51–83
 - B) Cooley and Tukey (1965)
 - C) Van Loan, SIAM (1992)
 - D) McClellan and Parks (1972)
-

22.17. Teacher's key

BEST PRACTICE

Item 1 — answer B. *Rationale:* this is Definition 22.1: no forward factor, minus sign in the exponent. *Distractors:* A is the convention with $1/N$ forward (used by some applied-mathematics textbooks); C is the crystallographic convention; D is the symmetric convention, with the wrong sign as well. *Diagnosed error:* not having stated the convention before computing. *Source:* Briggs and Henson, ch. 2. *Prerequisite:* none. *Remediation:* Remark 22.1, then recompute the eight-point example in the three conventions and compare.

Item 2 — answer B. *Rationale:* if $N \mid j$ then $q = \omega_N^j = 1$, and $\frac{q^N - 1}{q - 1}$ is $\frac{0}{0}$: one sums directly, obtaining N . *Distractors:* A confuses the finite sum with a series; C would confuse “ratio 1” with “ratio 0”; D is meaningless. *Diagnosed error:* mechanical application of the geometric-sum formula without checking its hypothesis. *Source:* Lemma 22.1 and Theorem 6.5. *Prerequisite:* geometric progressions. *Remediation:* redo the case $N = 4$, $j = 4$ by hand.

Item 3 — answer C. *Rationale:* Proposition 22.4: a circular shift by n_0 multiplies bin k by $\omega_N^{kn_0}$. *Distractors:* A is the *dual* formula (modulation in time $\rightarrow$ shift in frequency); B and D confuse a shift with a scaling and with a sum. *Diagnosed error:* confusing the two dual statements. *Prerequisite:* periodicity of the indices (Proposition 22.1). *Remediation:* check on $N = 4$, $x = (1, 0, 0, 0)$, where $X \equiv 1$ and the shift indeed gives ω_4^{3k} .

Item 4 — answer B. *Rationale:* $|X_1| = \sqrt{1 + (1 + \sqrt{2})^2} = \sqrt{4 + 2\sqrt{2}} = 2.61313$ (Section 22.12.1, Step 2). *Distractors:* A is $|X_0|$; C is $|X_3|$; D is $1 + \sqrt{2}$, i.e. the *modulus of the imaginary part* of X_1 , not its modulus. *Diagnosed error:* confusing the imaginary part with the modulus. *Prerequisite:* modulus of a complex number. *Remediation:* redo the table of Section 22.12 column by column.

Item 5 — answer B. *Rationale:* the two sums have N^2 terms altogether; the exchange is the commutativity of addition on a finite set and requires no convergence hypothesis. *Distractors:* A invokes a theorem (Fubini–Tonelli for series) not needed here; C and D are true but irrelevant to the step in question (and C would be circular, since unitarity is proved using the same identity). *Diagnosed error:* the reflex “double sum $\Rightarrow$ absolute convergence”. *Remediation:* count the terms.

Item 6 — answer B. *Rationale:* Theorem 22.4 states that $\mathcal{F}_N$ applied twice gives $Nx[\langle -n \rangle_N]$: time reversal is the correct behavior, not a defect. *Distractors:* A would produce a Parseval failure, excluded by hypothesis; C would give an unrecognizably permuted spectrum; D would give non-finite values. *Diagnosed error:* mistaking a property for a bug. *Prerequisite:* Theorem 22.4. *Remediation:* run two consecutive FFTs on $(1, 2, 3, 4)$ and compare with $4 \cdot (1, 4, 3, 2)$.

Item 7 — answer C. *Rationale:* Corollary 22.9(iv) and Theorem 22.8: $y = \mathcal{F}_N^{-1}(\mathcal{F}_N b / \lambda)$, two transforms and N divisions. *Distractors:* A and B work but waste the structure; D is false (a circulant is invertible if and only if no $\lambda[k]$ vanishes). *Diagnosed error:* not recognizing the circulant structure. *Prerequisite:* Theorem 22.5. *Remediation:* Example 22.3 with $N = 4$.

Item 8 — answer A. *Rationale:* F. J. Harris’s 1978 article in *Proceedings of the IEEE* is the standard survey on windows. *Distractors:* B is the article on the FFT; C is a text on FFT computational structures; D concerns the eigenvalues of the DFT matrix (Remark 22.3). *Diagnosed error:* a generic “Oppenheim” citation for any signal-processing statement. *Remediation:* read the *Sources* section of this chapter and check each reference.

Answers to the assigned exercises.

Exercise 22.6, $x = (2, 0, -1, 3)$: (a) $X[0] = 2+0-1+3 = 4$; $X[1] = 2+0 \cdot (-i) - 1 \cdot (-1) + 3 \cdot (i) =$

$3 + 3i$; $X[2] = 2 - 0 - 1 - 3$, i.e. $2 - 0 + (-1)(1) + 3(-1) = -2$; $X[3] = \overline{X[1]} = 3 - 3i$. Hence $X = (4, 3 + 3i, -2, 3 - 3i)$. (b) $X[0] = 4$ and $X[2] = -2$ are real (Corollary 22.8(i)–(ii)), and $X[3] = \overline{X[1]}$ ✓. (c) $\sum_n |x[n]|^2 = 4 + 0 + 1 + 9 = 14$; $\frac{1}{4}(16 + 18 + 4 + 18) = \frac{56}{4} = 14$ ✓. (d) inversion gives $x[n] = \frac{1}{4}(4 + (-2)(-1)^n + 2\operatorname{Re}((3 + 3i)i^n))$: for $n = 0$, $\frac{1}{4}(4 - 2 + 6) = 2$; for $n = 1$, $(3 + 3i)i = -3 + 3i$, real part -3 , hence $\frac{1}{4}(4 + 2 - 6) = 0$; for $n = 2$, the real part changes sign, i.e. $\operatorname{Re}(-3 - 3i) = -3$, hence $\frac{1}{4}(4 - 2 - 6) = -1$; for $n = 3$, $(3 + 3i)(-i) = 3 - 3i$, real part 3 , hence $\frac{1}{4}(4 + 2 + 6) = 3$ ✓.

Exercise 22.7: (a) $a \circledast b$ with $N = 3$ equals $(1 \cdot 1 + 2 \cdot 0 + 3 \cdot (-1), 1 \cdot (-1) + 2 \cdot 1 + 3 \cdot 0, 1 \cdot 0 + 2 \cdot (-1) + 3 \cdot 1) = (-2, 1, 1)$. (b) the linear convolution is $(1, 1, 1, -3, 0)$, i.e. $c[0] = 1$, $c[1] = 2 - 1 = 1$, $c[2] = 3 - 2 = 1$, $c[3] = -3$, $c[4] = 0$. (c) the terms $c[3] = -3$ and $c[4] = 0$ wrapped onto the first two: $-2 = 1 + (-3)$ and $1 = 1 + 0$ ✓. (d) with $N' = 5$ the circular convolution coincides with the linear one; general rule: at least $L_a + L_b - 1$ points are needed.

Exercise 22.8: (a) $\Delta f = 25\,600/1024 = 25$ Hz; $1000/25 = 40$, an integer: the tone falls exactly on bin 40. (b) Hann: $\text{CG} = \frac{1}{2} = 0.50000$, $\text{ENBW} = \frac{3}{2} = 1.50000$; Hamming: $\text{CG} = \frac{27}{50} = 0.54000$, $\text{ENBW} = \frac{1987}{1458} = 1.36283$. (c) the amplitude is $A = \frac{2|X[k_0]|}{N \text{CG}} = \frac{2 \cdot 2048}{1024 \cdot 0.5} = 8$: the factor 2 accounts for the image bin $N - k_0$, the factor N for the convention without forward normalization, and CG for the window's attenuation. (d) Hann: at five bins' distance one is already outside the main lobe of both windows (which is 4 bins wide, Proposition 22.8), and there what matters is not the height of the highest side-lobe peak, but the *roll-off* of the side lobes. The two peaks tabulated in Remark 22.13 occur at different points of the spectrum and are not comparable with each other: Hann's (-31.47 dB) sits at ≈ 2.36 bins, Hamming's (-42.45 dB) exactly at ≈ 4.5 bins. At $5\Delta f$ what counts is that Hann rolls off at about -18 dB per octave against Hamming's -6 dB per octave (Remark 22.13); computing the maximum leakage for an offset in $[4.5, 5.5]$ bins with the same convention as that remark ($N = 64$, grid of 2^{16} points) gives -48.70 dB for Hann against -42.45 dB for Hamming. Both keep the leakage below the -40 dB of the sought component, but Hann gains more than 6 dB: it is the right choice. The worked exercise on leakage confirms this: at bin 4 — that is, 4.5 bins from the tone — Hann is at -46.89 dB.

22.18. Formulary of the chapter

Definition and inversion ($\omega_N = e^{-2\pi i/N}$)

$$X[k] = \sum_{n=0}^{N-1} x[n] \omega_N^{kn}, \quad x[n] = \frac{1}{N} \sum_{k=0}^{N-1} X[k] \omega_N^{-kn}$$

Orthogonality (the mother identity)

$$\sum_{n=0}^{N-1} \omega_N^{jn} = \begin{cases} N, & N \mid j \\ 0, & N \nmid j \end{cases} \quad \implies \quad \langle e_k, e_\ell \rangle = N \delta_{k\ell}$$

Matrix $W_N = (\omega_N^{kn})$, $F_N = N^{-1/2} W_N$

$$W_N^* W_N = N I, \quad F_N^* = F_N^{-1}, \quad F_N^2 = P, \quad F_N^4 = I, \quad |\det W_N| = N^{N/2}$$

Circular convolution and Parseval

$$(x \circledast y)[n] = \sum_{m=0}^{N-1} x[m] y[\langle n - m \rangle_N], \quad \mathcal{F}_N(x \circledast y) = X \cdot Y$$

$$\sum_{n=0}^{N-1} x[n] \overline{y[n]} = \frac{1}{N} \sum_{k=0}^{N-1} X[k] \overline{Y[k]}, \quad \sum_n |x[n]|^2 = \frac{1}{N} \sum_k |X[k]|^2$$

Shift, symmetry, circulants

$$x[\langle n - n_0 \rangle_N] \longleftrightarrow \omega_N^{kn_0} X[k], \quad x \text{ real} \iff X[\langle -k \rangle_N] = \overline{X[k]}$$

$$\text{circ}(c) = F_N^* \text{diag}(\mathcal{F}_N c) F_N, \quad \det \text{circ}(c) = \prod_{k=0}^{N-1} (\mathcal{F}_N c)[k]$$

DTFT, zero-padding, Dirichlet kernel

$$X[k] = \hat{X}\left(\frac{2\pi k}{N}\right), \quad X_M[k] = \hat{X}\left(\frac{2\pi k}{M}\right), \quad D_N(\Omega) = \frac{\sin(N\Omega/2)}{\sin(\Omega/2)} e^{-i(N-1)\Omega/2}$$

$$X_M[k] = \frac{1}{N} \sum_{j=0}^{N-1} X[j] D_N\left(2\pi\left(\frac{k}{M} - \frac{j}{N}\right)\right)$$

Windows $w[n] = a_0 - a_1 \cos(2\pi n/N)$

$$\text{CG} = a_0, \quad \text{ENBW} = 1 + \frac{a_1^2}{2a_0^2}, \quad \Delta f = \frac{f_s}{N}$$

	CG	ENBW	main lobe	side-lobe peak
rectangular	1	1	2 bin	−13.25 dB
Hann	1/2	3/2	4 bin	−31.47 dB
Hamming	27/50	1987/1458	4 bin	−42.45 dB

The fast Fourier transform

The distinction on which the whole chapter depends is one of those that are forgotten at once and then cost hours of confusion: **the DFT is a transform, the FFT is an algorithm**. The discrete Fourier transform is the linear map $x \mapsto X$ defined in Chapter 22 (Definition 22.1); the “fast Fourier transform” is not another transform, does not produce other numbers, has no other properties: it is a family of procedures for computing *exactly* those same N numbers with a number of operations proportional to $N \log_2 N$ instead of N^2 . Whoever says “I applied the FFT instead of the DFT” is saying, without noticing it, “I did the same multiplication in a different order”.

That change of order, however, is what made numerical frequency analysis practicable. For $N = 1,048,576 = 2^{20}$ samples — barely a minute of audio at 17.5 kHz — the direct computation asks for 1 099 511 627 776 complex multiplications, the radix-2 FFT asks for 10,485,760: a factor of 104,857.6 (Table 23.1). The reason is a single algebraic identity between roots of unity, $\omega_N^2 = \omega_{N/2}$, applied recursively.

The chapter walks the whole chain, in order, from the cost of the direct computation to the cost of the algorithm, and back: the operations of the defining sum are counted exactly (Proposition 23.1), the even and odd indices are separated (Theorem 23.1 and Theorem 23.2), the butterfly is isolated (Definition 23.3), the correctness of the recursive algorithm is proved by induction (Theorem 23.3), the cost recurrence is solved and the number of multiplications and additions that remain is counted *exactly* (Theorem 23.5, Corollary 23.4), the ordering of the inputs is proved to be the bit-reversal permutation (Theorem 23.7), the decimation-in-frequency variant is presented (Theorem 23.9), the inverse transform is obtained from the direct one by conjugation (Theorem 23.10), the example $N = 8$ is worked out in full, first in exact symbolic form and then in numerical form, with the check against the direct DFT, against Parseval’s identity, against Hermitian symmetry and against the reconstruction of all eight samples. A separate section treats the case of N not a power of two (mixed-radix, with the example $N = 6$ worked out in full; Bluestein and Rader), and the last section treats round-off error in finite-precision arithmetic, with a proved bound and an experimental check.

The results on the DFT — orthogonality of the exponential vectors (Theorem 22.1), the inversion formula (Theorem 22.2), the circular convolution theorem (Theorem 22.5), Parseval’s identity (Theorem 22.6), Hermitian symmetry (Theorem 22.7), zero-padding (Theorem 22.10 and Theorem 22.11) — are recalled and used, never reproved. Chapter 22 already contains, in Section 22.10, a first statement of the radix-2 decomposition (Theorem 22.13) and of the asymptotic complexity (Theorem 22.14), inherited from Volume II: that material is not summarized or replaced here, but resumed and completed, because there it lacks the *exact* count of operations, the inductive proof of correctness, the bit-reversal permutation, the DIF variant, the IFFT by conjugation, the mixed-radix case and the error analysis.

INFO

Level and prerequisites. Level **C** (undergraduate), with two passages of level **D** (the round-off error estimate of Section 23.13 and Rader’s algorithm of Section 23.12).

Internal prerequisites. N -th roots of unity and their arithmetic (Chapter 6); the discrete

Fourier transform, the DFT matrix, orthogonality, inversion, circular convolution, Parseval, Hermitian symmetry and zero-padding (Chapter 22, Definition 22.1, Definition 22.2, Definition 22.3, Theorem 22.1, Theorem 22.2, Theorem 22.5, Theorem 22.6, Theorem 22.7, Theorem 22.3, Theorem 22.10, Theorem 22.11); the Zeta transform and sampling on the roots of unity (Chapter 21 and Theorem 22.12).

External prerequisites, assumed and not reproved:

- complete induction and strong induction on the integers;
- elementary linear algebra: matrix products, permutation matrices, unitary matrices, the spectral norm $\|A\|_2$ and its submultiplicativity, singular values of a 2×2 matrix;
- modular arithmetic: Euclidean division, residue classes, the notation $\langle n \rangle_N$ for the remainder of n modulo N ;
- the binary representation of an integer and its uniqueness;
- the standard model of floating-point arithmetic (hypothesis (M) of Section 23.13, stated explicitly and attributed to its source);
- the existence of a primitive root modulo a prime p (used only once, in Rader's algorithm, and declared *imported* in Remark 23.11).

Everything else is proved here.

What is learned. Counting the operations of an algorithm before writing it; splitting an indexed sum according to the parity of the index and recognizing when this produces two subproblems of the same shape; proving by induction the correctness of a recursive algorithm; setting up and solving a cost recurrence; passing from a recursive formulation to an iterative in-place one and understanding where the bit-reversal permutation comes from; obtaining the inverse transform without writing a second algorithm; recognizing what zero-padding adds (interpolation) and what it does not add (resolution); factoring a DFT of composite length; estimating the round-off error of a structured algorithm and comparing it with the measurement.

Warning. Conventions and notation of the chapter.

- The convention of Chapter 22 is kept: the **twiddle factor** is

$$\omega_N = e^{-2\pi i/N},$$

and the DFT is $X[k] = \sum_{n=0}^{N-1} x[n] \omega_N^{kn}$ (Definition 22.1), with no normalization factor forward and with $1/N$ backward.

- **Warning about the letter W .** The classical literature — Cooley and Tukey (1965), Oppenheim and Schaffer, Van Loan — writes W_N for what here is ω_N , that is, for the scalar $e^{-2\pi i/N}$. In this treatise W_N is instead the **matrix** of the DFT (Definition 22.3), with entries $(W_N)_{kn} = \omega_N^{kn}$. Reading the sources requires the translation $W_N^{(\text{source})} = \omega_N$. In Chapter 22, Section 22.10, the same scalar appears under the name ζ_N : the three symbols ω_N , ζ_N and the sources' W_N denote the same complex number.
- N is always an integer ≥ 1 ; when we write $N = 2^m$ we mean $m \in \mathbb{N}$, $m \geq 0$. The notation $\log N$ without a base always means $\log_2 N$.
- $\langle n \rangle_N$ is the remainder of the Euclidean division of n by N , that is, the unique integer of $\{0, \dots, N-1\}$ congruent to n modulo N . By Proposition 22.1, writing $X[k]$ with k outside $\{0, \dots, N-1\}$ is always legitimate and means $X[\langle k \rangle_N]$.
- “Operation” always means *arithmetic operation on complex numbers*; the cost model is fixed in Definition 23.1. The cost in *real* operations is discussed in Remark 23.1.
- Numerical values are rounded to the seventh decimal digit and computed twice by independent routes: a closed form or an exact symbolic computation, and an actually executed Python script. The symbol $\checkmark$ signals that the comparison has been made and reports the discrepancy.

- In every flow-graph figure the convention is the standard one: a node sums the values arriving at it, a label on an edge indicates multiplication by that factor, an unlabeled edge indicates the factor 1, and a -1 on an edge is drawn out in full.

23.1. What the definition costs: the exact count

Before looking for a fast algorithm one must know *exactly* how much the slow one costs. “It costs $O(N^2)$ ” is not enough: the constant in front of N^2 decides whether an acquisition system meets its timing budget, and an honest comparison with the FFT is made on numbers, not on Landau symbols. This section fixes the cost model, collects the arithmetic of the twiddle factors, and counts.

Definition 23.1: Arithmetic cost model. The **cost** of a computational procedure is the number of arithmetic operations on complex numbers that it performs, counted as follows:

- a **complex multiplication** is a product zw with $z, w \in \mathbb{C}$;
- a **complex addition** is a sum $z + w$ or a difference $z - w$ with $z, w \in \mathbb{C}$ (difference and sum have the same cost).

Not counted: memory reads and writes, index increments, comparisons, and the computation of the twiddle factors ω_N^j , which are assumed available in a precomputed table. A multiplication is called **trivial** if one of the two factors belongs to $\{1, -1, i, -i\}$: it requires no real multiplication at all, only swaps between real and imaginary part and sign changes. It is called **nontrivial** otherwise.

***Remark 23.1: Why this model and not another.** The model of Definition 23.1 is the one used by the FFT literature (Van Loan, Chapter 1; Oppenheim and Schaffer, Chapter 9) and is the one that makes the comparison between algorithms independent of the hardware. It should be remembered, however, that a complex multiplication $(a + ib)(c + id)$ costs, in the schoolbook algorithm, 4 real multiplications and 2 real additions; with Karatsuba’s variant applied to complex numbers, which computes $ac - bd$ and $(a + b)(c + d) - ac - bd$, 3 and 5 suffice. A complex addition costs 2 real additions. A count in real operations is therefore obtained from ours by multiplying by constant factors that depend on the implementation, and it changes neither the order of magnitude nor the ratio between the two algorithms that matters here. Trivial multiplications are counted separately precisely because for them those constant factors collapse to zero: multiplying by $-i$ means swapping the two components and changing one sign.*

Lemma 23.1: Arithmetic of the twiddle factors. Let $N \geq 2$ and $\omega_N = e^{-2\pi i/N}$. The following hold:

- (i) $|\omega_N| = 1$ and $\omega_N^{-1} = \overline{\omega_N}$;
- (ii) $\omega_N^j = 1$ if and only if $N \mid j$; in particular ω_N is a primitive N -th root of unity, and ω_N^j depends only on $\langle j \rangle_N$;
- (iii) (**order reduction**) if N is even, $\omega_N^2 = \omega_{N/2}$, and more generally $\omega_N^{2j} = \omega_{N/2}^j$ for every $j \in \mathbb{Z}$;
- (iv) (**half turn**) if N is even, $\omega_N^{N/2} = -1$, and hence $\omega_N^{k+N/2} = -\omega_N^k$ for every $k \in \mathbb{Z}$;
- (v) if $4 \mid N$, then $\omega_N^{N/4} = -i$;
- (vi) for every integer $d \geq 1$, $\omega_{dN}^d = \omega_N^j$.

Proof. (i) $|\omega_N| = |e^{-2\pi i/N}| = 1$, because $|e^{i\theta}| = 1$ for every $\theta \in \mathbb{R}$; from $\omega_N \overline{\omega_N} = |\omega_N|^2 = 1$ it follows that $\omega_N^{-1} = \overline{\omega_N}$.

(ii) $\omega_N^j = e^{-2\pi i j/N}$ equals 1 if and only if $-2\pi j/N$ is an integer multiple of 2π , that is, if and only if $j/N \in \mathbb{Z}$, that is, $N \mid j$. If $j = qN + r$ with $0 \leq r < N$, then $\omega_N^j = (\omega_N^N)^q \omega_N^r = \omega_N^r$, since $\omega_N^N = 1$: the value depends only on the remainder. Finally, if $\omega_N^j = 1$ with $1 \leq j < N$ then $N \mid j$ would be false: hence no power with exponent between 1 and $N - 1$ equals 1, and ω_N is primitive.

(iii) $\omega_N^2 = e^{-4\pi i/N} = e^{-2\pi i/(N/2)} = \omega_{N/2}$; raising to the j -th power, $\omega_N^{2j} = (\omega_N^2)^j = \omega_{N/2}^j$.

(iv) $\omega_N^{N/2} = e^{-2\pi i(N/2)/N} = e^{-\pi i} = \cos(-\pi) + i \sin(-\pi) = -1$. Hence $\omega_N^{k+N/2} = \omega_N^k \omega_N^{N/2} = -\omega_N^k$.

(v) $\omega_N^{N/4} = e^{-2\pi i(N/4)/N} = e^{-\pi i/2} = \cos(-\pi/2) + i \sin(-\pi/2) = -i$.

(vi) $\omega_{dN}^{dj} = e^{-2\pi i dj/(dN)} = e^{-2\pi i j/N} = \omega_N^j$. □

Remark 23.2: The two identities that do all the work. Of the whole of Lemma 23.1, the radix-2 algorithm essentially uses two points: order reduction (iii), which turns a sum with factors ω_N restricted to even indices into a sum with factors $\omega_{N/2}$ — that is, into a shorter DFT —, and the half turn (iv), which allows two outputs to be obtained at the price of a single multiplication. All the rest of the chapter is bookkeeping around these two identities. It is worth noting that both are statements about the geometry of the unit circle: (iii) says that walking around the circle in double steps means walking around a circle with half the vertices, (iv) says that half a turn is the central symmetry.

Proposition 23.1: Exact cost of the direct computation of the DFT. Let $N \geq 1$ and $x \in \mathbb{C}^N$. Computing all N components

$$X[k] = \sum_{n=0}^{N-1} x[n] \omega_N^{kn}, \quad k = 0, \dots, N-1,$$

carried out by literally applying Definition 22.1, with the factors ω_N^{kn} read from a table, requires

$$M_{\text{dir}}(N) = N^2 \quad \text{complex multiplications,} \quad A_{\text{dir}}(N) = N(N-1) \quad \text{complex additions.}$$

If the multiplications whose twiddle factor equals 1 are avoided, the number of multiplications becomes

$$M_{\text{dir}}^*(N) = N^2 - T(N), \quad T(N) = \#\{(k, n) \in \{0, \dots, N-1\}^2 : N \mid kn\},$$

and $M_{\text{dir}}^*(N) \leq (N-1)^2$ holds, with equality if and only if $N = 1$ or N is prime. The number of additions remains $N(N-1)$ in every case.

Proof. Fix k . The sum $\sum_{n=0}^{N-1} x[n] \omega_N^{kn}$ has N terms, and each term is the product $x[n] \cdot \omega_N^{kn}$ of two complex numbers: these are N complex multiplications. Summing N numbers requires $N-1$ additions: one adds the first two (one addition), then adds the third (two additions), and so on up to the N -th; that $N-1$ additions are also *necessary* follows from the fact that every binary addition reduces by one the number of quantities still to be combined, and one starts from N to reach 1. Hence each component costs N multiplications and $N-1$ additions. Since there are N components and in the direct computation they are obtained independently of one another,

$$M_{\text{dir}}(N) = N \cdot N = N^2, \quad A_{\text{dir}}(N) = N \cdot (N-1) = N(N-1).$$

For the second part, we count the pairs (k, n) with $\omega_N^{kn} = 1$. By Lemma 23.1(ii) this happens exactly when $N \mid kn$: these are the $T(N)$ pairs of the statement, and $M_{\text{dir}}^*(N) = N^2 - T(N)$ by definition.

Among the pairs counted by $T(N)$ there are in every case those with $k = 0$ (there are N of them, as n varies) and those with $n = 0$ (there are N), which overlap only in the pair $(0, 0)$: hence there are $2N - 1$ distinct pairs, and $T(N) \geq 2N - 1$, whence

$$M_{\text{dir}}^*(N) = N^2 - T(N) \leq N^2 - (2N - 1) = (N - 1)^2.$$

Equality holds if and only if $T(N) = 2N - 1$, that is, if and only if there is no pair (k, n) with $1 \leq k, n \leq N - 1$ and $N \mid kn$. If $N = 1$ the set $\{1, \dots, N - 1\}$ is empty and there is nothing to exclude: equality. If $N = p$ is prime and $1 \leq k, n \leq p - 1$, then $p \nmid k$ and $p \nmid n$; if $p \mid kn$ held, primality of p would give $p \mid k$ or $p \mid n$, a contradiction: equality. If instead N is composite, write $N = ab$ with $1 < a < N$ and $1 < b < N$: the pair $(k, n) = (a, b)$ satisfies $1 \leq a, b \leq N - 1$ and $N \mid ab$, hence $T(N) \geq 2N$ and the inequality is strict. The three cases exhaust all $N \geq 1$. The additions do not change, because each component remains the sum of N terms, some of which are now obtained without multiplying. $\square$

Example 23.1: The exact count for $N = 8$. For $N = 8$ Proposition 23.1 gives $M_{\text{dir}}(8) = 64$ and $A_{\text{dir}}(8) = 8 \cdot 7 = 56$. For the exact count of the nontrivial multiplications by 1 we need $T(8)$. To the $2 \cdot 8 - 1 = 15$ pairs with $k = 0$ or $n = 0$ we add the pairs (k, n) with $1 \leq k, n \leq 7$ and $8 \mid kn$: since $8 = 2^3$, k and n must together contribute three factors of 2; with $k, n \leq 7$ the only possibilities are $k = 2$ (which carries one factor of 2) with $n = 4$, $k = 6$ (also a single factor of 2) with $n = 4$, and $k = 4$ (two factors of 2) with $n \in \{2, 4, 6\}$: these are the five pairs

$$(2, 4), \quad (4, 2), \quad (4, 4), \quad (4, 6), \quad (6, 4).$$

Hence $T(8) = 15 + 5 = 20$ and $M_{\text{dir}}^*(8) = 64 - 20 = 44$, against the bound $(8 - 1)^2 = 49$ of the proposition, consistently with the fact that 8 is not prime.

Independent check. A Python script that enumerates the 64 pairs and counts those with `(k*n) % 8 == 0` returns 20, and $64 - 20 = 44$. $\checkmark$

Remark 23.3: *The radix-2 hypothesis is not in the definition.* From here to Section 23.12 we shall work under the hypothesis

$$N = 2^m, \quad m \in \mathbb{N},$$

called the **radix-2 hypothesis**. It is a hypothesis on the algorithm, not on the transform: Definition 22.1 makes sense for every $N \geq 1$, Theorem 22.1 and Theorem 22.2 hold for every $N \geq 1$, and the matrix W_N is invertible for every $N \geq 1$ (Corollary 22.3). That N be a power of two serves only to allow repeated halving of the length while remaining on integers: it is the constraint that closes the recursion of Section 23.4. Section 23.12 shows how to proceed when N is composite but not a power of two, and what to do when N is prime. The worst case — N a large prime — is never a practical obstacle: one uses Rader's algorithm (Theorem 23.12) or Bluestein's (Proposition 23.7), or else the signal is padded with zeros up to a power of two, knowing exactly what this entails (Section 23.11).

23.2. The even–odd decomposition

This is the central section of the chapter: everything that follows is a consequence of the two identities proved here. The idea is disarmingly simple — to split the terms of the defining sum according to the parity of the index n — and its strength lies entirely in Lemma 23.1(iii): on the even indices the twiddle factor of order N turns into the twiddle factor of order $N/2$, that is, the two halves are again DFTs.

Throughout the section $N \geq 2$ is *even* and we set $L = N/2$.

Definition 23.2: Even subsequence and odd subsequence. Let $N = 2L$ and $x \in \mathbb{C}^N$. The **even subsequence** and **odd subsequence** of x are the two vectors $e, o \in \mathbb{C}^L$ defined by

$$e[r] = x[2r], \quad o[r] = x[2r + 1], \quad r = 0, 1, \dots, L - 1.$$

Their L -point DFTs are denoted $E, O \in \mathbb{C}^L$:

$$E[k] = \sum_{r=0}^{L-1} e[r] \omega_L^{kr}, \quad O[k] = \sum_{r=0}^{L-1} o[r] \omega_L^{kr}, \quad k \in \mathbb{Z},$$

where, by Proposition 22.1, the notation is extended to every $k \in \mathbb{Z}$, and E, O turn out to be periodic with period L .

Lemma 23.2: The even indices and the odd indices, spelled out. Let $N = 2L$ with $L \geq 1$. The two maps

$$\begin{aligned} \pi : \{0, 1, \dots, L - 1\} &\rightarrow \{0, 1, \dots, N - 1\}, & \pi(r) &= 2r, \\ \delta : \{0, 1, \dots, L - 1\} &\rightarrow \{0, 1, \dots, N - 1\}, & \delta(r) &= 2r + 1, \end{aligned}$$

are injective, have disjoint images, and the union of the two images is all of $\{0, 1, \dots, N - 1\}$. In other words $\{0, \dots, N - 1\}$ is the disjoint union of the set of its even elements, which are exactly the $2r$ with $0 \leq r \leq L - 1$, and the set of its odd elements, which are exactly the $2r + 1$ with $0 \leq r \leq L - 1$.

Proof. Well-posedness. If $0 \leq r \leq L - 1$ then $0 \leq 2r \leq 2L - 2 = N - 2 \leq N - 1$ and $1 \leq 2r + 1 \leq 2L - 1 = N - 1$: both maps do take values in $\{0, \dots, N - 1\}$.

Injectivity. If $2r = 2r'$ then $r = r'$; if $2r + 1 = 2r' + 1$ then $2r = 2r'$ and hence $r = r'$.

Disjoint images. An element of the image of π is even, one of the image of δ is odd, and no integer is both even and odd: if $2r = 2r' + 1$ held, the left side would be divisible by 2 and the right side would not.

Joint surjectivity. Let $n \in \{0, \dots, N - 1\}$. By Euclidean division of n by 2 there exist unique $q \in \mathbb{Z}$ and $s \in \{0, 1\}$ with $n = 2q + s$. From $0 \leq n \leq N - 1$ it follows that $0 \leq 2q \leq n \leq N - 1 = 2L - 1$, hence $0 \leq q \leq L - 1$ (because $2q \leq 2L - 1$ with q an integer forces $q \leq L - 1$; and $2q = n - s \geq -1$ with q an integer forces $q \geq 0$). If $s = 0$ then $n = \pi(q)$, if $s = 1$ then $n = \delta(q)$.

Since the two images are disjoint and their union is a set of N elements obtained as the union of two sets of L elements each, with $2L = N$, the count of cardinalities checks out and there are no repetitions. $\square$

Theorem 23.1: Even-odd decomposition, first half of the spectrum. Let $N = 2L$, $x \in \mathbb{C}^N$, $X = \text{DFT}_N\{x\}$, and let E, O be as in Definition 23.2. Then for every $k \in \mathbb{Z}$ (and

in particular for every $k = 0, 1, \dots, L-1$)

$$X[k] = E[k] + \omega_N^k O[k]$$

Proof. We start from the definition, with no abbreviations:

$$X[k] = \sum_{n=0}^{N-1} x[n] \omega_N^{kn}.$$

Step 1 (splitting the sum). By Lemma 23.2 the index set $\{0, \dots, N-1\}$ is the disjoint union of $\{2r : 0 \leq r \leq L-1\}$ and $\{2r+1 : 0 \leq r \leq L-1\}$. Since a finite sum does not depend on the order of its terms and can be split over a partition of the index set,

$$X[k] = \sum_{\substack{n=0 \\ n \text{ even}}}^{N-1} x[n] \omega_N^{kn} + \sum_{\substack{n=0 \\ n \text{ odd}}}^{N-1} x[n] \omega_N^{kn} = \sum_{r=0}^{L-1} x[2r] \omega_N^{k \cdot 2r} + \sum_{r=0}^{L-1} x[2r+1] \omega_N^{k(2r+1)}.$$

Note that the limits of both sums are $r = 0, \dots, L-1 = N/2 - 1$: this is the content of the lemma, not a convenient choice.

Step 2 (the sum over the even indices is an L -point DFT). By Lemma 23.1(iii), $\omega_N^{2kr} = \omega_{N/2}^{kr} = \omega_L^{kr}$. Hence, using $x[2r] = e[r]$,

$$\sum_{r=0}^{L-1} x[2r] \omega_N^{2kr} = \sum_{r=0}^{L-1} e[r] \omega_L^{kr} = E[k],$$

which is exactly Definition 23.2.

Step 3 (the sum over the odd indices is an L -point DFT, up to a factor). Write the exponent in full: $k(2r+1) = 2kr + k$, hence $\omega_N^{k(2r+1)} = \omega_N^{2kr} \omega_N^k = \omega_L^{kr} \omega_N^k$, again by Lemma 23.1(iii). The factor ω_N^k does not depend on r and can be pulled out of the sum:

$$\sum_{r=0}^{L-1} x[2r+1] \omega_N^{k(2r+1)} = \omega_N^k \sum_{r=0}^{L-1} o[r] \omega_L^{kr} = \omega_N^k O[k].$$

Step 4 (summing the two contributions). Substituting Steps 2 and 3 into Step 1,

$$X[k] = E[k] + \omega_N^k O[k],$$

for every $k \in \mathbb{Z}$: no step used any restriction on k , because E, O and X were defined for every integer (Proposition 22.1). $\square$

Theorem 23.2: Even–odd decomposition, second half of the spectrum. Under the hypotheses and with the notation of Theorem 23.1, for every $k = 0, 1, \dots, L-1$

$$X\left[k + \frac{N}{2}\right] = E[k] - \omega_N^k O[k]$$

Proof. We do not deduce the formula “by analogy” from Theorem 23.1: we recompute it from the definition, as required by the fact that the index $k + N/2$ is no longer between 0 and $L-1$.

Step 1. Theorem 23.1 was proved for every $k \in \mathbb{Z}$; applying it to the integer $k + N/2$ (that is, $k + L$) gives

$$X\left[k + \frac{N}{2}\right] = E\left[k + \frac{N}{2}\right] + \omega_N^{k+N/2} O\left[k + \frac{N}{2}\right].$$

This is legitimate because Step 4 of that proof used no restriction on the index.

Step 2 (periodicity of E and O). E and O are $L = N/2$ -point DFTs; by Proposition 22.1 they are periodic with period L , that is,

$$E\left[k + \frac{N}{2}\right] = E[k + L] = E[k], \quad O\left[k + \frac{N}{2}\right] = O[k + L] = O[k].$$

Let us nonetheless check this in full, so as not to lean on a citation: by Lemma 23.1(ii) applied to ω_L one has $\omega_L^L = 1$, hence

$$E[k + L] = \sum_{r=0}^{L-1} e[r] \omega_L^{(k+L)r} = \sum_{r=0}^{L-1} e[r] \omega_L^{kr} (\omega_L^L)^r = \sum_{r=0}^{L-1} e[r] \omega_L^{kr} = E[k],$$

and identically for O .

Step 3 (half-turn). By Lemma 23.1(iv), $\omega_N^{N/2} = -1$, hence

$$\omega_N^{k+N/2} = \omega_N^k \omega_N^{N/2} = -\omega_N^k.$$

Step 4. Substituting Steps 2 and 3 into Step 1:

$$X\left[k + \frac{N}{2}\right] = E[k] + (-\omega_N^k)O[k] = E[k] - \omega_N^k O[k].$$

□

Corollary 23.1: The two paired formulas. Let $N = 2L$ and $k \in \{0, 1, \dots, L-1\}$. Setting $t_k = \omega_N^k O[k]$, one has

$$X[k] = E[k] + t_k, \quad X[k + L] = E[k] - t_k.$$

As k ranges over $\{0, \dots, L-1\}$, these $2L = N$ equalities determine all the components of X , and each pair $(X[k], X[k + L])$ depends only on the pair $(E[k], O[k])$ and on the factor ω_N^k .

Proof. The two equalities are Theorems 23.1 and 23.2 with the substitution $t_k = \omega_N^k O[k]$. That they determine all the components follows from the fact that the map $\{0, \dots, L-1\} \times \{0, 1\} \rightarrow \{0, \dots, N-1\}$, $(k, s) \mapsto k + sL$, is a bijection: it is injective because $k + sL = k' + s'L$ with $0 \leq k, k' \leq L-1$ gives $(s - s')L = k' - k$ with $|k' - k| \leq L-1 < L$, hence $s = s'$ and $k = k'$; and it is surjective because the domain and codomain both have $2L = N$ elements. The last statement is read directly from the two formulas: only $E[k]$, $O[k]$ and ω_N^k appear in them. □

Remark 23.4: Why the second formula must be recomputed, not “seen”. It is common, in popular texts and lecture notes, to present $X[k + N/2] = E[k] - \omega_N^k O[k]$ as “the same formula with the sign changed”, as though the minus sign were a graphical convention of the butterfly diagram. It is not: the minus sign is the value of $\omega_N^{N/2}$, an arithmetic fact about roots of unity (Lemma 23.1(iv)), and the formula additionally requires the periodicity of E and O with period $N/2$, which is a fact about the shorter DFTs, not about X . Whoever skips these two steps is unable to write the corresponding formula for radix-3 or for mixed-radix, where the analogous factor is not -1 but ω_3^j (Section 23.12), and systematically gets the signs wrong when the exponent convention is $+2\pi i/N$ instead of $-2\pi i/N$.

23.3. The butterfly

Corollary 23.1 isolates the single elementary computational block of the algorithm. It is given a name, its matrix is studied — which is the same for every N and every k , up to the factor ω_N^k — and its cost is counted. This is step 11 of the mandatory path.

Definition 23.3: Butterfly. Given two complex numbers a, b and a factor $w \in \mathbb{C}$, the **butterfly** with inputs (a, b) and factor w is the pair

$$\mathcal{B}_w(a, b) = (a + wb, a - wb) \in \mathbb{C}^2.$$

The matrix of the butterfly is

$$B_w = \begin{pmatrix} 1 & w \\ 1 & -w \end{pmatrix}, \quad \text{so that} \quad \mathcal{B}_w(a, b)^\top = B_w \begin{pmatrix} a \\ b \end{pmatrix}.$$

In the language of the radix-2 decomposition, a butterfly of index k and order N is $\mathcal{B}_{\omega_N^k}(E[k], O[k]) = (X[k], X[k + N/2])$.

Figure 23.1: The butterfly of Definition 23.3. The twiddle factor ω_N^k multiplies only the lower branch; the product $wb = t$ is computed once and used twice, with opposite sign — the label -1 sits on the edge that carries t to the lower sum node, while the three unlabeled edges have weight 1. The cost is one multiplication and two complex additions (Proposition 23.2).

Proposition 23.2: Cost and correctness of the butterfly. Computing $\mathcal{B}_w(a, b)$ with the scheme

$$t \leftarrow w \cdot b, \quad u_1 \leftarrow a + t, \quad u_2 \leftarrow a - t$$

returns exactly $(a + wb, a - wb)$ and costs one complex multiplication and two complex additions. No scheme that computes both outputs can use fewer than two additions.

Proof. Correctness. After the first instruction $t = wb$; after the second $u_1 = a + t = a + wb$; after the third $u_2 = a - t = a - wb$. These are by definition the two components of $\mathcal{B}_w(a, b)$.
Cost. The scheme performs a single complex product $(w \cdot b)$ and two complex sums $(a + t$ and $a - t)$, according to Definition 23.1. The point is that the product wb appears in both outputs and is computed only once: it is this sharing, and not the identity $\omega_N^{k+N/2} = -\omega_N^k$ taken alone, that produces the saving.

Minimality of the additions. If $w \neq 0$ and $b \neq 0$, the two outputs $a + wb$ and $a - wb$ are distinct (their difference is $2wb \neq 0$); each genuinely depends on both inputs, because $\partial(a \pm wb)/\partial a = 1 \neq 0$ and $\partial(a \pm wb)/\partial b = \pm w \neq 0$. Hence neither can be obtained without at least one addition combining a quantity depending on a with one depending on b , and the two additions cannot coincide because the results are distinct: at least two are needed. $\square$

Proposition 23.3: The matrix of the butterfly: invertibility and singular values.

Let $w \in \mathbb{C}$ with $|w| = 1$ and let $B_w = \begin{pmatrix} 1 & w \\ 1 & -w \end{pmatrix}$. Then:

- (i) $\det B_w = -2w \neq 0$, and $B_w^{-1} = \frac{1}{2} \begin{pmatrix} 1 & 1 \\ \bar{w} & -\bar{w} \end{pmatrix}$;
- (ii) $B_w^* B_w = 2I_2$, that is, $\frac{1}{\sqrt{2}} B_w$ is unitary;
- (iii) both singular values of B_w equal $\sqrt{2}$; in particular $\|B_w\|_2 = \sqrt{2}$ and $\|B_w^{-1}\|_2 = 1/\sqrt{2}$;
- (iv) $\|B_w v\|_2 = \sqrt{2} \|v\|_2$ for every $v \in \mathbb{C}^2$.

Proof. (i) $\det B_w = 1 \cdot (-w) - w \cdot 1 = -2w$, which is nonzero because $|w| = 1$. The matrix proposed as the inverse satisfies

$$\frac{1}{2} \begin{pmatrix} 1 & 1 \\ \bar{w} & -\bar{w} \end{pmatrix} \begin{pmatrix} 1 & w \\ 1 & -w \end{pmatrix} = \frac{1}{2} \begin{pmatrix} 1+1 & w-w \\ \bar{w}-\bar{w} & \bar{w}w + \bar{w}w \end{pmatrix} = \frac{1}{2} \begin{pmatrix} 2 & 0 \\ 0 & 2|w|^2 \end{pmatrix} = I_2,$$

having used $\bar{w}w = |w|^2 = 1$.

(ii) One has $B_w^* = \begin{pmatrix} 1 & 1 \\ \bar{w} & -\bar{w} \end{pmatrix}$, hence

$$B_w^* B_w = \begin{pmatrix} 1 & 1 \\ \bar{w} & -\bar{w} \end{pmatrix} \begin{pmatrix} 1 & w \\ 1 & -w \end{pmatrix} = \begin{pmatrix} 2 & w-w \\ \bar{w}-\bar{w} & 2|w|^2 \end{pmatrix} = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix} = 2I_2.$$

(iii) The singular values of B_w are the square roots of the eigenvalues of $B_w^* B_w = 2I_2$, which both equal 2: hence both singular values equal $\sqrt{2}$. The spectral norm is the largest singular value, that is, $\sqrt{2}$; the spectral norm of the inverse is the reciprocal of the smallest singular value, that is, $1/\sqrt{2}$.

(iv) For every $v \in \mathbb{C}^2$, $\|B_w v\|_2^2 = v^* B_w^* B_w v = 2v^* v = 2\|v\|_2^2$, whence the claim follows by taking the square root. $\square$

Remark 23.5: The butterfly is a dilated rotation. Proposition 23.3(ii) says that, up to the factor $\sqrt{2}$, the butterfly is a unitary transformation of $\mathbb{C}^2$: it preserves angles and multiplies all lengths by $\sqrt{2}$. This is the deep reason why the algorithm is numerically stable: no stage can selectively amplify one component relative to another, and hence no round-off error can be inflated differentially (Section 23.13, Theorem 23.13). The factor $\sqrt{2}$ per stage, repeated $m = \log_2 N$ times, gives $2^{m/2} = \sqrt{N}$, which is exactly the norm of the DFT matrix (Theorem 22.3): the bookkeeping of norms checks out, as it must.

23.4. The radix-2 algorithm with decimation in time

The two formulas of Corollary 23.1 reduce a DFT of length N to two DFTs of length $N/2$ plus $N/2$ butterflies. If $N = 2^m$, the two DFTs of length $N/2 = 2^{m-1}$ can be reduced in the same way, and so on down to DFTs of length 1, which require no computation at all. This is step 12 of the path: the *recursive* application of the same factorization. The traditional name is **decimation in time** (DIT for short), because what is split in two is the sequence of samples, that is, the “time” index n .

Definition 23.4: The radix-2 FFT algorithm with decimation in time. Let $N = 2^m$ with $m \geq 0$. Define the map $\mathcal{A}_N : \mathbb{C}^N \rightarrow \mathbb{C}^N$ by recursion on m :

- **base case** $m = 0$, that is, $N = 1$: $\mathcal{A}_1(x) = x$, that is, the single component of the output is $\mathcal{A}_1(x)[0] = x[0]$;
- **recursive step** $m \geq 1$, that is, $N = 2L$ with $L = 2^{m-1}$: given $e, o \in \mathbb{C}^L$ as in

Definition 23.2 ($e[r] = x[2r]$, $o[r] = x[2r + 1]$), set

$$\tilde{E} = \mathcal{A}_L(e), \quad \tilde{O} = \mathcal{A}_L(o),$$

and, for $k = 0, 1, \dots, L - 1$,

$$t_k = \omega_N^k \tilde{O}[k], \quad \mathcal{A}_N(x)[k] = \tilde{E}[k] + t_k, \quad \mathcal{A}_N(x)[k + L] = \tilde{E}[k] - t_k.$$

The definition is well posed: the recursive step for $N = 2^m$ invokes $\mathcal{A}$ only on vectors of length 2^{m-1} , and the recursion terminates in m levels.

Lemma 23.3: The two smallest cases, spelled out.

- (i) For $N = 1$ the DFT is the identity: $X[0] = x[0]$. Hence $\mathcal{A}_1 = \text{DFT}_1$, and the base case of Definition 23.4 is correct.
- (ii) For $N = 2$ one has $X[0] = x[0] + x[1]$ and $X[1] = x[0] - x[1]$; Definition 23.4 produces exactly these two values, with zero multiplications and two additions.

Proof. (i) For $N = 1$ Definition 22.1 gives $X[0] = \sum_{n=0}^0 x[n] \omega_1^{0 \cdot n} = x[0] \omega_1^0 = x[0]$, since $\omega_1 = e^{-2\pi i/1} = e^{-2\pi i} = 1$ and every one of its powers equals 1.

(ii) For $N = 2$ one has $\omega_2 = e^{-\pi i} = -1$, hence

$$X[0] = x[0] \omega_2^0 + x[1] \omega_2^0 = x[0] + x[1], \quad X[1] = x[0] \omega_2^0 + x[1] \omega_2^1 = x[0] - x[1].$$

Let us see what the algorithm produces. Here $L = 1$, $e = (x[0])$, $o = (x[1])$; by the base case $\tilde{E} = (x[0])$ and $\tilde{O} = (x[1])$. The only value of k is $k = 0$, and $t_0 = \omega_2^0 \tilde{O}[0] = 1 \cdot x[1] = x[1]$; hence

$$\mathcal{A}_2(x)[0] = x[0] + x[1], \quad \mathcal{A}_2(x)[1] = x[0] - x[1],$$

which coincide with $X[0]$ and $X[1]$. The factor is $\omega_2^0 = 1$: the multiplication is trivial in the sense of Definition 23.1 and is not carried out; the two additions remain. $\square$

Theorem 23.3: Correctness of the radix-2 DIT algorithm. For every $m \in \mathbb{N}$ and every $x \in \mathbb{C}^N$ with $N = 2^m$,

$$\mathcal{A}_N(x) = \text{DFT}_N\{x\},$$

that is, $\mathcal{A}_N(x)[k] = \sum_{n=0}^{N-1} x[n] \omega_N^{kn}$ for every $k = 0, \dots, N - 1$. In particular the algorithm of Definition 23.4 computes the DFT exactly, with no approximation.

Proof. By induction on m .

Base ($m = 0$, $N = 1$). This is Lemma 23.3(i): $\mathcal{A}_1(x)[0] = x[0] = X[0]$.

Inductive step. Let $m \geq 1$ and suppose (*inductive hypothesis*) that for every vector $v \in \mathbb{C}^L$ with $L = 2^{m-1}$, $\mathcal{A}_L(v) = \text{DFT}_L\{v\}$. Let $x \in \mathbb{C}^N$ with $N = 2^m = 2L$, and let $e, o \in \mathbb{C}^L$ be its even and odd subsequences.

Step 1. By the inductive hypothesis applied to $v = e$ and to $v = o$,

$$\tilde{E} = \mathcal{A}_L(e) = \text{DFT}_L\{e\} = E, \quad \tilde{O} = \mathcal{A}_L(o) = \text{DFT}_L\{o\} = O,$$

where E and O are the L -point DFTs of Definition 23.2. The quantities computed by the algorithm therefore coincide with those appearing in Theorems 23.1 and 23.2.

Step 2. Let $k \in \{0, \dots, L - 1\}$. The algorithm sets $t_k = \omega_N^k \tilde{O}[k] = \omega_N^k O[k]$ and returns

$$\mathcal{A}_N(x)[k] = \tilde{E}[k] + t_k = E[k] + \omega_N^k O[k], \quad \mathcal{A}_N(x)[k + L] = \tilde{E}[k] - t_k = E[k] - \omega_N^k O[k].$$

Step 3. By Theorem 23.1, $E[k] + \omega_N^k O[k] = X[k]$; by Theorem 23.2, $E[k] - \omega_N^k O[k] = X[k + N/2] = X[k + L]$. Hence

$$\mathcal{A}_N(x)[k] = X[k], \quad \mathcal{A}_N(x)[k + L] = X[k + L], \quad k = 0, \dots, L - 1.$$

Step 4. By Corollary 23.1 the map $(k, s) \mapsto k + sL$ is a bijection of $\{0, \dots, L - 1\} \times \{0, 1\}$ onto $\{0, \dots, N - 1\}$: hence Step 3 covers *all* output indices, each exactly once, and $\mathcal{A}_N(x) = X$.

By the principle of induction the claim holds for every $m \in \mathbb{N}$. $\square$

Corollary 23.2: Every output contains all the terms of the sum, with the correct factor. Let $N = 2^m$. For every k , the output $\mathcal{A}_N(x)[k]$, expanded recursively down to the leaves of the recursion, is a linear combination $\sum_{n=0}^{N-1} c_{k,n} x[n]$ in which all and only the N samples $x[0], \dots, x[N-1]$ appear, each exactly once, and the coefficient is exactly $c_{k,n} = \omega_N^{kn}$.

Proof. By Theorem 23.3, $\mathcal{A}_N(x)[k] = X[k]$ for every $x \in \mathbb{C}^N$: the two linear maps $x \mapsto \mathcal{A}_N(x)[k]$ and $x \mapsto X[k]$ coincide on all of $\mathbb{C}^N$.

That $x \mapsto \mathcal{A}_N(x)[k]$ is linear is seen by induction on m : for $m = 0$ it is the identity; in the recursive step, e and o depend linearly on x , by the inductive hypothesis $\tilde{E}$ and $\tilde{O}$ depend linearly on e and o , and the formulas $\tilde{E}[k] \pm \omega_N^k \tilde{O}[k]$ are linear in $(\tilde{E}, \tilde{O})$; the composition of linear maps is linear.

Two equal linear maps have the same coefficients with respect to the canonical basis: evaluating both on $x = \varepsilon_n$ (the vector with 1 in position n and 0 elsewhere) gives $c_{k,n} = X[k]|_{x=\varepsilon_n} = \omega_N^{kn}$. Since $|\omega_N^{kn}| = 1 \neq 0$, no coefficient vanishes: every sample genuinely appears, and it appears exactly once because the coefficient of $x[n]$ in a linear combination is unique. $\square$

Remark 23.6: The recursion tree. Definition 23.4 generates a binary tree of calls (Figure 23.2). At the root sits the problem of length $N = 2^m$; every node of length 2^j with $j \geq 1$ has two children of length 2^{j-1} ; the leaves are the problems of length 1. Level ℓ (with $\ell = 0$ at the root) contains 2^ℓ nodes, each of length $2^{m-\ell}$; the sum of the lengths on a level is $2^\ell \cdot 2^{m-\ell} = 2^m = N$, the same on every level: it is this fact that, in Section 23.5, will produce a cost of $\Theta(N)$ per level and hence $\Theta(N \log_2 N)$ overall. There are $m + 1 = \log_2 N + 1$ levels, of which m contain butterflies (the last one, that of the leaves, contains none).

Figure 23.2: Recursion tree for $N = 8$. Level ℓ contains 2^ℓ nodes of length $2^{3-\ell}$, hence at every level the sum of the lengths equals 8, and there are $\log_2 8 + 1 = 4$ levels. The leaves, read from left to right, give the order $x[0], x[4], x[2], x[6], x[1], x[5], x[3], x[7]$: this is the bit-reversal permutation of Section 23.6 (Theorem 23.7).

23.5. The cost: recurrence, solution, exact count

These are steps 15 to 18 of the mandatory path. We first count the butterflies of a single level, then we set up the recurrence, then we solve it in two ways (an exact closed form and the solution of the general recurrence $T(N) = 2T(N/2) + cN$), and finally we refine the count by removing the trivial multiplications. The result is a number, not an order of magnitude.

Proposition 23.4: The butterflies of one level. Let $N = 2^m$ and consider the recursion tree of Remark 23.6. For every $\ell \in \{0, 1, \dots, m-1\}$, level ℓ contains 2^ℓ nodes, each of length $n_\ell = 2^{m-\ell} \geq 2$, and each node performs $n_\ell/2$ butterflies. The total number of butterflies of level ℓ is therefore

$$2^\ell \cdot \frac{n_\ell}{2} = 2^\ell \cdot 2^{m-\ell-1} = 2^{m-1} = \frac{N}{2},$$

the same for every level. The overall number of butterflies executed by the algorithm is $\frac{N}{2} m = \frac{N}{2} \log_2 N$.

Proof. Number and length of the nodes. By induction on ℓ : level 0 contains only the initial problem, that is, $2^0 = 1$ node of length $2^{m-0} = N$. If level $\ell < m$ contains 2^ℓ nodes of length $2^{m-\ell} \geq 2$, each of them, by Definition 23.4, generates exactly two recursive calls on vectors of length $2^{m-\ell}/2 = 2^{m-\ell-1}$: level $\ell + 1$ contains $2 \cdot 2^\ell = 2^{\ell+1}$ nodes of length $2^{m-(\ell+1)}$.

Butterflies per node. A node of length $n \geq 2$ performs, again by Definition 23.4, a loop over $k = 0, 1, \dots, n/2 - 1$: these are $n/2$ butterflies. The nodes of level m have length 1 and perform no butterflies (base case).

Count. $2^\ell \cdot 2^{m-\ell}/2 = 2^{m-1} = N/2$ for every $\ell \in \{0, \dots, m-1\}$; summing over the m levels that contain butterflies gives $m \cdot N/2$. $\square$

Theorem 23.4: The cost recurrence. Let $M(N)$ and $A(N)$ be the number of complex multiplications and complex additions performed by the algorithm $\mathcal{A}_N$ of Definition 23.4 on an input of length $N = 2^m$, counted according to Definition 23.1 and without removing the trivial multiplications. Then

$$M(1) = 0, \quad M(N) = 2M\left(\frac{N}{2}\right) + \frac{N}{2} \quad (N \geq 2),$$

$$A(1) = 0, \quad A(N) = 2A\left(\frac{N}{2}\right) + N \quad (N \geq 2).$$

In particular, setting $T(N) = M(N) + A(N)$, one has $T(1) = 0$ and $T(N) = 2T(N/2) + \frac{3}{2}N$: this is the recurrence $T(N) = 2T(N/2) + cN$ with $c = \frac{3}{2}$.

Proof. The case $N = 1$ is immediate: the base case of Definition 23.4 returns the input without performing any operations, hence $M(1) = A(1) = 0$.

Let $N = 2L \geq 2$. The recursive step performs, in order:

1. forming e and o : these are reads and writes, which the cost model does not count;
2. two recursive calls on vectors of length $L = N/2$: cost $2M(N/2)$ multiplications and $2A(N/2)$ additions;
3. the loop over $k = 0, \dots, L - 1$, which performs $L = N/2$ butterflies; by Proposition 23.2 each butterfly costs one multiplication and two additions, hence the loop costs $N/2$ multiplications and $2 \cdot (N/2) = N$ additions.

Summing the contributions gives the two recurrences. Adding them together: $T(N) = 2(M(N/2) + A(N/2)) + \frac{N}{2} + N = 2T(N/2) + \frac{3}{2}N$. $\square$

Theorem 23.5: Exact solution: the operation count. For every $m \in \mathbb{N}$ and $N = 2^m$,

$$M(N) = \frac{N}{2} \log_2 N = \frac{Nm}{2}, \quad A(N) = N \log_2 N = Nm, \quad T(N) = \frac{3}{2} N \log_2 N$$

Proof. We give two independent proofs.

First proof: induction on m . For M . *Base* ($m = 0, N = 1$): $M(1) = 0$ and $\frac{1}{2} \cdot 1 \cdot \log_2 1 = 0$: equal. *Step*: let $m \geq 1$ and suppose $M(2^{m-1}) = \frac{2^{m-1}(m-1)}{2}$. Then, by Theorem 23.4,

$$M(2^m) = 2 M(2^{m-1}) + \frac{2^m}{2} = 2 \cdot \frac{2^{m-1}(m-1)}{2} + 2^{m-1} = 2^{m-1}(m-1) + 2^{m-1} = 2^{m-1}m = \frac{2^m m}{2},$$

which is the claim for m . Identically for A : base $A(1) = 0 = 1 \cdot \log_2 1$; step, with hypothesis $A(2^{m-1}) = 2^{m-1}(m-1)$,

$$A(2^m) = 2 \cdot 2^{m-1}(m-1) + 2^m = 2^m(m-1) + 2^m = 2^m m.$$

Finally $T = M + A = \frac{Nm}{2} + Nm = \frac{3}{2} Nm$.

Second proof: direct count over the levels. By Proposition 23.4 the algorithm performs exactly $N/2$ butterflies on each of the m levels $\ell = 0, \dots, m-1$, and none elsewhere; by Proposition 23.2 each butterfly costs one multiplication and two additions. Hence

$$M(N) = m \cdot \frac{N}{2}, \quad A(N) = m \cdot \frac{N}{2} \cdot 2 = mN.$$

The two routes give the same result. ✓

Independent numerical check. A Python script that simulates the iterative algorithm and increments two counters at every butterfly returns, for $N = 2, 4, 8, 16, 32, 1024$: multiplications 1, 4, 12, 32, 80, 5 120 and additions 2, 8, 24, 64, 160, 10 240, against the formulas $\frac{N}{2} \log_2 N$ and $N \log_2 N$, which give 1, 4, 12, 32, 80, 5 120 and 2, 8, 24, 64, 160, 10 240: an exact match in every case. ✓ □

Theorem 23.6: Solution of the general recurrence $T(N) = 2T(N/2) + cN$. Let $c > 0$ and $c_0 \geq 0$ be constants and let $T : \{2^m : m \in \mathbb{N}\} \rightarrow \mathbb{R}$ be defined by

$$T(1) = c_0, \quad T(N) = 2T\left(\frac{N}{2}\right) + cN \quad (N \geq 2).$$

Then for every $N = 2^m$

$$T(N) = cN \log_2 N + c_0 N.$$

In particular $T(N) = \Theta(N \log_2 N)$: there exist constants $0 < \alpha \leq \beta$ and N_0 such that $\alpha N \log_2 N \leq T(N) \leq \beta N \log_2 N$ for every $N = 2^m \geq N_0$.

Proof. **Closed form, by induction on m .** *Base* ($m = 0$): $T(1) = c_0 = c \cdot 1 \cdot 0 + c_0 \cdot 1$. *Step*: let $m \geq 1$ and suppose $T(2^{m-1}) = c 2^{m-1}(m-1) + c_0 2^{m-1}$. Then

$$T(2^m) = 2[c 2^{m-1}(m-1) + c_0 2^{m-1}] + c 2^m = c 2^m(m-1) + c_0 2^m + c 2^m = c 2^m m + c_0 2^m,$$

which is the claim for m .

Second route: the cost tree. Expanding the recurrence,

$$T(N) = 2T\left(\frac{N}{2}\right) + cN = 4T\left(\frac{N}{4}\right) + 2c\frac{N}{2} + cN = \dots = 2^m T(1) + \sum_{\ell=0}^{m-1} 2^\ell c \frac{N}{2^\ell}.$$

Formally: one proves by induction on $j \in \{0, \dots, m\}$ that $T(N) = 2^j T(N/2^j) + jcN$. For $j = 0$ it is an identity. If it holds for $j < m$, then

$$2^j T\left(\frac{N}{2^j}\right) + jcN = 2^j \left[2T\left(\frac{N}{2^{j+1}}\right) + c\frac{N}{2^j} \right] + jcN = 2^{j+1} T\left(\frac{N}{2^{j+1}}\right) + (j+1)cN.$$

For $j = m$ one obtains $T(N) = 2^m T(1) + mcN = c_0 N + cN \log_2 N$. The two routes agree. ✓
Asymptotic conclusion. From $T(N) = cN \log_2 N + c_0 N$ it follows at once that $T(N) \geq cN \log_2 N$ for every N , and for $N \geq 4$ (that is, $\log_2 N \geq 2$)

$$T(N) = cN \log_2 N + c_0 N \leq cN \log_2 N + \frac{c_0}{2} N \log_2 N = \left(c + \frac{c_0}{2}\right) N \log_2 N.$$

Hence the claim with $\alpha = c$, $\beta = c + c_0/2$ and $N_0 = 4$. □

Corollary 23.3: *The FFT costs $\Theta(N \log N)$, the direct computation $\Theta(N^2)$. With the previous notation, for $N = 2^m$*

$$\frac{M_{\text{dir}}(N) + A_{\text{dir}}(N)}{T(N)} = \frac{N^2 + N(N-1)}{\frac{3}{2} N \log_2 N} = \frac{2N-1}{\frac{3}{2} \log_2 N} \xrightarrow{N \rightarrow \infty} +\infty,$$

and the ratio is already ≥ 1 for $N \geq 4$. The gain therefore grows as $\Theta(N/\log_2 N)$.

Proof. By Proposition 23.1, $M_{\text{dir}}(N) + A_{\text{dir}}(N) = N^2 + N(N-1) = N(2N-1)$; by Theorem 23.5, $T(N) = \frac{3}{2} N \log_2 N$. The ratio is $\frac{N(2N-1)}{\frac{3}{2} N \log_2 N} = \frac{2(2N-1)}{3 \log_2 N}$, which tends to $+\infty$ because the

numerator grows linearly in N and the denominator logarithmically: formally, $\frac{2(2N-1)}{3 \log_2 N} \geq \frac{2N}{3 \log_2 N}$ for $N \geq 1$, and $N/\log_2 N \rightarrow +\infty$. For $N = 4$: $\frac{2 \cdot 7}{3 \cdot 2} = \frac{14}{6} > 1$.

That the ratio is *increasing* in m is seen as follows: setting $N = 2^m$ with $m \geq 1$, the ratio equals $g(m) = \frac{2(2^{m+1}-1)}{3m}$, and

$$\frac{g(m+1)}{g(m)} = \frac{2^{m+2}-1}{2^{m+1}-1} \cdot \frac{m}{m+1} > \frac{2(2^{m+1}-1)}{2^{m+1}-1} \cdot \frac{m}{m+1} = \frac{2m}{m+1} \geq 1 \quad (m \geq 1),$$

where the strict inequality uses $2^{m+2}-1 > 2(2^{m+1}-1) = 2^{m+2}-2$. □

Proposition 23.5: *How many multiplications are trivial. Let $N = 2^m$ with $m \geq 1$. Among the $\frac{N}{2}m$ butterflies performed by $\mathcal{A}_N$:*

- (i) *exactly $N-1$ have twiddle factor $\omega_n^0 = 1$;*
- (ii) *exactly $\max\{N/2-1, 0\}$ have twiddle factor $\omega_n^{n/4} = -i$;*
- (iii) *none has twiddle factor -1 or $+i$.*

Consequently the nontrivial multiplications are, for $m \geq 1$,

$$M^{**}(N) = \frac{N}{2} \log_2 N - (N-1) - \left(\frac{N}{2} - 1\right) = \frac{N}{2} \log_2 N - \frac{3N}{2} + 2.$$

Proof. By Proposition 23.4, the nodes of length $n = 2^j$ (with $1 \leq j \leq m$) number N/n , and each performs the butterflies of index $k = 0, 1, \dots, \frac{n}{2} - 1$ with factor ω_n^k .

(i) Within a node of length n , $\omega_n^k = 1$ with $0 \leq k \leq \frac{n}{2} - 1$ occurs, by Lemma 23.1(ii), if and only if $n \mid k$, that is (since $0 \leq k < n$) if and only if $k = 0$: a single butterfly per node.

Summing over all nodes,

$$\sum_{j=1}^m \frac{N}{2^j} = N \left(\frac{1}{2} + \frac{1}{4} + \cdots + \frac{1}{2^m} \right) = N \cdot \frac{\frac{1}{2}(1 - 2^{-m})}{1 - \frac{1}{2}} = N(1 - 2^{-m}) = N - 1,$$

having used $2^{-m} = 1/N$.

(ii) $\omega_n^k = -i = e^{-i\pi/2}$ with $0 \leq k \leq \frac{n}{2} - 1$ occurs if and only if $e^{-2\pi i k/n} = e^{-i\pi/2}$, that is, $\frac{2k}{n} \equiv \frac{1}{2} \pmod{2}$, that is, $k \equiv \frac{n}{4} \pmod{n}$; in the interval considered this requires $4 \mid n$ (hence $n \geq 4$, that is, $j \geq 2$) and gives the single value $k = \frac{n}{4}$, which satisfies $0 \leq \frac{n}{4} \leq \frac{n}{2} - 1$ precisely for $n \geq 4$. Hence a single butterfly per node, and only for the nodes of length ≥ 4 . Summing,

$$\sum_{j=2}^m \frac{N}{2^j} = N \left(\frac{1}{4} + \cdots + \frac{1}{2^m} \right) = N \left(1 - 2^{-m} - \frac{1}{2} \right) = \frac{N}{2} - 1,$$

valid for $m \geq 2$; for $m = 1$ there are no nodes of length ≥ 4 and the count is $0 = \max\{N/2 - 1, 0\}$ with $N = 2$.

(iii) $\omega_n^k = -1$ requires, by Lemma 23.1(iv) and the uniqueness of the representation, $k = \frac{n}{2}$, which is outside the interval $0 \leq k \leq \frac{n}{2} - 1$. $\omega_n^k = +i = e^{+i\pi/2} = e^{-i3\pi/2}$ requires $k = \frac{3n}{4} > \frac{n}{2} - 1$: also outside the interval.

Subtracting (i) and (ii) from the total $\frac{N}{2}m$ of Theorem 23.5 gives, for $m \geq 2$,

$$M^{**}(N) = \frac{N}{2}m - (N - 1) - \left(\frac{N}{2} - 1 \right) = \frac{N}{2}m - \frac{3N}{2} + 2,$$

and for $m = 1$ ($N = 2$): $1 - 1 - 0 = 0 = \frac{2}{2} \cdot 1 - 3 + 2$. The formula therefore holds for every $m \geq 1$. $\square$

Corollary 23.4: The final count. For $N = 2^m$, $m \geq 1$, the radix-2 DIT algorithm computes the DFT with

$$\frac{N}{2} \log_2 N - \frac{3N}{2} + 2 \quad \text{nontrivial complex multiplications,}$$

$$N \log_2 N \quad \text{complex additions.}$$

For $N = 8$ this means 2 nontrivial multiplications and 24 additions, against the 64 multiplications and 56 additions of the direct computation; for $N = 1,024$, 3,586 nontrivial multiplications and 10,240 additions, against 1,048,576 and 1,047,552.

Proof. This is Proposition 23.5 combined with Theorem 23.5 and Proposition 23.1. The numerical values: for $N = 8$, $m = 3$: $\frac{8}{2} \cdot 3 - \frac{24}{2} + 2 = 12 - 12 + 2 = 2$ and $8 \cdot 3 = 24$; the direct computation gives $8^2 = 64$ and $8 \cdot 7 = 56$. For $N = 1,024$, $m = 10$: $512 \cdot 10 - 1,536 + 2 = 5,120 - 1,534 = 3,586$ and $1,024 \cdot 10 = 10,240$; the direct computation gives $1,024^2 = 1,048,576$ and $1,024 \cdot 1,023 = 1,047,552$. $\checkmark$ (A Python script that counts the butterflies with factor different from 1, -1 , i , $-i$ returns 2 for $N = 8$ and 3,586 for $N = 1,024$.) $\square$

Remark 23.7: What this table says and what it does not say. Table 23.1 reports operation counts, not times. This is a distinction that the Plan of the work requires to be kept separate, and for a precise reason: on a real computer the time depends on the locality of memory accesses, on the size of the caches, on vectorization and on parallelism, and two implementations with the same operation count can differ by a factor of ten in the measured time (Remark 23.14). The count is, however, what makes the comparison reproducible and

Table 23.1: Cost of computing the DFT: direct computation (Proposition 23.1) against radix-2 FFT (Theorem 23.5 and Corollary 23.4). Every entry is an exact number, not an estimate. The last column is the ratio of the multiplications of the direct computation to those of the FFT.

N	direct computation		radix-2 FFT			ratio
	mult. N^2	add. $N(N-1)$	mult. $\frac{N}{2} \log_2 N$	add. $N \log_2 N$	nontrivial	
8	64	56	12	24	2	5.33
16	256	240	32	64	10	8.00
32	1,024	992	80	160	34	12.80
64	4,096	4,032	192	384	98	21.33
256	65,536	65,280	1,024	2,048	642	64.00
1,024	1,048,576	1,047,552	5,120	10,240	3,586	204.80
4,096	16,777,216	16,773,120	24,576	49,152	18,434	682.67
65,536	4 294 967 296	4 294 901 760	524,288	1,048,576	425,986	8,192.00
1,048,576	1 099 511 627 776	1 099 510 579 200	10,485,760	20,971,520	8,912,898	104,857.60

verifiable: anyone can recount it. Note also that the ratio in the last column equals 1 only for $N = 2$ and grows without bound: for $N = 1,048,576$ the FFT performs roughly one hundred-thousandth of the multiplications of the direct computation.

23.6. From recursion to a loop: the bit-reversal permutation

The algorithm of Definition 23.4 is recursive and allocates new vectors at every call. No serious implementation uses it in that form: the inputs are reordered once and for all, and then m nested loops are run that work *in place*, that is, overwriting the same vector. The reordering needed is the **bit-reversal** permutation, and it is step 19 of the path. That it is the right one is not a fact to be read off a figure: it is a theorem, and it must be proved.

Definition 23.5: Bit reversal. Let $m \geq 0$ and $N = 2^m$. Every $n \in \{0, \dots, N-1\}$ has a unique binary expansion

$$n = \sum_{t=0}^{m-1} b_t(n) 2^t, \quad b_t(n) \in \{0, 1\}.$$

The **bit reversal** of order m is the map $\rho_m : \{0, \dots, N-1\} \rightarrow \{0, \dots, N-1\}$ defined by

$$\rho_m(n) = \sum_{t=0}^{m-1} b_t(n) 2^{m-1-t},$$

that is: n is written in binary on m digits, the string is read from right to left, and the result is again interpreted as a binary number.

Lemma 23.4: ρ_m is an involution, hence a permutation. For every $m \geq 0$, $\rho_m \circ \rho_m = \text{id}$. In particular ρ_m is bijective and $\rho_m^{-1} = \rho_m$.

Proof. Let $n \in \{0, \dots, N-1\}$ and let $n' = \rho_m(n) = \sum_{t=0}^{m-1} b_t(n) 2^{m-1-t}$. We rewrite the sum by setting $s = m-1-t$, that is, $t = m-1-s$; as t ranges over $\{0, \dots, m-1\}$ so does s , and

$$n' = \sum_{s=0}^{m-1} b_{m-1-s}(n) 2^s.$$

The coefficients $b_{m-1-s}(n)$ lie in $\{0, 1\}$ and the binary expansion of an integer of $\{0, \dots, 2^m - 1\}$ on m digits is unique; hence

$$b_s(n') = b_{m-1-s}(n) \quad \text{for every } s \in \{0, \dots, m-1\}.$$

Applying ρ_m again,

$$\rho_m(n') = \sum_{s=0}^{m-1} b_s(n') 2^{m-1-s} = \sum_{s=0}^{m-1} b_{m-1-s}(n) 2^{m-1-s} = \sum_{t=0}^{m-1} b_t(n) 2^t = n,$$

with the substitution $t = m - 1 - s$ in the last step. Hence $\rho_m(\rho_m(n)) = n$. A map of a finite set into itself which, composed with itself, gives the identity is injective (if $\rho_m(n_1) = \rho_m(n_2)$, applying ρ_m gives $n_1 = n_2$) and hence, the domain being finite and equal to the codomain, bijective; and the relation $\rho_m \circ \rho_m = \text{id}$ is precisely the statement that $\rho_m^{-1} = \rho_m$. $\square$

Theorem 23.7: The order of the leaves is the bit-reversed order. Let $N = 2^m$ and consider the recursion tree of Definition 23.4 (Remark 23.6), in which at every node the left child receives the even subsequence and the right child the odd one. Number the leaves from left to right by $j = 0, 1, \dots, N - 1$. Then leaf j contains the sample

$$x[\rho_m(j)].$$

Equivalently: sample $x[n]$ ends up in the leaf at position $\rho_m(n)$.

Proof. Step 1: encoding the path. A path from the root to a leaf is a sequence of m choices $c_0, c_1, \dots, c_{m-1} \in \{0, 1\}$, where $c_\ell = 0$ means “at level ℓ go to the left (even) child” and $c_\ell = 1$ “go to the right (odd) one”. The position from the left of the leaf reached is

$$j = \sum_{\ell=0}^{m-1} c_\ell 2^{m-1-\ell} :$$

this is proved by induction on m . For $m = 0$ there are no choices and $j = 0$. For $m \geq 1$: the left subtree occupies positions $0, \dots, 2^{m-1} - 1$ and the right one positions $2^{m-1}, \dots, 2^m - 1$; hence the position is $c_0 2^{m-1}$ plus the position *relative* to inside the subtree, which by the inductive hypothesis (applied to a tree of height $m-1$) equals $\sum_{\ell=1}^{m-1} c_\ell 2^{(m-1)-1-(\ell-1)} = \sum_{\ell=1}^{m-1} c_\ell 2^{m-1-\ell}$. Adding gives the formula.

Step 2: which sample reaches the end of a path. We claim that the leaf reached with the choices $(c_0, \dots, c_{m-1})$ contains $x[n]$, where n is the unique integer of $\{0, \dots, N - 1\}$ with

$$b_\ell(n) = c_\ell \quad \text{for every } \ell = 0, \dots, m-1.$$

We prove this by induction on m .

Base $m = 0$: the vector has a single element, $x[0]$, and $n = 0$.

Step: let $m \geq 1$. By Definition 23.2, the left child receives e with $e[r] = x[2r]$ and the right one o with $o[r] = x[2r + 1]$; that is, in both cases, the child c_0 receives the vector v with

$$v[r] = x[2r + c_0], \quad r = 0, \dots, 2^{m-1} - 1.$$

By the inductive hypothesis applied to v (of length 2^{m-1}) and to the remaining choices $(c_1, \dots, c_{m-1})$, the leaf contains $v[r]$ with $b_{\ell-1}(r) = c_\ell$ for $\ell = 1, \dots, m-1$, that is, $r = \sum_{\ell=1}^{m-1} c_\ell 2^{\ell-1}$. Hence the leaf contains

$$x[2r + c_0] = x\left[c_0 + \sum_{\ell=1}^{m-1} c_\ell 2^\ell\right] = x\left[\sum_{\ell=0}^{m-1} c_\ell 2^\ell\right],$$

that is, $x[n]$ with $b_\ell(n) = c_\ell$, by the uniqueness of the binary expansion. Note the essential point: the choice at the *first* level is determined by the *least* significant bit of n , that at the second level by the next bit, and so on. It is this exchange between the order of the levels and the order of the bits that produces the reversal.

Step 3: conclusion. Combining Steps 1 and 2: the leaf at position $j = \sum_\ell c_\ell 2^{m-1-\ell}$ contains $x[n]$ with $n = \sum_\ell c_\ell 2^\ell$. But then $b_\ell(n) = c_\ell$ and

$$\rho_m(n) = \sum_{\ell=0}^{m-1} b_\ell(n) 2^{m-1-\ell} = \sum_{\ell=0}^{m-1} c_\ell 2^{m-1-\ell} = j.$$

Hence $x[n]$ sits in leaf $\rho_m(n)$; and since ρ_m is an involution (Lemma 23.4), leaf j contains $x[\rho_m^{-1}(j)] = x[\rho_m(j)]$. $\square$

Example 23.2: The bit-reversal permutation for $N = 8$ and $N = 16$. For $N = 8$ ($m = 3$):

n	0	1	2	3	4	5	6	7
binary	000	001	010	011	100	101	110	111
reversed	000	100	010	110	001	101	011	111
$\rho_3(n)$	0	4	2	6	1	5	3	7

The input must therefore be presented in the order $x[0], x[4], x[2], x[6], x[1], x[5], x[3], x[7]$, which is exactly the order of the leaves in Figure 23.2. $\checkmark$

Note that ρ_3 fixes 0, 2, 5, 7 and swaps $1 \leftrightarrow 4$ and $3 \leftrightarrow 6$: it is a product of two transpositions, consistently with Lemma 23.4. An implementation can therefore carry out the permutation with swaps alone, without an auxiliary vector.

For $N = 16$ ($m = 4$) one obtains

$$\rho_4 = (0, 8, 4, 12, 2, 10, 6, 14, 1, 9, 5, 13, 3, 11, 7, 15),$$

read as “ $\rho_4(0) = 0, \rho_4(1) = 8, \dots$ ”. *Independent check:* a Python script that computes ρ_m with m bit shifts returns $[0, 4, 2, 6, 1, 5, 3, 7]$ for $m = 3$ and $[0, 8, 4, 12, 2, 10, 6, 14, 1, 9, 5, 13, 3, 11, 7, 15]$ for $m = 4$, and verifies $\rho_m(\rho_m(n)) = n$ for every n . $\checkmark$

Definition 23.6: The in-place iterative algorithm. Let $N = 2^m$. The **iterative DIT FFT algorithm** receives $x \in \mathbb{C}^N$ and performs:

- (P) *permutation:* $a[j] \leftarrow x[\rho_m(j)]$ for $j = 0, \dots, N - 1$;
- (S) *stages:* for $s = 1, 2, \dots, m$, setting $n_s = 2^s$, and for every $b \in \{0, n_s, 2n_s, \dots, N - n_s\}$ and every $k \in \{0, \dots, \frac{n_s}{2} - 1\}$:

$$t \leftarrow \omega_{n_s}^k \cdot a[b + k + \frac{n_s}{2}], \quad u \leftarrow a[b + k], \quad a[b + k] \leftarrow u + t, \quad a[b + k + \frac{n_s}{2}] \leftarrow u - t.$$

The output is the vector a at the end of stage m . All writes take place on the same vector a : the algorithm uses no auxiliary memory beyond the two variables t and u (*in-place* computation).

Theorem 23.8: Correctness of the iterative algorithm. The algorithm of Definition 23.6 returns $\text{DFT}_N\{x\}$, with the same operation count as Theorem 23.5.

Proof. We prove by induction on $s \in \{0, 1, \dots, m\}$ the following *invariant*: after stage s (with $s = 0$ meaning “after permutation (P) alone”), for every $p \in \{0, 1, \dots, 2^{m-s} - 1\}$ the block of

indices

$$\mathcal{I}_{s,p} = \{p2^s, p2^s + 1, \dots, p2^s + 2^s - 1\}$$

contains, in the natural order, the 2^s -point DFT of the vector $v^{(s,p)} \in \mathbb{C}^{2^s}$ of components

$$v^{(s,p)}[r] = x[r2^{m-s} + \rho_{m-s}(p)], \quad r = 0, \dots, 2^s - 1.$$

Base $s = 0$. The blocks are the singletons $\mathcal{I}_{0,p} = \{p\}$ with $p = 0, \dots, N - 1$, and $v^{(0,p)}$ is the length-1 vector with single component $x[\rho_m(p)]$; its 1-point DFT is itself (Lemma 23.3(i)). And indeed after (P) cell p contains $x[\rho_m(p)]$: the invariant holds.

Step. Let $1 \leq s \leq m$ and suppose the invariant holds after stage $s - 1$. Stage s works on blocks of size $n_s = 2^s$: the block starting at $b = p2^s$ is the union of the two blocks of size 2^{s-1} starting at $2p2^{s-1}$ and at $(2p + 1)2^{s-1}$, that is, of the blocks $\mathcal{I}_{s-1,2p}$ and $\mathcal{I}_{s-1,2p+1}$; by the inductive hypothesis, these contain the 2^{s-1} -point DFTs of $v^{(s-1,2p)}$ and of $v^{(s-1,2p+1)}$. Now observe that, setting $q = \rho_{m-s}(p)$ and $L = 2^{s-1}$,

$$v^{(s-1,2p)}[r] = x[r2^{m-s+1} + \rho_{m-s+1}(2p)] = x[2r2^{m-s} + q],$$

$$v^{(s-1,2p+1)}[r] = x[r2^{m-s+1} + \rho_{m-s+1}(2p + 1)] = x[(2r + 1)2^{m-s} + q],$$

having used $\rho_{m-s+1}(2p) = \rho_{m-s}(p) = q$ and $\rho_{m-s+1}(2p + 1) = \rho_{m-s}(p) + 2^{m-s} = q + 2^{m-s}$: indeed adding a 0 (resp. a 1) as the *least* significant bit of p means adding a 0 (resp. a 1) as the *most* significant bit of $\rho(p)$, by Definition 23.5. Hence $v^{(s-1,2p)}$ and $v^{(s-1,2p+1)}$ are exactly the even subsequence and the odd subsequence of $v^{(s,p)}$, in the sense of Definition 23.2: $v^{(s,p)}[2r] = v^{(s-1,2p)}[r]$ and $v^{(s,p)}[2r + 1] = v^{(s-1,2p+1)}[r]$.

Stage s performs, for $k = 0, \dots, L - 1$, the butterfly $a[b + k] \leftarrow a[b + k] + \omega_{2L}^k a[b + k + L]$, $a[b + k + L] \leftarrow a[b + k] - \omega_{2L}^k a[b + k + L]$ (with the values *before* the update, saved in u and t : this is why Definition 23.6 uses the two temporary variables, and the in-place computation is correct). By Theorems 23.1 and 23.2, applied to $N' = 2L = 2^s$, the result is the 2^s -point DFT of $v^{(s,p)}$, and it sits in the block $\mathcal{I}_{s,p}$ in the natural order ($X[k]$ at position $b + k$, $X[k + L]$ at position $b + k + L$). The invariant holds after stage s .

Conclusion. For $s = m$ there is a single block, $p = 0$, $\mathcal{I}_{m,0} = \{0, \dots, N - 1\}$, $\rho_0(0) = 0$ and $v^{(m,0)}[r] = x[r]$: the vector a contains DFT $_N\{x\}$ in the natural order.

Count. Stage s performs $\frac{N}{n_s}$ blocks of $\frac{n_s}{2}$ butterflies each, that is, $\frac{N}{2}$ butterflies; there are m stages; by Proposition 23.2 the total is $\frac{N}{2}m$ multiplications and Nm additions, as in Theorem 23.5. Permutation (P) performs no arithmetic operations. $\square$

Best practice. Three errors that the invariant of Theorem 23.8 prevents. (1)

Overwriting before reading: if $a[b + k]$ is written before t has been computed, the second output of the butterfly uses an already altered value; the two temporary variables u and t of Definition 23.6 are not an ornament. (2) *Using ω_N^k instead of $\omega_{n_s}^k$* : at a generic stage the factor has order $n_s = 2^s$, not N ; equivalently one may use ω_N^{kN/n_s} , which is the form that allows all the factors to be read from a single table of $N/2$ elements (Lemma 23.1(vi)). (3) *Forgetting the permutation*: without step (P) the algorithm still computes something, but not the DFT — it computes the DFT of the vector $x \circ \rho_m$, that is, the spectrum of a signal whose samples have been shuffled. This is the hardest error to diagnose, because the wrong spectrum has *exactly the same energy* as the correct one (Parseval's identity, Theorem 22.6, is satisfied, because a permutation of the samples does not change $\sum_n |x[n]|^2$): the most common numerical check does not notice it. Solved Exercise 23.6 shows this on numbers.

23.7. The decimation-in-frequency variant

Decimation in time splits the sample index n in two. One can instead split the frequency index k in two, separating the components of even index from those of odd index: this gives the **decimation-in-frequency** variant (DIF), due to Gentleman and Sande and also known as the Sande–Tukey algorithm. This is step 20 of the path. The cost is identical; what changes is *where* the bit-reversal permutation sits: at the input for DIT, at the output for DIF.

Theorem 23.9: Decomposition with decimation in frequency. Let $N = 2L$ and $x \in \mathbb{C}^N$, $X = \text{DFT}_N\{x\}$. Define $\alpha, \beta \in \mathbb{C}^L$ by

$$\alpha[n] = x[n] + x[n+L], \quad \beta[n] = (x[n] - x[n+L]) \omega_N^n, \quad n = 0, 1, \dots, L-1.$$

Then, for $k = 0, 1, \dots, L-1$,

$$X[2k] = (\text{DFT}_L\{\alpha\})[k], \quad X[2k+1] = (\text{DFT}_L\{\beta\})[k]$$

Proof. **Step 1 (splitting the sum in half, over the index n).** For every $j \in \mathbb{Z}$,

$$X[j] = \sum_{n=0}^{N-1} x[n] \omega_N^{jn} = \sum_{n=0}^{L-1} x[n] \omega_N^{jn} + \sum_{n=L}^{N-1} x[n] \omega_N^{jn}.$$

In the second sum set $n = n' + L$ with $n' = 0, \dots, L-1$: the substitution is a bijection between $\{0, \dots, L-1\}$ and $\{L, \dots, N-1\}$, because it is injective and both images have L elements. One obtains

$$\sum_{n=L}^{N-1} x[n] \omega_N^{jn} = \sum_{n'=0}^{L-1} x[n'+L] \omega_N^{j(n'+L)} = \omega_N^{jL} \sum_{n'=0}^{L-1} x[n'+L] \omega_N^{jn'}.$$

Step 2 (the factor ω_N^{jL}). Since $L = N/2$, Lemma 23.1(iv) gives $\omega_N^L = \omega_N^{N/2} = -1$, hence $\omega_N^{jL} = (\omega_N^L)^j = (-1)^j$. Substituting into Step 1 and combining the two sums (which now have the same index set),

$$X[j] = \sum_{n=0}^{L-1} (x[n] + (-1)^j x[n+L]) \omega_N^{jn}.$$

Step 3 (even indices). Let $j = 2k$. Then $(-1)^j = +1$ and, by Lemma 23.1(iii), $\omega_N^{2kn} = \omega_L^{kn}$. Hence

$$X[2k] = \sum_{n=0}^{L-1} (x[n] + x[n+L]) \omega_L^{kn} = \sum_{n=0}^{L-1} \alpha[n] \omega_L^{kn} = (\text{DFT}_L\{\alpha\})[k].$$

Step 4 (odd indices). Let $j = 2k+1$. Then $(-1)^j = -1$ and $\omega_N^{(2k+1)n} = \omega_N^{2kn} \omega_N^n = \omega_L^{kn} \omega_N^n$. Hence

$$X[2k+1] = \sum_{n=0}^{L-1} (x[n] - x[n+L]) \omega_N^n \omega_L^{kn} = \sum_{n=0}^{L-1} \beta[n] \omega_L^{kn} = (\text{DFT}_L\{\beta\})[k].$$

Step 5 (all indices are covered). The indices $2k$ and $2k+1$ with $0 \leq k \leq L-1$ exhaust $\{0, \dots, N-1\}$ without repetitions, by Lemma 23.2 applied to j in place of n . $\square$

Definition 23.7: The radix-2 DIF FFT algorithm. Let $N = 2^m$. The algorithm $\mathcal{D}_N : \mathbb{C}^N \rightarrow \mathbb{C}^N$ is defined by recursion: $\mathcal{D}_1(x) = x$; for $N = 2L \geq 2$ one computes

$\alpha, \beta \in \mathbb{C}^L$ as in Theorem 23.9 and sets

$$\mathcal{D}_N(x)[2k] = \mathcal{D}_L(\alpha)[k], \quad \mathcal{D}_N(x)[2k+1] = \mathcal{D}_L(\beta)[k], \quad k = 0, \dots, L-1.$$

In the in-place iterative version the same scheme is executed *without* rewriting the indices, obtaining the output in bit-reversed order, and the permutation ρ_m is applied at the *end* rather than at the beginning.

Corollary 23.5: Correctness and cost of the DIF. For every $N = 2^m$ and every $x \in \mathbb{C}^N$, $\mathcal{D}_N(x) = \text{DFT}_N\{x\} = \mathcal{A}_N(x)$, and the DIF algorithm performs exactly the same number of operations as the DIT: $\frac{N}{2} \log_2 N$ complex multiplications (of which $\frac{N}{2} \log_2 N - \frac{3N}{2} + 2$ nontrivial) and $N \log_2 N$ complex additions.

Proof. Correctness, by induction on m . Base $m = 0$: $\mathcal{D}_1(x) = x$ and $\text{DFT}_1\{x\} = x$ by Lemma 23.3(i). Step: let $m \geq 1$; by the inductive hypothesis $\mathcal{D}_L(\alpha) = \text{DFT}_L\{\alpha\}$ and $\mathcal{D}_L(\beta) = \text{DFT}_L\{\beta\}$; by Theorem 23.9 these equal $X[2k]$ and $X[2k+1]$ respectively, and by Step 5 of that proof all indices are covered exactly once. Hence $\mathcal{D}_N(x) = X$. Equality with $\mathcal{A}_N(x)$ follows from Theorem 23.3.

Cost. The recursive step on length N performs: $L = N/2$ sums $x[n] + x[n+L]$ and L differences $x[n] - x[n+L]$, that is, N additions; then $L = N/2$ multiplications $(\cdot) \omega_N^n$ for $n = 0, \dots, L-1$. The count per level is therefore identical to that of the DIT (Proposition 23.4), and the recurrences are the same as in Theorem 23.4; the solution is that of Theorem 23.5.

Trivial multiplications. At the step on length $n = 2^j$ the factors used are $\omega_n^0, \omega_n^1, \dots, \omega_n^{n/2-1}$: exactly the same set of factors as the DIT on the same length. The count of Proposition 23.5 applies word for word, and gives $\frac{N}{2} \log_2 N - \frac{3N}{2} + 2$ nontrivial multiplications. $\square$

Remark 23.8: DIT and DIF: where the bit reversal sits, and why they are two transposed graphs. In the DIT the multiplication by the twiddle factor precedes the sum/difference pair; in the DIF it follows it. From this follows the position of the permutation:

- **DIT:** input in bit-reversed order, output in natural order;
- **DIF:** input in natural order, output in bit-reversed order.

There also exist “natural-to-natural” variants, which pay for the reordering with auxiliary memory, and variants that avoid the reordering altogether when the FFT is used solely for a circular convolution (Theorem 22.5): in that case one applies a DIF without reordering, multiplies pointwise — the order does not matter, provided it is the same for both factors — and applies a DIT that restores the natural order. This is a real saving in an industrial implementation.

It is finally worth noting that the two flow graphs are each the transpose of the other: reversing the direction of every arrow of the DIT graph and swapping inputs with outputs gives the DIF graph. This is a manifestation of the transposition principle for linear networks; we do not need it here, and we merely note it, having proved the DIF directly from Theorem 23.9.

23.8. The example $N = 8$: exact symbolic form

These are steps 21 and 23 of the path. The example is worked out *in full*: first in generic form, with the samples $x[0], \dots, x[7]$ left indeterminate, then with exact roots of unity and a concrete input. The numerical check and the comparison with the direct DFT is in Section 23.9.

Stage 1 ($n_1 = 2$, four blocks, a single value $k = 0$, factor $\omega_2^0 = 1$). The butterflies act on the pairs of cells $(0, 1)$, $(2, 3)$, $(4, 5)$, $(6, 7)$:

$$\begin{aligned} a_0 &= x[0] + x[4], & a_1 &= x[0] - x[4], & a_2 &= x[2] + x[6], & a_3 &= x[2] - x[6], \\ a_4 &= x[1] + x[5], & a_5 &= x[1] - x[5], & a_6 &= x[3] + x[7], & a_7 &= x[3] - x[7]. \end{aligned}$$

Each pair is the two-point DFT of Lemma 23.3(ii): 8 additions, 0 nontrivial multiplications.

Stage 2 ($n_2 = 4$, two blocks $\{0, 1, 2, 3\}$ and $\{4, 5, 6, 7\}$, values $k = 0, 1$, factors $\omega_4^0 = 1$ and $\omega_4^1 = -i$). The butterflies act on the pairs $(0, 2)$, $(1, 3)$ in the first block and $(4, 6)$, $(5, 7)$ in the second:

$$\begin{aligned} b_0 &= a_0 + a_2, & b_1 &= a_1 - i a_3, & b_2 &= a_0 - a_2, & b_3 &= a_1 + i a_3, \\ b_4 &= a_4 + a_6, & b_5 &= a_5 - i a_7, & b_6 &= a_4 - a_6, & b_7 &= a_5 + i a_7. \end{aligned}$$

Again 8 additions and 0 nontrivial multiplications (the four factors are 1 and $-i$).

Stage 3 ($n_3 = 8$, a single block, $k = 0, 1, 2, 3$, factors 1, ω_8 , $-i$, ω_8^3). The butterflies act on the pairs $(0, 4)$, $(1, 5)$, $(2, 6)$, $(3, 7)$:

$$\begin{aligned} X[0] &= b_0 + b_4, & X[4] &= b_0 - b_4, \\ X[1] &= b_1 + \omega_8 b_5, & X[5] &= b_1 - \omega_8 b_5, \\ X[2] &= b_2 - i b_6, & X[6] &= b_2 + i b_6, \\ X[3] &= b_3 + \omega_8^3 b_7, & X[7] &= b_3 - \omega_8^3 b_7. \end{aligned}$$

Eight additions; the only nontrivial multiplications of the whole computation are $\omega_8 b_5$ and $\omega_8^3 b_7$.

Balance. 24 complex additions and 2 nontrivial complex multiplications, in agreement with Theorem 23.5 ($A(8) = 8 \cdot 3 = 24$) and with Corollary 23.4 (2). ✓

Example 23.5: Recomposition: the first output contains all eight samples. Let us verify Corollary 23.2 on two outputs, expanding backward the formulas of Example 23.4 (step 23 of the path).

Output $X[0]$.

$$X[0] = b_0 + b_4 = (a_0 + a_2) + (a_4 + a_6) = (x[0] + x[4]) + (x[2] + x[6]) + (x[1] + x[5]) + (x[3] + x[7]),$$

that is, $X[0] = \sum_{n=0}^7 x[n]$: all eight samples, each with coefficient $1 = \omega_8^{0 \cdot n}$. ✓

Output $X[2]$. One has $X[2] = b_2 - i b_6 = (a_0 - a_2) - i(a_4 - a_6)$, hence

$$X[2] = (x[0] + x[4]) - (x[2] + x[6]) - i((x[1] + x[5]) - (x[3] + x[7])).$$

Collecting the coefficients of the individual samples:

$$X[2] = x[0] - i x[1] - x[2] + i x[3] + x[4] - i x[5] - x[6] + i x[7].$$

On the other hand the definition gives $X[2] = \sum_n x[n] \omega_8^{2n}$ with $\omega_8^2 = -i$, that is, coefficients $(-i)^n = 1, -i, -1, i, 1, -i, -1, i$ for $n = 0, \dots, 7$: they coincide one by one with those just found. ✓

Note that no sample is missing and none appears twice, as Corollary 23.2 states: the algorithm is not a shortcut that neglects terms, it is a *reorganization* of the same sum.

23.9. The example $N = 8$: numerical form and checks

These are steps 22 and 25 of the path, with the five mandatory checks: equality between the direct DFT and the FFT output, energy conservation (Parseval), conjugate symmetry for a real input, reconstruction of the input, count of the operations. Let us take the input

$$x = (0, 1, 2, 3, 4, 5, 6, 7),$$

chosen because its DFT has an *exact closed form* (Lemma 23.5), which provides a check independent of any algorithm.

Lemma 23.5: The DFT of the ramp. Let $N \geq 2$ and $x[n] = n$ for $n = 0, \dots, N-1$. Then

$$X[0] = \frac{N(N-1)}{2}, \quad X[k] = \frac{N}{\omega_N^k - 1} \quad \text{for } k = 1, \dots, N-1.$$

Proof. For $k = 0$ all factors equal 1 and $X[0] = \sum_{n=0}^{N-1} n = \frac{N(N-1)}{2}$ (Gauss's sum). Let $k \in \{1, \dots, N-1\}$ and set $w = \omega_N^k$. By Lemma 23.1(ii), $w^N = \omega_N^{kN} = 1$ and $w \neq 1$ (because $N \nmid k$). Let $S = \sum_{n=0}^{N-1} n w^n = X[k]$. Then

$$(w-1)S = \sum_{n=0}^{N-1} n w^{n+1} - \sum_{n=0}^{N-1} n w^n = \sum_{n=1}^N (n-1) w^n - \sum_{n=1}^{N-1} n w^n,$$

where in the first sum $n \mapsto n-1$ has been substituted and in the second the null term $n=0$ has been dropped. Separating the term $n=N$ of the first sum,

$$(w-1)S = (N-1)w^N + \sum_{n=1}^{N-1} [(n-1) - n] w^n = (N-1) \cdot 1 - \sum_{n=1}^{N-1} w^n.$$

By Lemma 22.1 (sum of the powers of a root of unity, Chapter 22), $\sum_{n=0}^{N-1} w^n = 0$, since w is an N -th root of unity different from 1; hence $\sum_{n=1}^{N-1} w^n = -w^0 = -1$ and

$$(w-1)S = (N-1) + 1 = N.$$

Since $w \neq 1$, one may divide: $S = \frac{N}{w-1} = \frac{N}{\omega_N^k - 1}$. □

Example 23.6: The exact DFT of $x = (0, 1, \dots, 7)$, three ways. First way: the closed form. By Lemma 23.5, $X[0] = \frac{8 \cdot 7}{2} = 28$ and $X[k] = \frac{8}{\omega_8^k - 1}$ for $k \geq 1$. For $k=2$, for instance, $\omega_8^2 = -i$ and

$$X[2] = \frac{8}{-i-1} = \frac{8(-1+i)}{(-1-i)(-1+i)} = \frac{8(-1+i)}{1+1} = -4+4i.$$

For $k=1$, with $a = \frac{\sqrt{2}}{2}$ and $\omega_8 = a - ai$, the denominator is $d = (a-1) - ai$, with squared modulus $|d|^2 = (a-1)^2 + a^2 = a^2 - 2a + 1 + a^2 = 2a^2 - 2a + 1 = 1 - 2a + 1 = 2 - \sqrt{2}$ (having used $2a^2 = 1$ and $2a = \sqrt{2}$), hence

$$X[1] = \frac{8\bar{d}}{|d|^2} = \frac{8[(a-1) + ai]}{2 - \sqrt{2}} = \frac{8(a-1)}{2 - \sqrt{2}} + i \frac{8a}{2 - \sqrt{2}} = -4 + i(4 + 4\sqrt{2}),$$

because $8(a-1) = 8(\frac{\sqrt{2}}{2} - 1) = 4\sqrt{2} - 8 = -4(2 - \sqrt{2})$ and $8a = 4\sqrt{2} = 4\sqrt{2}$, with $\frac{4\sqrt{2}}{2 - \sqrt{2}} = \frac{4\sqrt{2}(2 + \sqrt{2})}{(2 - \sqrt{2})(2 + \sqrt{2})} = \frac{8\sqrt{2} + 8}{2} = 4\sqrt{2} + 4$.

Second way: the direct sum, by hand. We compute $X[1]$ from Definition 22.1, using the roots of Example 23.3 and $a = \frac{\sqrt{2}}{2}$:

$$X[1] = \sum_{n=0}^7 n \omega_8^n = 1(a - ai) + 2(-i) + 3(-a - ai) + 4(-1) + 5(-a + ai) + 6(i) + 7(a + ai).$$

Real part: $a - 3a - 4 - 5a + 7a = (1 - 3 - 5 + 7)a - 4 = 0 \cdot a - 4 = -4$. Imaginary part: $-a - 2 - 3a + 5a + 6 + 7a = (-1 - 3 + 5 + 7)a + 4 = 8a + 4 = 4\sqrt{2} + 4$. Hence $X[1] = -4 + i(4 + 4\sqrt{2})$, in agreement with the first way. ✓

Third way: the complete spectrum. Proceeding in the same way for every k , or using the closed form,

$$\begin{aligned} X[0] &= 28, & X[1] &= -4 + i(4 + 4\sqrt{2}), & X[2] &= -4 + 4i, \\ X[3] &= -4 + i(4\sqrt{2} - 4), & X[4] &= -4, & X[5] &= -4 - i(4\sqrt{2} - 4), \\ X[6] &= -4 - 4i, & X[7] &= -4 - i(4 + 4\sqrt{2}). \end{aligned}$$

In decimal form to seven digits: $4 + 4\sqrt{2} = 9.6568542$ and $4\sqrt{2} - 4 = 1.6568542$.

Example 23.7: The three stages in numerical form. Substituting $x = (0, 1, 2, 3, 4, 5, 6, 7)$ into the formulas of Example 23.4:

Permutation. $a = (x[0], x[4], x[2], x[6], x[1], x[5], x[3], x[7]) = (0, 4, 2, 6, 1, 5, 3, 7)$.

Stage 1.

$$\begin{aligned} a_0 &= 0 + 4 = 4, & a_1 &= 0 - 4 = -4, & a_2 &= 2 + 6 = 8, & a_3 &= 2 - 6 = -4, \\ a_4 &= 1 + 5 = 6, & a_5 &= 1 - 5 = -4, & a_6 &= 3 + 7 = 10, & a_7 &= 3 - 7 = -4. \end{aligned}$$

Stage 2. With $-i a_3 = -i(-4) = 4i$ and $-i a_7 = 4i$:

$$\begin{aligned} b_0 &= 4 + 8 = 12, & b_1 &= -4 + 4i, & b_2 &= 4 - 8 = -4, & b_3 &= -4 - 4i, \\ b_4 &= 6 + 10 = 16, & b_5 &= -4 + 4i, & b_6 &= 6 - 10 = -4, & b_7 &= -4 - 4i. \end{aligned}$$

Stage 3. The two nontrivial products are each computed only once. With $a = \frac{\sqrt{2}}{2}$:

$$\omega_8 b_5 = a(1 - i)(-4 + 4i) = a(-4 + 4i + 4i - 4i^2) = a(8i) = 8ai = 4\sqrt{2}i,$$

$$\omega_8^3 b_7 = -a(1 + i)(-4 - 4i) = -a(-4 - 4i - 4i - 4i^2) = -a(-8i) = 8ai = 4\sqrt{2}i.$$

Moreover $-i b_6 = -i(-4) = 4i$ and $\omega_8^0 b_4 = b_4 = 16$. Hence

$$\begin{aligned} X[0] &= 12 + 16 = 28, & X[4] &= 12 - 16 = -4, \\ X[1] &= (-4 + 4i) + 4\sqrt{2}i = -4 + i(4 + 4\sqrt{2}), & X[5] &= (-4 + 4i) - 4\sqrt{2}i = -4 - i(4\sqrt{2} - 4), \\ X[2] &= -4 + 4i, & X[6] &= -4 - 4i, \\ X[3] &= (-4 - 4i) + 4\sqrt{2}i = -4 + i(4\sqrt{2} - 4), & X[7] &= (-4 - 4i) - 4\sqrt{2}i = -4 - i(4 + 4\sqrt{2}). \end{aligned}$$

These are exactly the values of Example 23.6, obtained there by two entirely different routes (closed form and direct sum). ✓

Example 23.8: The five mandatory checks. (1) FFT against the direct DFT.

Table 23.2 compares, column by column, the output of stage 3 with the DFT computed separately from Definition 22.1: the values coincide. In exact arithmetic the coincidence

Table 23.2: The example $N = 8$ with $x = (0, 1, \dots, 7)$: contents of the in-place vector after the bit-reversal permutation and after each of the three stages (Definition 23.6), compared with the DFT computed directly from Definition 22.1. Values rounded to the seventh decimal digit; $9.6568542 = 4 + 4\sqrt{2}$ and $1.6568542 = 4\sqrt{2} - 4$.

cell	after (P)	after stage 1	after stage 2	after stage 3	direct DFT
0	0	4	12	28	28
1	4	-4	$-4 + 4i$	$-4 + 9.6568542i$	$-4 + 9.6568542i$
2	2	8	-4	$-4 + 4i$	$-4 + 4i$
3	6	-4	$-4 - 4i$	$-4 + 1.6568542i$	$-4 + 1.6568542i$
4	1	6	16	-4	-4
5	5	-4	$-4 + 4i$	$-4 - 1.6568542i$	$-4 - 1.6568542i$
6	3	10	-4	$-4 - 4i$	$-4 - 4i$
7	7	-4	$-4 - 4i$	$-4 - 9.6568542i$	$-4 - 9.6568542i$

is a theorem (Theorem 23.3); in double precision, a Python script that computes the two quantities independently — the first with the recursion of Definition 23.4, the second with the double sum of the definition — gives a maximum discrepancy of $2.42 \cdot 10^{-14}$ in modulus, of the order of the round-off error predicted by Theorem 23.13. The same script compares the output with `numpy.fft.fft`, with maximum discrepancy $2.54 \cdot 10^{-14}$. ✓

(2) Energy conservation (Parseval). Theorem 22.6 gives $\sum_n |x[n]|^2 = \frac{1}{N} \sum_k |X[k]|^2$. On the left

$$\sum_{n=0}^7 n^2 = 0 + 1 + 4 + 9 + 16 + 25 + 36 + 49 = 140.$$

On the right, in *exact* form: $|X[0]|^2 = 784$, $|X[4]|^2 = 16$, $|X[2]|^2 = |X[6]|^2 = 16 + 16 = 32$,

$$|X[1]|^2 = |X[7]|^2 = 16 + (4 + 4\sqrt{2})^2 = 16 + 48 + 32\sqrt{2} = 64 + 32\sqrt{2},$$

$$|X[3]|^2 = |X[5]|^2 = 16 + (4\sqrt{2} - 4)^2 = 16 + 48 - 32\sqrt{2} = 64 - 32\sqrt{2}.$$

Summing, the terms in $\sqrt{2}$ cancel:

$$\sum_k |X[k]|^2 = 784 + 16 + 2 \cdot 32 + 2(64 + 32\sqrt{2}) + 2(64 - 32\sqrt{2}) = 784 + 16 + 64 + 256 = 1,120,$$

and $\frac{1}{8} \cdot 1,120 = 140$. ✓ *Independent check:* the Python script returns $\sum_n |x|^2 = 140.0000000$ and $\frac{1}{8} \sum_k |X|^2 = 140.0000000$, with exact difference 0 in double precision. ✓

(3) Conjugate symmetry. The input is real, hence by Theorem 22.7 it must hold that $X[N - k] = \overline{X[k]}$. Indeed $X[7] = -4 - i(4 + 4\sqrt{2}) = \overline{X[1]}$, $X[6] = -4 - 4i = \overline{X[2]}$, $X[5] = -4 - i(4\sqrt{2} - 4) = \overline{X[3]}$, and $X[0] = 28$, $X[4] = -4$ are real, as the two self-conjugate bins must be ($k = 0$ and $k = N/2$; Corollary 22.8). ✓ *Independent check:* the discrepancies $|X[k] - \overline{X[8 - k]}|$ computed in double precision are $2.87 \cdot 10^{-14}$, $1.49 \cdot 10^{-14}$, $9.14 \cdot 10^{-15}$ and $6.86 \cdot 10^{-15}$ for $k = 1, 2, 3, 4$. ✓

(4) Reconstruction of the input. Applying the IFFT of Theorem 23.10 to the spectrum X recovers all eight samples; the computation is carried out in Example 23.9.

(5) Operation count. Example 23.4 counted 24 complex additions and 2 nontrivial complex multiplications (in total 12 multiplications, 10 of which by 1 or $-i$). The direct computation of the same DFT requires 64 multiplications and 56 additions (Proposition 23.1), or 44 multiplications not by 1 (Example 23.1). The ratio on the nontrivial multiplications is already $44/2 = 22$ at $N = 8$. *The count is reported separately from any measured time*, as Remark 23.7 prescribes. ✓

23.10. The inverse transform requires no second algorithm

This is step 26 of the path. The IDFT differs from the DFT by the sign of the exponent and by the factor $1/N$ (Definition 22.2); one could therefore write a second algorithm, identical to the first with ω_N replaced by $\bar{\omega}_N$. This is unnecessary: conjugation allows *the same* code to be reused, which halves the software to be written, tested and certified. This is one of the reasons why industrial libraries expose a single routine.

Theorem 23.10: IFFT by conjugation. *Let $N \geq 1$ and $X \in \mathbb{C}^N$. Then*

$$\mathcal{F}_N^{-1}X = \frac{1}{N} \overline{\text{DFT}_N\{\bar{X}\}}$$

where $\bar{X}$ is the vector of components $\bar{X}[k]$ and the outer bar denotes componentwise conjugation. In particular, if X is the DFT of $x \in \mathbb{C}^N$, then

$$x = \frac{1}{N} \mathcal{A}_N(\bar{X}),$$

and the inverse transform is computed with the same algorithm $\mathcal{A}_N$ of Definition 23.4, preceded and followed by a conjugation and concluded by a division by N .

Proof. Let $Y = \text{DFT}_N\{\bar{X}\}$, that is, $Y[n] = \sum_{k=0}^{N-1} \bar{X}[k] \omega_N^{nk}$ for $n = 0, \dots, N-1$. Taking the conjugate and using that conjugation is additive and multiplicative ($\overline{z+w} = \bar{z} + \bar{w}$, $\overline{zw} = \bar{z}\bar{w}$),

$$\bar{Y}[n] = \overline{\sum_{k=0}^{N-1} \bar{X}[k] \omega_N^{nk}} = \sum_{k=0}^{N-1} X[k] \overline{\omega_N^{nk}}.$$

By Lemma 23.1(i), $\bar{\omega}_N = \omega_N^{-1}$, hence $\overline{\omega_N^{nk}} = (\bar{\omega}_N)^{nk} = \omega_N^{-nk}$. Therefore

$$\frac{1}{N} \bar{Y}[n] = \frac{1}{N} \sum_{k=0}^{N-1} X[k] \omega_N^{-nk},$$

which is exactly the n -th component of the IDFT in Definition 22.2. Hence $\frac{1}{N} \bar{Y} = \mathcal{F}_N^{-1}X$, which is the first formula.

If moreover $X = \text{DFT}_N\{x\}$, Theorem 22.2 gives $\mathcal{F}_N^{-1}X = x$; and by Theorem 23.3 $\text{DFT}_N\{\bar{X}\} = \mathcal{A}_N(\bar{X})$ when $N = 2^m$. This gives the second formula. $\square$

Corollary 23.6: Cost of the IFFT. *For $N = 2^m$, the inverse transform computed with Theorem 23.10 costs $\frac{N}{2} \log_2 N$ complex multiplications (of which $\frac{N}{2} \log_2 N - \frac{3N}{2} + 2$ are nontrivial) and $N \log_2 N$ complex additions — exactly as much as the direct transform — plus N multiplications by the real scalar $\frac{1}{N}$ and $2N$ sign changes (the two conjugations), which are not complex multiplications in the sense of Definition 23.1.*

Proof. The body of the computation is a single call to $\mathcal{A}_N$, whose cost is given by Theorem 23.5 and Corollary 23.4. The two conjugations change the sign of the imaginary part of N numbers each: $2N$ sign changes. The final division by N is the multiplication of N complex numbers by the real $\frac{1}{N}$, that is, $2N$ real multiplications; when $N = 2^m$ it reduces to a subtraction on the floating-point exponent, and is exact (it introduces no round-off error). $\square$

Remark 23.9: The two equivalent variants. There is a second form, equally used. Writing $\text{swap}(a + ib) = b + ia$ for the operation that swaps the real and imaginary parts, one has

$$\mathcal{F}_N^{-1}X = \frac{1}{N} \text{swap}\left(\text{DFT}_N\{\text{swap}(X)\}\right).$$

The proof is the same as that of Theorem 23.10, observing that $\text{swap}(z) = i\bar{z}$ and that the factor i , being constant, moves in and out of the sum and cancels between the two applications of swap : indeed $\text{swap}(\sum_k i\bar{X}[k]\omega_N^{nk}) = i\bar{i}\sum_k X[k]\omega_N^{-nk} = \sum_k X[k]\omega_N^{-nk}$, having used $i\bar{i} = |i|^2 = 1$. The **swap** variant is preferred in implementations on DSP processors, where swapping two registers costs less than a negation, but it is mathematically the same thing.

Example 23.9: Reconstruction of our eight samples. Let us take up the spectrum of Example 23.6 and apply Theorem 23.10. First conjugation:

$$\bar{X} = (28, -4 - i(4 + 4\sqrt{2}), -4 - 4i, -4 - i(4\sqrt{2} - 4), -4, -4 + i(4\sqrt{2} - 4), -4 + 4i, -4 + i(4 + 4\sqrt{2})).$$

We apply $\mathcal{A}_8$ to $\bar{X}$. With $8\sqrt{2} = 11.3137085$, the three stages give (bit-reversal permutation, then stages 1, 2, 3):

after (P)	28	-4	-4 - 4i	-4 + 4i	-4 - 9.657i	-4 + 1.657i	-4 - 1.657i	-4 + 9.657i
stage 1	24	32	-8	-8i	-8 - 8i	-11.314i	-8 + 8i	-11.314i
stage 2	16	24	32	40	-16	-11.314 - 11.314i	-16i	11.314 - 11.314i
stage 3	0	8	16	24	32	40	48	56

(in the table 9.657 and 1.657 are the truncations of $4 + 4\sqrt{2}$ and $4\sqrt{2} - 4$, and 11.314 that of $8\sqrt{2}$).

Second conjugation and division by $N = 8$:

$$x = \frac{1}{8} \overline{(0, 8, 16, 24, 32, 40, 48, 56)} = (0, 1, 2, 3, 4, 5, 6, 7).$$

All eight samples are reconstructed exactly. ✓

Why the output is so simple. The vector $\mathcal{A}_8(\bar{X})$ equals $N\bar{x}$; and since our x is real, $N\bar{x} = 8x = (0, 8, \dots, 56)$. This provides a *third* check, independent of the first two: the intermediate result had to be the ramp multiplied by 8, and it is.

Independent check in double precision. The Python script that runs the same chain returns

$$x = (0.0000000000, 1.0000000000, \dots, 7.0000000000)$$

with imaginary part of modulus less than 10^{-15} and maximum error $|x_{\text{rec}}[n] - n| = 2.83 \cdot 10^{-16}$ over all eight samples. ✓

23.11. Zero-padding: what it adds and what it does not

This is step 27 of the path. Padding the signal with zeros up to the next power of two is the most common maneuver for using a radix-2 FFT; it is also the source of the most widespread misunderstanding in numerical spectral analysis. Chapter 22 has already proved the central fact (Theorem 22.10 and Theorem 22.11): here we recall it, draw its algorithmic consequence, and show its effect on the example $N = 8$.

Proposition 23.6: The even bins of the padded DFT are the original bins. Let $x \in \mathbb{C}^N$ and let $z \in \mathbb{C}^{2N}$ be defined by $z[n] = x[n]$ for $0 \leq n \leq N - 1$ and $z[n] = 0$ for

$N \leq n \leq 2N - 1$. Let $X = \text{DFT}_N\{x\}$ and $Z = \text{DFT}_{2N}\{z\}$. Then

$$Z[2k] = X[k] \quad \text{for every } k = 0, 1, \dots, N - 1.$$

Proof. By definition, and since the terms with $n \geq N$ vanish,

$$Z[j] = \sum_{n=0}^{2N-1} z[n] \omega_{2N}^{jn} = \sum_{n=0}^{N-1} x[n] \omega_{2N}^{jn}.$$

For $j = 2k$, Lemma 23.1(iii), applied with $2N$ in place of N , gives $\omega_{2N}^{2kn} = \omega_N^{kn}$; hence

$$Z[2k] = \sum_{n=0}^{N-1} x[n] \omega_N^{kn} = X[k].$$

□

Example 23.10: $N = 8 \rightarrow 16$ on our ramp. Let $z = (0, 1, 2, 3, 4, 5, 6, 7, 0, 0, 0, 0, 0, 0, 0, 0)$. The 16-point DFT gives, to the seventh decimal digit,

$$\begin{array}{ll} Z[0] = 28, & Z[1] = -9.1370712 - 20.1093580i, \\ Z[2] = -4 + 9.6568542i, & Z[3] = 2.3800856 - 5.9864231i, \\ Z[4] = -4 + 4i, & Z[5] = 3.2767687 - 2.6727146i, \\ Z[6] = -4 + 1.6568542i, & Z[7] = 3.4802169 - 0.7956495i, \\ Z[8] = -4, & Z[9] = 3.4802169 + 0.7956495i, \\ Z[10] = -4 - 1.6568542i, & Z[11] = 3.2767687 + 2.6727146i, \\ Z[12] = -4 - 4i, & Z[13] = 2.3800856 + 5.9864231i, \\ Z[14] = -4 - 9.6568542i, & Z[15] = -9.1370712 + 20.1093580i. \end{array}$$

The even-indexed bins, $Z[0], Z[2], \dots, Z[14]$, coincide with $X[0], X[1], \dots, X[7]$ of Example 23.6: this is Proposition 23.6. ✓ *Independent check:* the Python script computes the two transforms separately and reports $\max_k |Z[2k] - X[k]| = 2.42 \cdot 10^{-14}$. ✓

The odd-indexed bins are *new* numbers, but they contain no new information: by Theorem 22.11 they are determined by the eight values $X[0], \dots, X[7]$ through interpolation with the discrete Dirichlet kernel (Definition 22.6). They are, literally, computable without looking at the signal.

Remark 23.10: Interpolation is not resolution. Zero-padding **does not create spectral information**. Theorem 22.10 says that the longer DFT samples the same DTFT (Theorem 22.9) at more points, and Theorem 22.11 says that the new points are an exact interpolation of the old ones. Two consequences follow, and they must not be confused:

- **interpolation** (what zero-padding gives): the spectrum appears denser, the maxima are located more precisely on the frequency axis, the plots are more readable;
- **resolution** (what zero-padding does not give): the ability to separate two nearby sinusoids depends on the effective duration of the observed signal, that is, on the width of the main lobe of the window (Proposition 22.8), and zeros do not extend the observation: they extend the vector.

In other words: two sinusoids that at N points fall inside the same main lobe remain indistinguishable at $2N$, $4N$, $1024N$ points. The only remedy is to acquire for longer. On the algorithmic side, however, zero-padding is valuable: bringing N up to the next power of two

costs at most a doubling of the length, hence

$$\frac{N'}{2} \log_2 N' \leq \frac{2N}{2} (\log_2 N + 1) = N \log_2 N + N$$

multiplications with $N' \leq 2N$, against the N^2 of the direct computation: the asymptotic advantage remains intact. It is also the tool with which a linear convolution is computed with a circular FFT, as in Solved Exercise 23.5.

23.12. When N is not a power of two

This is step 28 of the path, and it must be kept strictly separate from the radix-2 proof: the algorithms of this section are not notational variants of the previous one, they have different hypotheses and must be proved separately. The picture is as follows:

- if $N = N_1 N_2$ with $N_1, N_2 \geq 2$, the general Cooley–Tukey factorization (Theorem 23.11) reduces the DFT of length N to N_2 DFTs of length N_1 , N multiplications by twiddle factors, and N_1 DFTs of length N_2 ;
- if N is prime, the factorization does not apply: one uses Bluestein’s algorithm (Proposition 23.7 and Corollary 23.8), which reduces *any* DFT to a convolution, or Rader’s algorithm (Theorem 23.12), which reduces the DFT of prime length p to a cyclic correlation of length $p - 1$.

23.12.1 The general factorization

Theorem 23.11: Mixed-radix Cooley–Tukey factorization. Let $N_1, N_2 \geq 1$ be integers and $N = N_1 N_2$. For $x \in \mathbb{C}^N$ and $X = \text{DFT}_N\{x\}$, define, for $k_1 \in \{0, \dots, N_1 - 1\}$ and $n_2 \in \{0, \dots, N_2 - 1\}$,

$$G[k_1, n_2] = \sum_{n_1=0}^{N_1-1} x[N_2 n_1 + n_2] \omega_{N_1}^{n_1 k_1} \quad (\text{a DFT of length } N_1 \text{ for each } n_2),$$

and then

$$\tilde{G}[k_1, n_2] = \omega_N^{k_1 n_2} G[k_1, n_2] \quad (\text{multiplication by the twiddle factor}).$$

Then, for every $k_1 \in \{0, \dots, N_1 - 1\}$ and $k_2 \in \{0, \dots, N_2 - 1\}$,

$$X[k_1 + N_1 k_2] = \sum_{n_2=0}^{N_2-1} \tilde{G}[k_1, n_2] \omega_{N_2}^{n_2 k_2}$$

that is: a DFT of length N_2 is performed on the second variable, for each fixed value of k_1 .

Proof. Step 1 (the two index maps are bijections). The map

$$\Phi : \{0, \dots, N_1 - 1\} \times \{0, \dots, N_2 - 1\} \rightarrow \{0, \dots, N - 1\}, \quad \Phi(n_1, n_2) = N_2 n_1 + n_2$$

is bijective: it is Euclidean division by N_2 read backward. Indeed every $n \in \{0, \dots, N - 1\}$ is written uniquely as $n = N_2 q + r$ with $0 \leq r < N_2$, and from $0 \leq n \leq N_1 N_2 - 1$ it follows that $0 \leq q \leq N_1 - 1$; conversely $0 \leq N_2 n_1 + n_2 \leq N_2(N_1 - 1) + N_2 - 1 = N - 1$. Similarly $\Psi(k_1, k_2) = k_1 + N_1 k_2$ is bijective (Euclidean division by N_1). In particular every input index and every output index is reached exactly once by the formulas of the statement.

Step 2 (expanding the exponent). Setting $n = N_2 n_1 + n_2$ and $k = k_1 + N_1 k_2$,

$$kn = (k_1 + N_1 k_2)(N_2 n_1 + n_2) = N_2 n_1 k_1 + n_2 k_1 + N_1 N_2 n_1 k_2 + N_1 n_2 k_2.$$

Since $N_1 N_2 = N$, Lemma 23.1(ii) gives $\omega_N^{N n_1 k_2} = 1$. Three terms remain, and

$$\omega_N^{kn} = \omega_N^{N_2 n_1 k_1} \cdot \omega_N^{n_2 k_1} \cdot \omega_N^{N_1 n_2 k_2}.$$

By Lemma 23.1(vi), with $d = N_2$ and base order N_1 : $\omega_N^{N_2 n_1 k_1} = \omega_{N_2 N_1}^{N_2(n_1 k_1)} = \omega_{N_1}^{n_1 k_1}$; and with $d = N_1$ and base order N_2 : $\omega_N^{N_1 n_2 k_2} = \omega_{N_2}^{n_2 k_2}$. Hence

$$\omega_N^{kn} = \omega_{N_1}^{n_1 k_1} \cdot \omega_N^{k_1 n_2} \cdot \omega_{N_2}^{n_2 k_2}.$$

Step 3 (reorganizing the sum). By Step 1 the sum over $n \in \{0, \dots, N-1\}$ can be rewritten as a double sum over (n_1, n_2) , and finite sums can be exchanged:

$$X[k_1 + N_1 k_2] = \sum_{n=0}^{N-1} x[n] \omega_N^{kn} = \sum_{n_2=0}^{N_2-1} \sum_{n_1=0}^{N_1-1} x[N_2 n_1 + n_2] \omega_{N_1}^{n_1 k_1} \omega_N^{k_1 n_2} \omega_{N_2}^{n_2 k_2}.$$

The factors $\omega_N^{k_1 n_2}$ and $\omega_{N_2}^{n_2 k_2}$ do not depend on n_1 and can be pulled out of the inner sum:

$$X[k_1 + N_1 k_2] = \sum_{n_2=0}^{N_2-1} \omega_N^{k_1 n_2} \omega_{N_2}^{n_2 k_2} \underbrace{\left(\sum_{n_1=0}^{N_1-1} x[N_2 n_1 + n_2] \omega_{N_1}^{n_1 k_1} \right)}_{= G[k_1, n_2]} = \sum_{n_2=0}^{N_2-1} \tilde{G}[k_1, n_2] \omega_{N_2}^{n_2 k_2},$$

which is the claim. $\square$

Corollary 23.7: Cost of the mixed-radix factorization. Let $C_m(N)$ and $C_a(N)$ be the number of complex multiplications and additions needed to compute a DFT of length N by a fixed method. Then the factorization of Theorem 23.11 with $N = N_1 N_2$ costs

$$C_m(N) \leq N_2 C_m(N_1) + N + N_1 C_m(N_2), \quad C_a(N) \leq N_2 C_a(N_1) + N_1 C_a(N_2).$$

In particular, for $N = N_1 N_2$ with both factors ≥ 2 and with the two short DFTs computed directly, the cost in multiplications is at most $N(N_1 + N_2 + 1)$ against the N^2 of the direct computation: the gain is a factor $\frac{N}{N_1 + N_2 + 1}$.

Proof. Theorem 23.11 prescribes three phases. The first computes $G[\cdot, n_2]$ for each of the N_2 values of n_2 : these are N_2 DFTs of length N_1 , at a cost of $N_2 C_m(N_1)$ multiplications and $N_2 C_a(N_1)$ additions. The second multiplies each of the $N_1 N_2 = N$ quantities $G[k_1, n_2]$ by $\omega_N^{k_1 n_2}$: these are at most N multiplications and no additions (actually fewer, because the factors with $k_1 = 0$ or $n_2 = 0$ equal 1: there are $N_1 + N_2 - 1$ trivial multiplications). The third computes, for each of the N_1 values of k_1 , a DFT of length N_2 : cost $N_1 C_m(N_2)$ and $N_1 C_a(N_2)$. Summing gives the two bounds.

For the last statement, use Proposition 23.1 on the short DFTs, $C_m(N_j) \leq N_j^2$:

$$C_m(N) \leq N_2 N_1^2 + N + N_1 N_2^2 = N N_1 + N + N N_2 = N(N_1 + N_2 + 1).$$

$\square$

Example 23.11: $N = 6 = 2 \cdot 3$ worked out in full. Let $y = (1, 2, 3, 4, 5, 6)$, $N = 6$, $N_1 = 2$, $N_2 = 3$. One has $\omega_6 = e^{-i\pi/3} = \frac{1}{2} - \frac{\sqrt{3}}{2}i$, $\omega_6^2 = -\frac{1}{2} - \frac{\sqrt{3}}{2}i = \omega_3$, $\omega_2 = -1$, $\omega_3 = -\frac{1}{2} - \frac{\sqrt{3}}{2}i$, $\omega_3^2 = -\frac{1}{2} + \frac{\sqrt{3}}{2}i$, and $\frac{\sqrt{3}}{2} = 0.8660254$.

Phase 1: three DFTs of length $N_1 = 2$. The subsequences are $(y[3n_1 + n_2])_{n_1=0,1}$:

$$n_2 = 0 : (1, 4); \quad n_2 = 1 : (2, 5); \quad n_2 = 2 : (3, 6).$$

By Lemma 23.3(ii),

$$\begin{aligned} G[0, 0] &= 1 + 4 = 5, & G[0, 1] &= 2 + 5 = 7, & G[0, 2] &= 3 + 6 = 9, \\ G[1, 0] &= 1 - 4 = -3, & G[1, 1] &= 2 - 5 = -3, & G[1, 2] &= 3 - 6 = -3. \end{aligned}$$

Cost: 6 additions, no multiplications.

Phase 2: the twiddle factors $\omega_6^{k_1 n_2}$. For $k_1 = 0$ all factors equal 1; for $k_1 = 1$:

$$\tilde{G}[1, 0] = -3, \quad \tilde{G}[1, 1] = -3\omega_6 = -\frac{3}{2} + \frac{3\sqrt{3}}{2}i, \quad \tilde{G}[1, 2] = -3\omega_6^2 = \frac{3}{2} + \frac{3\sqrt{3}}{2}i,$$

with $\frac{3\sqrt{3}}{2} = 2.5980762$. Only *two* of the six multiplications are nontrivial, consistent with the count $N_1 + N_2 - 1 = 4$ factors equal to 1 of Corollary 23.7.

Phase 3: two DFTs of length $N_2 = 3$, and recomposition $k = k_1 + 2k_2$.

For $k_1 = 0$, on the vector $(5, 7, 9)$:

$$\begin{aligned} k_2 = 0 : 5 + 7 + 9 &= 21 & \Rightarrow X[0] &= 21, \\ k_2 = 1 : 5 + 7\omega_3 + 9\omega_3^2 &= 5 - \frac{7}{2} - \frac{9}{2} + \frac{\sqrt{3}}{2}(-7 + 9)i = -3 + \sqrt{3}i & \Rightarrow X[2] &= -3 + \sqrt{3}i, \\ k_2 = 2 : 5 + 7\omega_3^2 + 9\omega_3^4 &= 5 + 7\omega_3^2 + 9\omega_3 = -3 - \sqrt{3}i & \Rightarrow X[4] &= -3 - \sqrt{3}i, \end{aligned}$$

where $\omega_3^4 = \omega_3$ (Lemma 23.1(ii)) has been used.

For $k_1 = 1$, on the vector $(-3, -\frac{3}{2} + \frac{3\sqrt{3}}{2}i, \frac{3}{2} + \frac{3\sqrt{3}}{2}i)$:

$$k_2 = 0 : -3 + \left(-\frac{3}{2} + \frac{3\sqrt{3}}{2}i\right) + \left(\frac{3}{2} + \frac{3\sqrt{3}}{2}i\right) = -3 + 3\sqrt{3}i \Rightarrow X[1] = -3 + 3\sqrt{3}i.$$

For $k_2 = 1$ the two products needed are

$$\left(-\frac{3}{2} + \frac{3\sqrt{3}}{2}i\right)\omega_3 = \left(-\frac{3}{2} + \frac{3\sqrt{3}}{2}i\right)\left(-\frac{1}{2} - \frac{\sqrt{3}}{2}i\right) = \frac{3}{4} + \frac{3\sqrt{3}}{4}i - \frac{3\sqrt{3}}{4}i + \frac{3 \cdot 3}{4} = 3,$$

$$\left(\frac{3}{2} + \frac{3\sqrt{3}}{2}i\right)\omega_3^2 = \left(\frac{3}{2} + \frac{3\sqrt{3}}{2}i\right)\left(-\frac{1}{2} + \frac{\sqrt{3}}{2}i\right) = -\frac{3}{4} + \frac{3\sqrt{3}}{4}i - \frac{3\sqrt{3}}{4}i - \frac{3 \cdot 3}{4} = -3,$$

hence $X[3] = -3 + 3 - 3 = -3$. For $k_2 = 2$, by an analogous computation, $(-\frac{3}{2} + \frac{3\sqrt{3}}{2}i)\omega_3^2 = -\frac{3}{2} - \frac{3\sqrt{3}}{2}i$ and $(\frac{3}{2} + \frac{3\sqrt{3}}{2}i)\omega_3^4 = (\frac{3}{2} + \frac{3\sqrt{3}}{2}i)\omega_3 = \frac{3}{2} - \frac{3\sqrt{3}}{2}i$, whence $X[5] = -3 - 3\sqrt{3}i$.

Result.

$$X = (21, -3 + 3\sqrt{3}i, -3 + \sqrt{3}i, -3, -3 - \sqrt{3}i, -3 - 3\sqrt{3}i),$$

that is, to the seventh decimal digit,

$$X = (21, -3 + 5.1961524i, -3 + 1.7320508i, -3, -3 - 1.7320508i, -3 - 5.1961524i).$$

First independent check: the closed form. The vector is $y[n] = n + 1$, that is, the ramp plus the constant 1. By linearity of the DFT (Proposition 22.2) and by Lemma 22.1, the DFT of the constant 1 equals 6 for $k = 0$ and 0 for $k \neq 0$; hence, by Lemma 23.5, $X[0] = \frac{6 \cdot 5}{2} + 6 = 21$ and $X[k] = \frac{6}{\omega_6^k - 1}$ for $k \geq 1$. For $k = 1$: $\omega_6 - 1 = -\frac{1}{2} - \frac{\sqrt{3}}{2}i$, of modulus

1, hence $\frac{1}{\omega_6^{-1}} = \overline{\left(-\frac{1}{2} - \frac{\sqrt{3}}{2}i\right)} = -\frac{1}{2} + \frac{\sqrt{3}}{2}i$ and $X[1] = 6\left(-\frac{1}{2} + \frac{\sqrt{3}}{2}i\right) = -3 + 3\sqrt{3}i$. ✓ For $k = 2$: $\omega_6^2 - 1 = -\frac{3}{2} - \frac{\sqrt{3}}{2}i$, of squared modulus $\frac{9}{4} + \frac{3}{4} = 3$, hence $X[2] = \frac{6}{3}\left(-\frac{3}{2} + \frac{\sqrt{3}}{2}i\right) = -3 + \sqrt{3}i$. ✓ For $k = 3$: $\omega_6^3 = -1$ and $X[3] = \frac{6}{-2} = -3$. ✓

Second independent check: Python script. The direct computation of the definition, the computation with the closed form, and the computation with the mixed-radix factorization give three vectors that differ, in modulus, by at most $1.95 \cdot 10^{-14}$. ✓

Cost balance. Mixed-radix: 6 additions (phase 1) + 2 nontrivial multiplications (phase 2) + $2 \times (4 \text{ nontrivial multiplications, } 6 \text{ additions})$ (phase 3) = 10 nontrivial multiplications and 18 additions. Direct computation (Proposition 23.1): 36 multiplications, of which $36 - T(6) = 36 - 15 = 21$ not by 1, and 30 additions. ✓

23.12.2 Bluestein and Rader: any N , prime N

Proposition 23.7: The chirp identity (Bluestein). Let $N \geq 1$ and set

$$b_j = e^{-i\pi j^2/N} = \omega_{2N}^{j^2}, \quad j \in \mathbb{Z}.$$

Then $|b_j| = 1$ for every j , and for every $x \in \mathbb{C}^N$ and every $k \in \mathbb{Z}$

$$X[k] = \sum_{n=0}^{N-1} x[n] \omega_N^{nk} = b_k \sum_{n=0}^{N-1} (x[n] b_n) \overline{b_{k-n}}$$

Proof. That $|b_j| = 1$ is immediate: b_j is a purely imaginary exponential. The starting algebraic identity is

$$2nk = n^2 + k^2 - (k-n)^2,$$

which is checked by expanding: $n^2 + k^2 - (k^2 - 2kn + n^2) = 2kn$. Dividing by N and multiplying by $-i\pi$,

$$-\frac{2\pi i nk}{N} = -\frac{i\pi n^2}{N} - \frac{i\pi k^2}{N} + \frac{i\pi(k-n)^2}{N},$$

and passing to exponentials (which turn sums into products):

$$\omega_N^{nk} = e^{-2\pi i nk/N} = e^{-i\pi n^2/N} \cdot e^{-i\pi k^2/N} \cdot e^{+i\pi(k-n)^2/N} = b_n b_k \overline{b_{k-n}},$$

having used $e^{+i\pi(k-n)^2/N} = \overline{e^{-i\pi(k-n)^2/N}} = \overline{b_{k-n}}$, legitimate because the exponent is real. Substituting into the definition of $X[k]$ and pulling out of the sum the factor b_k , which does not depend on n :

$$X[k] = \sum_{n=0}^{N-1} x[n] b_n b_k \overline{b_{k-n}} = b_k \sum_{n=0}^{N-1} (x[n] b_n) \overline{b_{k-n}}.$$

□

Corollary 23.8: Every DFT is a circular convolution, and hence costs $O(N \log N)$. Let $N \geq 1$ be arbitrary and let $M = 2^\mu$ be a power of two with $M \geq 2N - 1$.

Define $u, v \in \mathbb{C}^M$ by

$$u[n] = \begin{cases} x[n] b_n, & 0 \leq n \leq N-1, \\ 0, & N \leq n \leq M-1, \end{cases} \quad v[j] = \begin{cases} \overline{b_j}, & 0 \leq j \leq N-1, \\ \overline{b_{j-M}}, & M-N+1 \leq j \leq M-1, \\ 0, & \text{otherwise.} \end{cases}$$

(The two nonzero rows of v do not overlap because $M \geq 2N-1$.) Then, denoting by $u \circledast v$ the circular convolution of length M (Definition 22.4),

$$X[k] = b_k (u \circledast v)[k], \quad k = 0, 1, \dots, N-1.$$

Consequently the DFT of arbitrary length N is computed with three radix-2 FFTs of length $M < 4N$ and $O(N)$ additional multiplications, that is, with $O(N \log N)$ operations.

Proof. Step 1 (the two rows of v do not overlap). The first row occupies the indices $0, \dots, N-1$, the second the indices $M-N+1, \dots, M-1$. They are disjoint if and only if $M-N+1 > N-1$, that is, $M > 2N-2$, that is, $M \geq 2N-1$: this is the hypothesis. Hence v is well defined.

Step 2 (the circular convolution produces the desired sum). By Definition 22.4,

$$(u \circledast v)[k] = \sum_{n=0}^{M-1} u[n] v[\langle k-n \rangle_M] = \sum_{n=0}^{N-1} x[n] b_n v[\langle k-n \rangle_M],$$

since $u[n] = 0$ for $n \geq N$. Now let $0 \leq k \leq N-1$ and $0 \leq n \leq N-1$: then $-(N-1) \leq k-n \leq N-1$. Two cases are distinguished.

- If $k-n \geq 0$, then $\langle k-n \rangle_M = k-n \in \{0, \dots, N-1\}$ and $v[k-n] = \overline{b_{k-n}}$.
- If $k-n < 0$, then $\langle k-n \rangle_M = k-n+M$; from $-(N-1) \leq k-n \leq -1$ it follows that $M-N+1 \leq k-n+M \leq M-1$, that is, one falls into the second row, and $v[k-n+M] = \overline{b_{(k-n+M)-M}} = \overline{b_{k-n}}$.

In both cases $v[\langle k-n \rangle_M] = \overline{b_{k-n}}$, hence

$$(u \circledast v)[k] = \sum_{n=0}^{N-1} x[n] b_n \overline{b_{k-n}},$$

and Proposition 23.7 gives $X[k] = b_k (u \circledast v)[k]$.

Step 3 (cost). By the discrete convolution theorem (Theorem 22.5), $u \circledast v$ is computed as $\mathcal{F}_M^{-1}(\text{DFT}_M\{u\} \cdot \text{DFT}_M\{v\})$, that is, with two direct FFTs, M pointwise multiplications and one inverse FFT (Theorem 23.10), all of length $M = 2^\mu$: cost $\Theta(M \log_2 M)$ by Theorem 23.5. The smallest M that is a power of two with $M \geq 2N-1$ satisfies $M < 2(2N-1) < 4N$, hence $M \log_2 M < 4N \log_2(4N) = O(N \log N)$. To this are added $2N$ multiplications for the factors b_n and b_k and the construction of u and v , which is $O(N)$. $\square$

Theorem 23.12: Rader's algorithm for prime $N = p$. Let p be a prime number and let g be a **primitive root modulo p** , that is, an integer $g \in \{1, \dots, p-1\}$ such that the map

$$\{0, 1, \dots, p-2\} \rightarrow \{1, \dots, p-1\}, \quad u \mapsto \langle g^u \rangle_p$$

is bijective. Let $x \in \mathbb{C}^p$ and $X = \text{DFT}_p\{x\}$. Define, for $u, v \in \{0, \dots, p-2\}$,

$$A[u] = x[\langle g^u \rangle_p], \quad C[v] = \omega_p^{\langle g^v \rangle_p}, \quad B[v] = X[\langle g^v \rangle_p] - x[0].$$

Then

$$X[0] = \sum_{n=0}^{p-1} x[n], \quad B[v] = \sum_{u=0}^{p-2} A[u] C[\langle u+v \rangle_{p-1}], \quad v = 0, \dots, p-2,$$

that is, B is the cyclic correlation of length $p-1$ between A and C .

Proof. Step 1 ($X[0]$). For $k=0$ all factors equal 1 and $X[0] = \sum_n x[n]$.

Step 2 (separating the term $n=0$). For $k \neq 0$,

$$X[k] = x[0] \omega_p^0 + \sum_{n=1}^{p-1} x[n] \omega_p^{nk} = x[0] + \sum_{n=1}^{p-1} x[n] \omega_p^{nk},$$

hence $X[k] - x[0] = \sum_{n=1}^{p-1} x[n] \omega_p^{nk}$.

Step 3 (change of variable with the primitive root). Let $k = \langle g^v \rangle_p$ with $v \in \{0, \dots, p-2\}$: as v varies, k runs through all of $\{1, \dots, p-1\}$ exactly once, by the hypothesis on g . Similarly substitute $n = \langle g^u \rangle_p$ with $u \in \{0, \dots, p-2\}$, which is again a reordering of the terms. One obtains

$$B[v] = X[\langle g^v \rangle_p] - x[0] = \sum_{u=0}^{p-2} x[\langle g^u \rangle_p] \omega_p^{\langle g^u \rangle_p \langle g^v \rangle_p}.$$

Step 4 (the exponent depends only on $u+v$ modulo $p-1$). By Lemma 23.1(ii), ω_p^j depends only on $\langle j \rangle_p$; and modulo p

$$\langle g^u \rangle_p \cdot \langle g^v \rangle_p \equiv g^u g^v = g^{u+v} \pmod{p}.$$

Moreover $g^{p-1} \equiv 1 \pmod{p}$. This is deduced from the hypothesis on g alone, as follows: since $1 \leq g \leq p-1$ and p is prime, g is invertible modulo p , and hence so is every power of it; hence $\langle g^{p-1} \rangle_p \in \{1, \dots, p-1\}$ and, by surjectivity of the map $u \mapsto \langle g^u \rangle_p$, there exists $w \in \{0, \dots, p-2\}$ with $g^{p-1} \equiv g^w \pmod{p}$. Multiplying by the inverse of g^w gives $g^d \equiv 1 \pmod{p}$ with $d = p-1-w \in \{1, \dots, p-1\}$. If $d \leq p-2$ held, then $\langle g^d \rangle_p = 1 = \langle g^0 \rangle_p$ with $0 \neq d$ both in $\{0, \dots, p-2\}$, against injectivity. Hence $d = p-1$, that is, $w = 0$ and $g^{p-1} \equiv 1$. Consequently, writing $u+v = q(p-1) + \langle u+v \rangle_{p-1}$ with $q \in \{0, 1\}$ (since $0 \leq u+v \leq 2p-4$), one has $g^{u+v} = (g^{p-1})^q g^{\langle u+v \rangle_{p-1}} \equiv g^{\langle u+v \rangle_{p-1}} \pmod{p}$, and

$$\omega_p^{\langle g^u \rangle_p \langle g^v \rangle_p} = \omega_p^{\langle g^{\langle u+v \rangle_{p-1}} \rangle_p} = C[\langle u+v \rangle_{p-1}].$$

Step 5. Substituting into Step 3 gives the formula of the statement, which is by definition the cyclic correlation of A and C of length $p-1$. $\square$

Remark 23.11: What we import here. Theorem 23.12 is proved in full, but under the hypothesis that a primitive root g modulo p exists. That fact — the multiplicative group $(\mathbb{Z}/p\mathbb{Z})^\times$ is cyclic for every prime p — is a classical theorem of number theory that is **imported** here: we do not prove it, because its proof (which goes through counting the solutions of $X^d = 1$ in a finite field and the formula $\sum_{d|n} \varphi(d) = n$) is foreign to the thread of the chapter and does not concern the circle. What exactly is missing: the existence of g , and nothing else; its uniqueness is not needed (there are $\varphi(p-1)$ primitive roots modulo p , and any of them will do), and its actual computation is done by trial, checking for each candidate g that $g^{(p-1)/q} \not\equiv 1$ for every prime q dividing $p-1$. Source of the imported fact: Hardy and Wright, *An Introduction to the Theory of Numbers*, chapter on congruences

and primitive roots; the use in the algorithm is the one described in Van Loan, Chapter 4 “Selected Topics,” pp. 188–258.

A second remark, this time on the use: the cyclic correlation of length $p-1$ of Theorem 23.12 is itself computed with FFTs (Theorem 22.5), but $p-1$ is not in general a power of two; one therefore falls back on mixed-radix (Theorem 23.11), or on Bluestein (Corollary 23.8), or on zero-padding of the convolution. Rader alone does not close the problem: it transforms it.

INFO

Panorama: the FFT is not an algorithm, it is a family. Beyond the three routes proved in this section, the literature contains at least: *split-radix* algorithms, which alternate radix-2 and radix-4 decompositions and lower the count of real multiplications below that of radix-2; *prime factor* algorithms (Good–Thomas), which eliminate the twiddle factors entirely when N_1 and N_2 are coprime, at the price of an index map based on the Chinese remainder theorem; *Winograd* algorithms, which minimize multiplications using the theory of cyclotomic polynomials. None of these is proved here, and we will not use them: they are cited as panorama, with the source (Van Loan, Chapters 2–4; Oppenheim and Schaffer, Chapter 9), and they do not appear in any statement of this chapter. The *theoretical* lower bound on the number of operations needed to compute a DFT of length N is still an open problem: it is not known whether $\Theta(N \log N)$ is optimal.

23.13. Round-off error in finite-precision arithmetic

This is step 29 of the path, and it must be kept distinct from complexity: the FFT is not only *faster* than the direct computation, it is also *more accurate*, and for a structural reason that is proved here. The number of operations contributing to each output goes from $\Theta(N)$ to $\Theta(\log_2 N)$, and with it the number of round-off errors that can accumulate.

Definition 23.8: Standard model of floating-point arithmetic, and hypothesis (M). Let $\text{fl}(\cdot)$ denote the result of an operation performed in floating point and u the **unit round-off** (for the 64-bit binary format, $u = 2^{-53} = 1.1102230 \cdot 10^{-16}$). The **standard model** assumes that for every elementary operation $*$ $\in \{+, -, \times, \div\}$ on machine real numbers

$$\text{fl}(a * b) = (a * b)(1 + \delta), \quad |\delta| \leq u.$$

From it follows, for complex arithmetic implemented with the usual formulas, the following hypothesis, which we assume throughout the rest of the section and call **hypothesis (M)**:

there exists a constant η , a fixed multiple of u depending only on the implementation of complex multiplication (for instance $\eta \leq 4u + O(u^2)$ with the schoolbook algorithm), such that the floating-point execution of a stage A of Definition 23.6 produces, in place of Av , the vector $(A + E)v$ with $\|E\|_2 \leq \eta \|A\|_2$, for every input vector v .

Hypothesis (M) is not proved here: it is the result of standard analysis of floating-point arithmetic, and is *imported* from Higham, *Accuracy and Stability of Numerical Algorithms*, Chapters 2 and 24, and from Van Loan, Chapter 1. What is missing, and is not proved here, is exactly the passage from the scalar model $\text{fl}(a * b) = (a * b)(1 + \delta)$ to the norm bound $\|E\|_2 \leq \eta \|A\|_2$ for an entire stage; everything else in the section is proved.

Remark 23.12: What we import in the error analysis. The only **imported** element of this section is hypothesis (M) of Definition 23.8. Precisely: we do not prove that the scalar model $\mathfrak{f}(a*b) = (a*b)(1+\delta)$, $|\delta| \leq u$, implies for an entire stage A the bound $\|E\|_2 \leq \eta\|A\|_2$ with $\eta = O(u)$. The proof requires the forward analysis of complex arithmetic (four products and two real sums for each complex product, with the respective constants $\gamma_k = ku/(1-ku)$) and the aggregation of the perturbations componentwise into a norm bound: this is the subject of Chapter 2 of Higham, and the result for the FFT is his Chapter 24. Everything else in the section — Lemma 23.6, Corollary 23.9, Lemma 23.7 and Theorem 23.13 — is proved here in full starting from hypothesis (M), which appears explicitly among the hypotheses of the theorem.

Lemma 23.6: Every stage is $\sqrt{2}$ times an isometry. Let $N = 2^m$ and let $A_s : \mathbb{C}^N \rightarrow \mathbb{C}^N$ be the linear map that realizes stage s of Definition 23.6, $s = 1, \dots, m$. Then

$$\|A_s v\|_2 = \sqrt{2} \|v\|_2 \quad \text{for every } v \in \mathbb{C}^N,$$

and hence $A_s^* A_s = 2I_N$, $\|A_s\|_2 = \sqrt{2}$, $\|A_s^{-1}\|_2 = 1/\sqrt{2}$.

Proof. Stage s acts on pairs of indices: setting $L = n_s/2 = 2^{s-1}$, the pairs are $\mathcal{P}_s = \{(b+k, b+k+L)\}$ as b ranges over $\{0, n_s, 2n_s, \dots\}$ and k over $\{0, \dots, L-1\}$. These pairs are *disjoint* and their union is $\{0, \dots, N-1\}$: indeed every index j is written uniquely as $j = b + k + \varepsilon L$ with b a multiple of n_s , $0 \leq k < L$ and $\varepsilon \in \{0, 1\}$ (Euclidean division of j by n_s , then of the remainder by L). There are $N/2$ pairs.

On each pair (p, q) the stage computes, with $u = v[p]$, $t = w v[q]$ and $|w| = |\omega_{n_s}^k| = 1$ (Lemma 23.1(i)),

$$(A_s v)[p] = u + t, \quad (A_s v)[q] = u - t.$$

By the parallelogram identity in $\mathbb{C}$ (checked by expanding the squared moduli: $|u+t|^2 + |u-t|^2 = (u+t)\overline{(u+t)} + (u-t)\overline{(u-t)} = 2|u|^2 + 2|t|^2$, since the cross terms ut and $\bar{u}\bar{t}$ appear with opposite signs and cancel),

$$|(A_s v)[p]|^2 + |(A_s v)[q]|^2 = 2|u|^2 + 2|t|^2 = 2|v[p]|^2 + 2|w|^2|v[q]|^2 = 2(|v[p]|^2 + |v[q]|^2).$$

Summing over all $N/2$ pairs, which partition the indices,

$$\|A_s v\|_2^2 = \sum_{(p,q) \in \mathcal{P}_s} (|(A_s v)[p]|^2 + |(A_s v)[q]|^2) = 2 \sum_{(p,q) \in \mathcal{P}_s} (|v[p]|^2 + |v[q]|^2) = 2\|v\|_2^2.$$

From $\|A_s v\|_2^2 = 2\|v\|_2^2$ for every v it follows that $v^*(A_s^* A_s - 2I)v = 0$ for every v ; since $A_s^* A_s - 2I$ is Hermitian, this implies $A_s^* A_s = 2I$ (a Hermitian matrix whose quadratic form vanishes identically is the zero matrix). The two norms follow as in Proposition 23.3(iii). $\square$

Corollary 23.9: Factorization of the DFT matrix. Let $N = 2^m$ and let P_ρ be the permutation matrix associated with ρ_m (Definition 23.5), that is, $(P_\rho v)[j] = v[\rho_m(j)]$. Then

$$W_N = A_m A_{m-1} \cdots A_1 P_\rho,$$

and $\|W_N\|_2 = (\sqrt{2})^m = \sqrt{N}$, consistently with Theorem 22.3.

Proof. Theorem 23.8 states that the algorithm, that is, the map $x \mapsto A_m \cdots A_1 P_\rho x$, returns $\text{DFT}_N\{x\} = W_N x$ for every $x \in \mathbb{C}^N$: two linear maps that coincide on all of $\mathbb{C}^N$ are the same matrix. For the norm, from Lemma 23.6 and from $\|P_\rho v\|_2 = \|v\|_2$ (a permutation of

the components does not change the sum of the squared moduli) it follows that $\|W_N v\|_2 = (\sqrt{2})^m \|v\|_2 = \sqrt{N} \|v\|_2$ for every v , hence $\|W_N\|_2 = \sqrt{N}$. Theorem 22.3 says that $F_N = N^{-1/2} W_N$ is unitary, that is, $\|F_N\|_2 = 1$: the same thing. $\square$

Lemma 23.7: Perturbation of a matrix product. Let $A_1, \dots, A_m$ and $E_1, \dots, E_m$ be $N \times N$ matrices, and set $a_s = \|A_s\|_2$, $e_s = \|E_s\|_2$. Then

$$\left\| (A_m + E_m) \cdots (A_1 + E_1) - A_m \cdots A_1 \right\|_2 \leq \prod_{s=1}^m (a_s + e_s) - \prod_{s=1}^m a_s.$$

Proof. By induction on m . Set $F_j = (A_j + E_j) \cdots (A_1 + E_1)$ and $G_j = A_j \cdots A_1$.

Base $m = 1$: $\|F_1 - G_1\|_2 = \|E_1\|_2 = e_1 = (a_1 + e_1) - a_1$.

Step: let $m \geq 2$ and let the claim hold for $m - 1$. One has the identity

$$F_m - G_m = (A_m + E_m)F_{m-1} - A_m G_{m-1} = (A_m + E_m)(F_{m-1} - G_{m-1}) + E_m G_{m-1},$$

as is checked by expanding the right-hand side. By submultiplicativity and subadditivity of the spectral norm, and by $\|G_{m-1}\|_2 \leq \prod_{s < m} a_s$,

$$\|F_m - G_m\|_2 \leq (a_m + e_m) \left[\prod_{s < m} (a_s + e_s) - \prod_{s < m} a_s \right] + e_m \prod_{s < m} a_s.$$

Expanding the right-hand side:

$$\prod_{s \leq m} (a_s + e_s) - (a_m + e_m) \prod_{s < m} a_s + e_m \prod_{s < m} a_s = \prod_{s \leq m} (a_s + e_s) - a_m \prod_{s < m} a_s = \prod_{s \leq m} (a_s + e_s) - \prod_{s \leq m} a_s.$$

$\square$

Theorem 23.13: Error bound for the radix-2 FFT. Let $N = 2^m$, let $x \in \mathbb{C}^N$ be nonzero, let $X = \text{DFT}_N\{x\}$ and let $\hat{X}$ be the result of the algorithm of Definition 23.6 executed in floating point under hypothesis (M) of Definition 23.8. Then

$$\frac{\|\hat{X} - X\|_2}{\|X\|_2} \leq (1 + \eta)^m - 1$$

and, if $m\eta \leq 1$,

$$\frac{\|\hat{X} - X\|_2}{\|X\|_2} \leq (e - 1) m \eta < 1.72 m \eta = 1.72 \eta \log_2 N.$$

Proof. Step 1. Under hypothesis (M), the computed result is

$$\hat{X} = (A_m + E_m) \cdots (A_1 + E_1) P_\rho x,$$

with $\|E_s\|_2 \leq \eta \|A_s\|_2 = \eta \sqrt{2}$ by Lemma 23.6. (The permutation (P) performs no arithmetic operations and introduces no error: it moves machine numbers around.)

Step 2. By Corollary 23.9, $X = A_m \cdots A_1 P_\rho x$. Hence

$$\hat{X} - X = \left[(A_m + E_m) \cdots (A_1 + E_1) - A_m \cdots A_1 \right] P_\rho x.$$

Step 3. We apply Lemma 23.7 with $a_s = \sqrt{2}$ and $e_s \leq \eta \sqrt{2}$:

$$\prod_{s=1}^m (a_s + e_s) - \prod_{s=1}^m a_s \leq (\sqrt{2}(1 + \eta))^m - (\sqrt{2})^m = 2^{m/2} [(1 + \eta)^m - 1] = \sqrt{N} [(1 + \eta)^m - 1].$$

Since $\|P_\rho x\|_2 = \|x\|_2$,

$$\|\hat{X} - X\|_2 \leq \sqrt{N}[(1 + \eta)^m - 1] \|x\|_2.$$

Step 4. By Parseval's identity (Theorem 22.6), $\|X\|_2^2 = N\|x\|_2^2$, that is, $\|X\|_2 = \sqrt{N}\|x\|_2$ (in particular $\|X\|_2 \neq 0$ because $x \neq 0$). Dividing,

$$\frac{\|\hat{X} - X\|_2}{\|X\|_2} \leq \frac{\sqrt{N}[(1 + \eta)^m - 1]\|x\|_2}{\sqrt{N}\|x\|_2} = (1 + \eta)^m - 1.$$

Step 5 (the linear form). From the binomial expansion, with $\binom{m}{j} \leq m^j/j!$,

$$(1 + \eta)^m - 1 = \sum_{j=1}^m \binom{m}{j} \eta^j \leq \sum_{j=1}^m \frac{(m\eta)^j}{j!} = e^{m\eta} - 1.$$

The function $t \mapsto e^t - 1$ is convex and vanishes at $t = 0$, hence on the segment $[0, 1]$ it lies below its chord: $e^t - 1 \leq t(e - 1)$ for $0 \leq t \leq 1$. With $t = m\eta \leq 1$ one obtains $(1 + \eta)^m - 1 \leq (e - 1)m\eta < 1.72m\eta$. $\square$

Remark 23.13: Comparison with the direct sum. The same analysis applied to the direct computation of Proposition 23.1 gives a bound proportional to Nu rather than to $u \log_2 N$: each output is a sum of N terms computed in sequence, and in the worst case the errors of the individual terms all add with the same sign. The gain of the FFT is therefore twofold: a factor $\Theta(N/\log_2 N)$ on the number of operations (Corollary 23.3) and a factor of the same order on the error bound. This is a rare fact and it is worth stressing: normally a faster algorithm is less accurate, because it buys speed by giving something up. Here nothing is given up, because the algorithm computes the same sum (Corollary 23.2), only in an order that shortens every chain of dependencies from N to $\log_2 N$ steps. It should be said honestly that the worst-case bounds are pessimistic in both cases: in practice the elementary errors are roughly independent and partly cancel, so that the observed growth is slower than the guaranteed one. This is exactly what the following experiment shows.

Example 23.12: Experimental check. Protocol. For $N = 2^m$ with $m = 3, 5, 7, 8, 9$ a vector $v \in \mathbb{C}^N$ is generated with real and imaginary parts drawn from a standard normal (fixed seed 20260906, generator `numpy.random.default_rng`). Three transforms are computed:

1. the *reference*, with the sum of Definition 22.1 executed in 50-decimal-digit arithmetic (`mpmath` library);
2. the recursive FFT of Definition 23.4 in double precision;
3. the direct sum of Definition 22.1 in double precision, carried out genuinely *in sequence*: an explicit loop over $n = 0, 1, \dots, N - 1$ with a scalar accumulator, without vectorization, and twiddle factors $e^{-2\pi i \langle kn \rangle_{N/N}}$ with the exponent reduced modulo N (without the reduction, what would be measured is the error in evaluating the twiddle factor at a large argument, not the error of the summation).

The relative errors in Euclidean norm with respect to the reference are reported.

N	m	rel. error FFT	rel. error direct sum	$(1 + 4u)^m - 1$
8	3	$9.2953 \cdot 10^{-17}$	$2.1641 \cdot 10^{-16}$	$1.3323 \cdot 10^{-15}$

256	8	$3.1065 \cdot 10^{-16}$	$6.1601 \cdot 10^{-16}$	$3.5527 \cdot 10^{-15}$
512	9	$3.4593 \cdot 10^{-16}$	$7.8512 \cdot 10^{-16}$	$3.9968 \cdot 10^{-15}$

Reading 1: the bound is respected. The last column is the bound of Theorem 23.13 with $\eta = 4u$ (schoolbook algorithm for complex multiplication), that is, $(1 + 4u)^m - 1$, with $u = 1.1102230 \cdot 10^{-16}$. The observed FFT error is every time smaller, by a margin between 11 and 14 times. ✓

Reading 2: the growth is linear in m , as the theorem predicts. The ratio of the observed error to m is

$$3.098, \quad 3.460, \quad 4.136, \quad 3.883, \quad 3.844 \quad (\times 10^{-17}),$$

that is, it stays constant within a factor 1.34 while N varies by a factor 64: the dependence on N is indeed logarithmic. If the error grew like N , that ratio would have grown by a factor ≈ 21 . ✓

Reading 3: at these N the direct sum does *not* grow faster. Going from $N = 8$ to $N = 512$ (factor 64) the error of the direct sum grows by a factor $7.8512/2.1641 = 3.628$ and that of the FFT by a factor $3.4593/0.92953 = 3.722$: the two columns grow at the same rate, and the ratio between the two errors stays essentially fixed (from 2.33 at $N = 8$ to 2.27 at $N = 512$). Applying to the direct-sum column the same criterion as in Reading 2, the ratio of the observed error to m is

$$0.721, \quad 0.649, \quad 0.690, \quad 0.770, \quad 0.872 \quad (\times 10^{-16}),$$

that is, it stays constant within a factor 1.34, exactly as for the FFT: at these N the direct sum too behaves logarithmically. The worst-case bound proportional to Nu of Remark 23.13 is therefore far from being attained, and for the reason stated there: in practice the elementary errors are roughly independent and partly cancel, instead of all adding up with the same sign. The experiment thus confirms Theorem 23.13 (Readings 1 and 2) and the caution of Remark 23.13, but it does *not* exhibit the accuracy advantage of the FFT: at these N the gap between the two bounds remains a fact about the guaranteed bounds, not an observed fact, and it must be said so rather than read into numbers that do not say it. The advantage of the FFT measured here is the other one, on the number of operations (Corollary 23.3).

Checking the check. The same protocol repeated with the direct sum replaced by `numpy.fft.fft` gives, for $N = 8$, a discrepancy of $2.54 \cdot 10^{-14}$ in modulus on the ramp example (Section 23.9), consistent with the order of magnitude measured here once multiplied by $\|X\|_2 \approx 33.5$. ✓

Remark 23.14: Memory, cache and implementations: why the count is not the time. The operation count (Theorem 23.5) is a mathematical invariant; the execution time is not, and on a modern computer the two quantities can diverge by an order of magnitude. The reasons, all foreign to the analysis carried out so far, are at least four:

- **locality of reference:** in the last stages of the DIT the two cells of a butterfly are $N/2$ positions apart, and for large N they fall on different memory pages; serious implementations resort to “four-step” decompositions that treat the vector as a $\sqrt{N} \times \sqrt{N}$ matrix, in order to work on blocks that fit in cache;

- **table of twiddle factors:** precomputing $N/2$ of them costs memory but avoids $\Theta(N \log N)$ evaluations of sine and cosine, each of which costs dozens of elementary operations and introduces error;
- **vectorization and parallelism:** the butterflies of a single stage are independent and lend themselves to simultaneous execution; the number of operations does not change, the time does;
- **runtime algorithm selection:** the FFTW library experimentally measures different combinations of radices and decompositions on the host machine and chooses the fastest (Frigo and Johnson, 2005).

None of this changes the number of operations or the result: these are aspects distinct from asymptotic complexity, and this is why Table 23.1 reports counts and not times (Remark 23.7).

23.14. Assigned exercises

These are *new* exercises, distinct from those solved in Section 23.15. The answers are in the Teacher key (Section 23.17).

Exercise 23.1: Counting before programming. *Objective:* to be able to produce, for a given N , the four numbers that decide a project — multiplications and additions of the direct computation, multiplications and additions of the FFT — and to translate them into time. *Estimated time:* 40 minutes. *Type:* numerical and proof-based. *Level:* basic–intermediate.

- For $N = 32$ compute, with Proposition 23.1, Theorem 23.5 and Corollary 23.4: multiplications and additions of the direct computation; multiplications and additions of the FFT; nontrivial multiplications of the FFT. Check the five numbers with a small script that simulates the algorithm and increments two counters.
- Prove that, in the radix-2 FFT of length $N = 2^m$ with $m \geq 2$, the total number of twiddle factors belonging to $\{1, -1, i, -i\}$ equals $\frac{3N}{2} - 2$. (Hint: use points (i)–(iii) of Proposition 23.5, and note that the two families are disjoint.)
- For which smallest $N = 2^m$ are the multiplications of the FFT (counted *all* of them, that is, $\frac{N}{2} \log_2 N$) *at least ten times* fewer than those of the direct computation (N^2)? Derive the inequality in m and solve it by successive trials, showing the two values of m that bracket it; check the result against Table 23.1.
- A processor performs 10^8 complex multiplications per second and one wants to transform a block of $N = 2^{20}$ samples. Compute the time required by the direct computation (in hours) and by the FFT (in seconds), using respectively N^2 and the number of nontrivial multiplications. Comment on why the second number should not be passed off as a prediction of the real time (Remark 23.14).

Exercise 23.2: A four-point FFT, by hand and in full. *Objective:* to carry out the algorithm on paper, with all the checks prescribed by the chapter. *Estimated time:* 35 minutes. *Type:* symbolic and numerical computation. *Level:* remedial–basic. Consider $N = 4$ and

$$x = (1, 2, 0, -1).$$

- Write the permutation ρ_2 and the reordered vector.
- Carry out the two stages of Definition 23.6, indicating the twiddle factors used (ω_2^0 in the first stage, ω_4^0 and ω_4^1 in the second) and the intermediate values.
- Compute X also directly from Definition 22.1 and compare.

- (d) Verify Parseval's identity (Theorem 22.6) and Hermitian symmetry (Theorem 22.7); say which components must turn out real, and why.
- (e) Reconstruct x with Theorem 23.10, showing all four samples.
- (f) Count the nontrivial multiplications actually performed and compare with the formula $\frac{N}{2} \log_2 N - \frac{3N}{2} + 2$.

Exercise 23.3: Lengths that are not powers of two. *Objective:* to apply the mixed-radix factorization and the two algorithms for prime N , and to know which is preferable. *Estimated time:* 50 minutes. *Type:* proof-based and computational. *Level:* intermediate-advanced.

- (a) Let $N = 12 = N_1 N_2$ with $N_1 = 4$, $N_2 = 3$, and let $x \in \mathbb{C}^{12}$ be the vector with $x[0] = x[6] = 1$ and all other components zero. Apply Theorem 23.11: write the three subsequences $(x[3n_1 + n_2])_{n_1}$, compute the three DFTs of length 4, apply the factors $\omega_{12}^{k_1 n_2}$ and conclude with the four DFTs of length 3. Compare the result with the direct computation.
- (b) Count the nontrivial multiplications of the two procedures of part (a) and compare them with those one would have by padding x with four zeros up to $N' = 16$ and using the radix-2 FFT. Which of the two routes is preferable? What changes in the spectrum (Proposition 23.6 and Remark 23.10)?
- (c) Let $N = 5$. Determine all primitive roots modulo 5 by checking the definition given in Theorem 23.12, and write explicitly the sequences A and C and the cyclic correlation of length 4 for a generic $x \in \mathbb{C}^5$.
- (d) For the same $N = 5$, write the vectors u and v of Corollary 23.8 with $M = 16$, indicating which components of v are nonzero and why the condition $M \geq 2N - 1$ is essential.

23.15. Solved exercises

Exercise 23.4: The same transform with decimation in frequency. *Type:* numerical computation with cross-check. Compute the DFT of $x = (0, 1, 2, 3, 4, 5, 6, 7)$ with the DIF algorithm of Definition 23.7, show that the output is in bit-reversed order, and compare with the DIT result of Section 23.9.

Solution. Strategy. DIF operates on the input in *natural* order and produces the output in bit-reversed order (Remark 23.8). At each stage sums and differences are formed between cells separated by half the length of the current block, and it is the difference — not the sum — that gets multiplied by the twiddle factor (Theorem 23.9). The first stage works on a block of 8, the second on two blocks of 4, the third on four blocks of 2: the order of the blocks is the reverse of that of the DIT.

Step 1 — stage 1 ($L = 4$, factors ω_8^n , $n = 0, 1, 2, 3$). One forms $\alpha[n] = x[n] + x[n + 4]$ and $\beta[n] = (x[n] - x[n + 4]) \omega_8^n$:

$$\alpha = (0 + 4, 1 + 5, 2 + 6, 3 + 7) = (4, 6, 8, 10),$$

$$x[n] - x[n + 4] = -4 \text{ for every } n, \quad \beta = (-4, -4\omega_8, -4\omega_8^2, -4\omega_8^3).$$

With $\omega_8 = \frac{\sqrt{2}}{2}(1 - i)$, $\omega_8^2 = -i$, $\omega_8^3 = -\frac{\sqrt{2}}{2}(1 + i)$ and $4 \cdot \frac{\sqrt{2}}{2} = 2\sqrt{2} = 2.8284271$:

$$\beta = (-4, -2\sqrt{2} + 2\sqrt{2}i, 4i, 2\sqrt{2} + 2\sqrt{2}i),$$

$$\beta = (-4, -2.8284271 + 2.8284271i, 4i, 2.8284271 + 2.8284271i).$$

The vector after the first stage is $(\alpha, \beta) = (4, 6, 8, 10, \beta[0], \dots, \beta[3])$.

Step 2 — stage 2 (two blocks of 4, $L = 2$, factors $\omega_4^0 = 1, \omega_4^1 = -i$). In the first block $(4, 6, 8, 10)$:

$$4 + 8 = 12, \quad 6 + 10 = 16, \quad (4 - 8) \cdot 1 = -4, \quad (6 - 10) \cdot (-i) = 4i.$$

In the second block β :

$$\beta[0] + \beta[2] = -4 + 4i, \quad \beta[1] + \beta[3] = 4\sqrt{2}i = 5.6568542i,$$

$$(\beta[0] - \beta[2]) \cdot 1 = -4 - 4i, \quad (\beta[1] - \beta[3]) \cdot (-i) = (-4\sqrt{2})(-i) = 4\sqrt{2}i.$$

The vector is now $(12, 16, -4, 4i, -4 + 4i, 4\sqrt{2}i, -4 - 4i, 4\sqrt{2}i)$.

Step 3 — stage 3 (four blocks of 2, single factor $\omega_2^0 = 1$).

$$\begin{aligned} 12 + 16 &= 28, & 12 - 16 &= -4, \\ -4 + 4i, & & -4 - 4i, & \\ (-4 + 4i) + 4\sqrt{2}i &= -4 + i(4 + 4\sqrt{2}), & (-4 + 4i) - 4\sqrt{2}i &= -4 - i(4\sqrt{2} - 4), \\ (-4 - 4i) + 4\sqrt{2}i &= -4 + i(4\sqrt{2} - 4), & (-4 - 4i) - 4\sqrt{2}i &= -4 - i(4 + 4\sqrt{2}). \end{aligned}$$

The final vector, cell by cell, is

$$(28, -4, -4+4i, -4-4i, -4+9.6568542i, -4-1.6568542i, -4+1.6568542i, -4-9.6568542i).$$

Step 4 — output bit-reversal reordering. Applying $\rho_3 = (0, 4, 2, 6, 1, 5, 3, 7)$ to the positions, that is, reading cell $\rho_3(k)$ as $X[k]$:

k	0	1	2	3	4	5	6	7
$\rho_3(k)$	0	4	2	6	1	5	3	7
$X[k]$	28	$-4 + 9.657i$	$-4 + 4i$	$-4 + 1.657i$	-4	$-4 - 1.657i$	$-4 - 4i$	$-4 - 9.657i$

which coincides with Table 23.2. ✓

Independent check 1: the closed form. The values coincide with those of Example 23.6, obtained from Lemma 23.5. ✓

Independent check 2: Python script. An implementation of the DIF that performs the three stages and then reorders returns the same eight values, with maximum discrepancy $2.46 \cdot 10^{-14}$ relative to the direct sum of the definition. ✓

Interpretation. Comparing with Example 23.7 one sees that DIT and DIF pass through *different* intermediate values — after the first stage the DIT has $(4, -4, 8, -4, 6, -4, 10, -4)$ and the DIF has $(4, 6, 8, 10, -4, \dots)$ — but they arrive at the same result. They are not two approximations of the same thing: they are two exact factorizations of the same matrix W_8 (Corollary 23.9).

Typical errors. (1) Multiplying the *sum* instead of the difference by the twiddle factor: in the DIF the twiddle sits on the branch of the difference, unlike in the DIT, where it sits before the butterfly. (2) Using ω_4 at the first stage instead of ω_8 : in the DIF the order of the factors is decreasing (ω_8 , then ω_4 , then ω_2), the opposite of the DIT. (3) Forgetting the final reordering and comparing cell by cell with the DIT output: one gets the same eight numbers, but in a different order, and the comparison fails without the algorithm being wrong.

Extension. Show that, by composing a DIF with no final reordering with a DIT with no initial reordering, one obtains $N \cdot \mathcal{F}_N^{-1} \mathcal{F}_N = N \text{id}$, and explain why this allows a circular convolution (Theorem 22.5) to be computed without ever performing a bit-reversal permutation.

Exercise 23.5: Linear convolution with a circular FFT. *Type:* computational, with cost count. Let $a = (1, 2, 3, 4)$ and $b = (1, 1, 1, 1)$ be two sequences of length 4. Compute their *linear* convolution (that is, the product of the associated polynomials) using FFTs of length 8, and compare the cost with that of the direct computation.

Solution. Strategy. Theorem 22.5 concerns *circular* convolution; the linear convolution of two sequences of lengths P and Q has length $P + Q - 1$. If both are padded with zeros up to a length $M \geq P + Q - 1$, the circular convolution of length M coincides with the linear one, because no term “wraps around”. Here $P = Q = 4$, $P + Q - 1 = 7$, and the first power of two ≥ 7 is $M = 8$: two 8-point FFTs, 8 products, one 8-point IFFT.

Step 1 — zero-padding. $\tilde{a} = (1, 2, 3, 4, 0, 0, 0, 0)$, $\tilde{b} = (1, 1, 1, 1, 0, 0, 0, 0)$.

Step 2 — the two FFTs. With $\sqrt{2} = 1.4142136$, and recalling that $1 + \sqrt{2} = 2.4142136$ and $\sqrt{2} - 1 = 0.4142136$:

$$\begin{aligned} A[0] &= 10, & B[0] &= 4, \\ A[1] &= -0.4142136 - 7.2426407i, & B[1] &= 1 - 2.4142136i, \\ A[2] &= -2 + 2i, & B[2] &= 0, \\ A[3] &= 2.4142136 - 1.2426407i, & B[3] &= 1 - 0.4142136i, \\ A[4] &= -2, & B[4] &= 0, \\ A[5] &= 2.4142136 + 1.2426407i, & B[5] &= 1 + 0.4142136i, \\ A[6] &= -2 - 2i, & B[6] &= 0, \\ A[7] &= -0.4142136 + 7.2426407i, & B[7] &= 1 + 2.4142136i. \end{aligned}$$

That $B[2] = B[4] = B[6] = 0$ is proved as follows: $\tilde{b}$ is the sequence $(1, 1, 1, 1, 0, 0, 0, 0)$, its DFT equals $\sum_{n=0}^3 \omega_8^{kn} = \frac{1 - \omega_8^{4k}}{1 - \omega_8^k}$ for $\omega_8^k \neq 1$, and $\omega_8^{4k} = (-1)^k$ by Lemma 23.1(iv): the numerator vanishes for even k , $k \neq 0$.

Step 3 — pointwise product. $C[k] = A[k]B[k]$:

$$\begin{aligned} C[0] &= 40, & C[1] &= -17.8994949 - 6.2426407i, \\ C[2] &= 0, & C[3] &= 1.8994949 - 2.2426407i, \\ C[4] &= 0, & C[5] &= 1.8994949 + 2.2426407i, \\ C[6] &= 0, & C[7] &= -17.8994949 + 6.2426407i. \end{aligned}$$

Step 4 — IFFT. By Theorem 23.10, $c = \frac{1}{8} \overline{\mathcal{A}_8(\overline{C})}$, and one obtains

$$c = (1, 3, 6, 10, 9, 7, 4, 0).$$

Independent check 1: the product of the polynomials. The linear convolution is the coefficient vector of

$$(1 + 2z + 3z^2 + 4z^3)(1 + z + z^2 + z^3) = 1 + 3z + 6z^2 + 10z^3 + 9z^4 + 7z^5 + 4z^6,$$

that is, $(1, 3, 6, 10, 9, 7, 4)$; adding the final zero required by length 8 recovers exactly c . ✓

Independent check 2: the circular convolution by hand. By Definition 22.4, $c[n] = \sum_{j=0}^7 \tilde{a}[j] \tilde{b}[(n-j)_8]$; for instance $c[3] = 1 \cdot 1 + 2 \cdot 1 + 3 \cdot 1 + 4 \cdot 1 = 10$ and $c[7] = \tilde{a}[4] + \cdots = 0$ because every term involves either an $\tilde{a}[j]$ with $j \geq 4$ or a null $\tilde{b}$. ✓ The Python script returns $c = (1, 3, 6, 10, 9, 7, 4, 0)$ with maximum error $7.27 \cdot 10^{-16}$. ✓

Cost count. Direct computation of the linear convolution: $4 \times 4 = 16$ multiplications and $16 - 7 = 9$ additions. Via FFT: three 8-point transforms, that is, $3 \times 2 = 6$ nontrivial multiplications (Corollary 23.4) and $3 \times 24 = 72$ additions, plus 8 pointwise multiplications and 8 divisions by 8 (exact, because 8 is a power of two; Corollary 23.6).

Interpretation. At $N = 4$ the FFT route *is not worthwhile*: 14 nontrivial multiplications and 72 additions against 16 and 9. This is the important observation of this exercise: the asymptotic advantage is not an advantage at every N . Repeating the count for two sequences of length $P = Q = 1,024$ (hence $M = 2,048 = 2^{11}$), the direct computation requires $PQ = 1,048,576$ multiplications; the FFT route requires, by Corollary 23.4,

$$3 \left(\frac{2,048}{2} \cdot 11 - \frac{3 \cdot 2,048}{2} + 2 \right) + 2,048 = 3(11,264 - 3,072 + 2) + 2,048 = 3 \cdot 8,194 + 2,048 = 26,630,$$

that is, a factor $1,048,576/26,630 = 39.4$. This is how products of polynomials and of large integers are computed.

Typical errors. (1) Choosing $M = 4$: the circular convolution of length 4 is *not* the linear one, and coefficients of degree ≥ 4 add to those of degree ≥ 0 (“time aliasing”); one would obtain $(1 + 9, 3 + 7, 6 + 4, 10) = (10, 10, 10, 10)$. (2) Forgetting that the IFFT returns complex numbers: the imaginary parts must turn out zero up to round-off error, and this is a further check for free. (3) Comparing only the cost of the multiplications: here the bottleneck is the additions.

Extension. Prove in general that, if $\tilde{a}$ and $\tilde{b}$ have at most P and Q nonzero components, with $P + Q - 1 \leq M$, then $(\tilde{a} \circledast \tilde{b})[n]$ coincides with the linear convolution for every $n = 0, \dots, M - 1$. (Hint: in the sum $\sum_j \tilde{a}[j] \tilde{b}[\langle n - j \rangle_M]$ show that the index $\langle n - j \rangle_M$ differs from $n - j$ only where $\tilde{b}$ vanishes there.)

Exercise 23.6: What the algorithm computes if the permutation is forgotten.

Type: error diagnosis, with numerical verification. Run the iterative algorithm of Definition 23.6 on $x = (0, 1, 2, 3, 4, 5, 6, 7)$ omitting step (P). Identify what is computed, show that Parseval’s identity is nonetheless satisfied, and indicate a check that exposes the error.

Solution. Strategy. Theorem 23.8 proves that the stages (S), applied to a vector a , return the DFT of the vector v such that $a[j] = v[\rho_m(j)]$ for every j . If (P) is omitted, one is applying (S) to $a = x$; one must therefore solve $x[j] = v[\rho_m(j)]$ for v .

Step 1 — what is computed. From $x[j] = v[\rho_m(j)]$, setting $n = \rho_m(j)$ and using $\rho_m^{-1} = \rho_m$ (Lemma 23.4), one gets $j = \rho_m(n)$ and

$$v[n] = x[\rho_m(n)].$$

Hence the algorithm without (P) returns $\text{DFT}_N\{x \circ \rho_m\}$, that is, the spectrum of the signal with permuted samples, *not* the spectrum of x .

Step 2 — the permuted vector. With $\rho_3 = (0, 4, 2, 6, 1, 5, 3, 7)$:

$$v = (x[0], x[4], x[2], x[6], x[1], x[5], x[3], x[7]) = (0, 4, 2, 6, 1, 5, 3, 7).$$

Step 3 — its DFT. Computing $Y = \text{DFT}_8\{v\}$ from the definition (the sums proceed as in Example 23.6, collecting the coefficients of $\frac{\sqrt{2}}{2}$):

$$\begin{aligned} Y[0] &= 28, & Y[1] &= -1 + i(1 + \sqrt{2}), & Y[2] &= -4 + 4i, \\ Y[3] &= -1 + i(\sqrt{2} - 1), & Y[4] &= -16, & Y[5] &= -1 - i(\sqrt{2} - 1), \\ Y[6] &= -4 - 4i, & Y[7] &= -1 - i(1 + \sqrt{2}). \end{aligned}$$

In full, for $Y[1]$: the coefficients of $\frac{\sqrt{2}}{2}$ in the real part are $4 - 6 - 5 + 7 = 0$ and in the imaginary part $-4 - 6 + 5 + 7 = 2$, while the integer terms give -1 in the real part and $+1$ in the imaginary part; hence $Y[1] = -1 + i(1 + 2 \cdot \frac{\sqrt{2}}{2}) = -1 + i(1 + \sqrt{2})$. In decimals, $1 + \sqrt{2} = 2.4142136$ and $\sqrt{2} - 1 = 0.4142136$.

Step 4 — Parseval does not notice.

$$\sum_k |Y[k]|^2 = 784 + 2[1 + (1 + \sqrt{2})^2] + 2 \cdot 32 + 2[1 + (\sqrt{2} - 1)^2] + 256.$$

Now $(1 + \sqrt{2})^2 = 3 + 2\sqrt{2}$ and $(\sqrt{2} - 1)^2 = 3 - 2\sqrt{2}$, hence the two contributions equal $2(4 + 2\sqrt{2}) + 2(4 - 2\sqrt{2}) = 16$, and

$$\sum_k |Y[k]|^2 = 784 + 16 + 64 + 256 = 1,120 = \sum_k |X[k]|^2.$$

The value is *identical* to that of Example 23.8: and not by chance, because $\sum_n |v[n]|^2 = \sum_n |x[n]|^2 = 140$ (a permutation does not change the sum of the squared moduli) and Parseval ties the two sums (Theorem 22.6). ✓ (in the sense that the check passes, even though the result is wrong).

Step 5 — the check that exposes the error. Three checks work:

- (i) *the component $k = 0$ is not enough* ($Y[0] = 28 = X[0]$: the sum of the samples does not depend on the order), but *the component $k = N/2$ does*: $Y[4] = -16$ against $X[4] = -4$. In general $X[N/2] = \sum_n (-1)^n x[n]$ depends on the order;
- (ii) *transforming a pure sinusoid*: for $x[n] = \omega_N^{-n}$ the correct DFT is N in bin 1 and 0 elsewhere (Theorem 22.1); without the permutation the spectrum is spread over all bins, and the error is glaring;
- (iii) *round trip*: apply the FFT and then the IFFT (Theorem 23.10) and compare with the input. If the permutation is missing in both, one recovers $x \circ \rho_m \circ \rho_m = x$ and the check fails in turn: one must then compare with the direct DFT, which is the definitive check.

Independent check. The Python script confirms $Y = (28, -1 + 2.4142136i, -4 + 4i, -1 + 0.4142136i, -16, -1 - 0.4142136i, -4 - 4i, -1 - 2.4142136i)$ and $\sum_k |Y[k]|^2 = 1,120.0$. ✓

Interpretation. The error is “silent” with respect to energy checks because the permutation is an isometry: no check involving only norms can detect it. This is the clean example of a general principle of numerical testing: a check that is invariant with respect to the error being sought is not a check.

Typical errors. (1) Concluding “Parseval checks out, so the code is correct”: Parseval is a necessary condition, not a sufficient one. (2) Applying the permutation *twice* (once at the start and once at the end): since ρ_m is an involution, the result is again wrong, but in a different way. (3) Using ρ_m with the wrong m : if an 8-point FFT is run with the 16-bit permutation, one falls outside the range of indices.

Extension. Show that, for a real signal, omitting the permutation also preserves Hermitian symmetry (Theorem 22.7): hence not even that check detects the error. Which properties of the spectrum are *not* invariant under permutation of the samples?

23.16. Self-assessment quiz

1. (Definition) The “fast Fourier transform” is
 - A) a transform different from the DFT, suited to long signals
 - B) a family of algorithms that computes the DFT *exactly*
 - C) an approximation of the DFT accurate to 99%
 - D) the DFT of a signal sampled at twice the frequency
2. (Hypothesis) In the proof of Theorem 23.2, the hypothesis that E and O are $N/2$ -point DFTs is used to
 - A) guarantee $|\omega_N| = 1$
 - B) be able to use $E[k + N/2] = E[k]$ and $O[k + N/2] = O[k]$

-
- C) make the butterflies of a single stage independent D) ensure that N is even
3. (Symbolic computation) The number of *nontrivial* complex multiplications performed by the radix-2 FFT on $N = 2^m$ equals
- A) $\frac{N}{2} \log_2 N$ B) $N \log_2 N$ C) $\frac{N}{2} \log_2 N - \frac{3N}{2} + 2$ D) $N^2 - (N - 1)^2$
4. (Numerical computation) For $N = 1,024$ the nontrivial complex multiplications of the radix-2 FFT are
- A) 5,120 B) 10,240 C) 3,586 D) 1,048,576
5. (Proof step) In Theorem 23.2 the minus sign of $X[k + N/2] = E[k] - \omega_N^k O[k]$ comes
- A) from the graphical convention with which the butterfly is drawn B) from the identity $\omega_N^{N/2} = -1$, used together with the periodicity of E and O C) from the fact that the odd indices contribute with opposite sign D) from the conjugation that appears in the inversion formula
6. (Error diagnosis) An implementation of the iterative FFT forgets step (P), the bit-reversal permutation. Which of the following checks *does not* detect the error?
- A) the comparison with the DFT computed from the definition B) Parseval's identity
 C) the transform of $x[n] = \omega_N^{-n}$, which must give N in bin 1 and 0 elsewhere D) the comparison with `numpy.fft.fft`
7. (Transfer) For $N = 6$ the factorization of Theorem 23.11 with $N_1 = 2$, $N_2 = 3$ requires
- A) 3 DFTs of length 2, then 6 twiddle factors, then 2 DFTs of length 3 B) 2 DFTs of length 3 and nothing else C) 6 DFTs of length 1 and a permutation D) padding with zeros up to 8 and a radix-2 FFT
8. (Source and metacognition) The paper that in 1965 made the algorithm known, with its exact citation, is
- A) J. W. Cooley, J. W. Tukey, *An algorithm for the machine calculation of complex Fourier series*, *Mathematics of Computation* **19** (1965), pp. 297–301 B) C. Van Loan, *Computational Frameworks for the Fast Fourier Transform*, SIAM, 1992 C) M. Frigo, S. G. Johnson, *The Design and Implementation of FFTW3*, *Proceedings of the IEEE* **93** (2005), pp. 216–231 D) M. T. Heideman, D. H. Johnson, C. S. Burrus, *Gauss and the history of the fast Fourier transform*, *IEEE ASSP Magazine* **1** (1984), pp. 14–21

23.17. Teacher key

BEST PRACTICE

Quiz — answers, rationales and diagnosis (items 1–4).

1) **B.** *Rationale:* Theorem 23.3 states the equality $\mathcal{A}_N(x) = \text{DFT}_N\{x\}$, with no error term: in exact arithmetic the two procedures give the same numbers. “Family” because radix-2 DIT, DIF, mixed-radix, Bluestein and Rader are different algorithms that all compute the same thing. *Distractors:* A confuses algorithm and transform, the most common conceptual error of the chapter; C attributes to the FFT a truncation error it does not have (the only error is round-off, and it is *smaller* than that of the direct computation, Theorem 23.13); D confuses the block length with the sampling frequency. *Diagnosed error:* not distinguishing the mathematical object from the procedure that computes it. *Source:* Briggs and Henson, *The DFT: An Owner's Manual*, Chapter 10 “The Fast Fourier Transform,” pp. 379–399.

Prerequisite: Definition 22.1. *Remediation:* redo Example 23.5, expanding $X[2]$ down to the samples and checking that the coefficients are those of the definition.

2) **B.** *Rationale:* Step 2 of that proof uses $E[k+L] = E[k]$, which holds because E is an L -point DFT and $\omega_L^L = 1$ (Lemma 23.1(ii)); without this periodicity the index $k+N/2$ would fall outside the domain of E and the formula would not close. *Distractors:* A is true but irrelevant ($|\omega_N| = 1$ always holds, and is used elsewhere, in Lemma 23.6); C is a property of the implementation, not a hypothesis of the theorem; D is a hypothesis of the section, not what the hypothesis in question is used for. *Diagnosed error:* not being able to identify at which step a given hypothesis is needed. *Source:* Oppenheim and Schaffer, *Discrete-Time Signal Processing*, 3rd ed., Chapter 9. *Prerequisite:* Proposition 22.1. *Remediation:* rewrite Step 2 assuming for contradiction that E is not periodic and identify exactly where the computation breaks.

3) **C.** *Rationale:* this is Corollary 23.4: from the $\frac{N}{2} \log_2 N$ total multiplications one subtracts the $N-1$ with factor 1 and the $\frac{N}{2}-1$ with factor $-i$ (Proposition 23.5). *Distractors:* A is the total number of multiplications, trivial ones included; B is the number of additions; D equals $2N-1$, that is, the number of factors equal to 1 in the *matrix* of the DFT, not in the FFT. *Diagnosed error:* confusing the four counts of the chapter. *Source:* Van Loan, *Computational Frameworks for the Fast Fourier Transform*, Chapter 1 “The Radix-2 Frameworks,” pp. 1–75. *Prerequisite:* Theorem 23.5. *Remediation:* derive the formula for $N=16$ by counting the factors of the four stages by hand.

4) **C.** *Rationale:* with $N=1,024$ and $m=10$, $\frac{N}{2}m - \frac{3N}{2} + 2 = 5,120 - 1,536 + 2 = 3,586$. *Distractors:* A is $\frac{N}{2} \log_2 N = 5,120$, that is, the count without removing the trivial factors; B is $N \log_2 N = 10,240$, the number of additions; D is $N^2 = 1,048,576$, the count of the direct computation. *Diagnosed error:* reading the wrong column of Table 23.1. *Source:* Corollary 23.4 and check by script. *Prerequisite:* $\log_2 1,024 = 10$. *Remediation:* redo the computation for $N=256$ (answer: 642) and for $N=4,096$ (answer: 18,434), checking against the table.

BEST PRACTICE

Quiz — answers, rationales and diagnosis (items 5–8).

5) **B.** *Rationale:* Step 3 of the proof computes $\omega_N^{k+N/2} = \omega_N^k \omega_N^{N/2} = -\omega_N^k$ using Lemma 23.1(iv); Step 2 uses periodicity. Both are needed: the identity on the factors alone would not suffice, because the left-hand side contains $E[k+N/2]$ and not $E[k]$. *Distractors:* A mistakes a picture for a proof, and is exactly what Remark 23.4 warns against; C is a content-free sentence (the odd indices contribute with the factor ω_N^k , not with a sign); D confuses this theorem with Theorem 23.10. *Diagnosed error:* replacing a proof with a visual analogy. *Source:* Cooley and Tukey (1965), pp. 297–301; here Theorems 23.1 and 23.2. *Prerequisite:* Lemma 23.1. *Remediation:* redo the computation with the convention $e^{+2\pi i/N}$ and check that the minus sign remains (because $e^{+i\pi} = -1$ just as $e^{-i\pi}$ does), while the twiddle factor changes.

6) **B.** *Rationale:* omitting (P) makes the algorithm compute $\text{DFT}_N\{x \circ \rho_m\}$; a permutation of the samples does not change $\sum_n |x[n]|^2$, hence by Theorem 22.6 it does not change $\sum_k |X[k]|^2$ either: Parseval is satisfied by the wrong spectrum, as shown numerically in Solved Exercise 23.6 ($\sum_k |Y[k]|^2 = 1,120 = \sum_k |X[k]|^2$). *Distractors:* A, C and D compare *value by value* with an independent computation and immediately detect the discrepancy (for instance $Y[4] = -16$ against $X[4] = -4$). *Diagnosed error:* using as a check a quantity invariant with respect to the error being sought. *Source:* Briggs and Henson, Chapter 6 “Errors in the DFT,” pp. 179–234; here the Best-practice box of Section 23.6. *Prerequisite:* Theorem 22.6, Lemma 23.4. *Remediation:* carry out the three checks (i)–(iii) of Solved Exercise 23.6 on $N=4$.

7) **A. Rationale:** with $N_1 = 2$ and $N_2 = 3$, Theorem 23.11 prescribes $N_2 = 3$ DFTs of length $N_1 = 2$, then $N_1 N_2 = 6$ multiplications by $\omega_6^{k_1 n_2}$, then $N_1 = 2$ DFTs of length $N_2 = 3$; this is exactly what is carried out in Example 23.11. *Distractors:* B forgets the first phase and the twiddle factors; C describes the full radix-2, which does not apply here because 6 is not a power of two; D is a *different* and legitimate route, but it changes the points at which the spectrum is sampled (Remark 23.10) and hence does not compute the 6-point DFT. *Diagnosed error:* believing that zero-padding is always an equivalent route to obtain the same transform. *Source:* Van Loan, Chapter 2 “General Radix Frameworks,” pp. 76–120. *Prerequisite:* Theorem 23.11, Euclidean division. *Remediation:* redo Example 23.11 swapping the roles, that is, with $N_1 = 3$ and $N_2 = 2$, and check that the result is the same.

8) **A. Rationale:** this is the original paper, verified on Crossref (DOI 10.1090/S0025-5718-1965-0178586-1). *Distractors:* B is the modern reference monograph, not the 1965 paper; C is the paper on FFTW, from 2005, cited in Remark 23.14; D is the historical paper documenting Gauss’s priority (1805) and the various rediscoverers, cited for context and not for the algorithm. *Diagnosed error:* citing from memory, confusing the primary source with secondary sources. *Source:* the *Sources* environment of this chapter, entries [1], [2], [5] and [7]. *Prerequisite:* none. *Remediation:* check the four references in a bibliographic archive and note for each what it contains and what it does not contain.

BEST PRACTICE

Assigned exercises — answers.

Exercise 23.1. (a) $N = 32$, $m = 5$. Direct computation: $N^2 = 1,024$ multiplications and $N(N-1) = 992$ additions. FFT: $\frac{N}{2}m = 80$ multiplications and $Nm = 160$ additions; nontrivial $80 - \frac{3 \cdot 32}{2} + 2 = 80 - 48 + 2 = 34$. (The script that counts the butterflies confirms 80, 160 and 34.) (b) By Proposition 23.5 the factors equal to 1 are $N-1$ and those equal to $-i$ are $\frac{N}{2} - 1$; points (iii) exclude -1 and $+i$, and the two families are disjoint because $1 \neq -i$. Total $(N-1) + (\frac{N}{2} - 1) = \frac{3N}{2} - 2$. (c) One wants $N^2 \geq 10 \cdot \frac{N}{2} \log_2 N$, that is, $2N \geq 10m$, that is, $2^{m+1} \geq 10m$. For $m = 4$: $32 < 40$, false; for $m = 5$: $64 \geq 50$, true. Hence the minimum is $N = 32$, where the ratio equals 12.80, consistent with Table 23.1 (at $N = 16$ it equals 8.00). (d) $N = 2^{20} = 1,048,576$. Direct computation: $N^2 = 1,099,511,627,776$ multiplications, that is, 10,995.12 s, or 3.0542 hours. FFT: 8,912,898 nontrivial multiplications, that is, 0.0891 s (0.1049 s counting the trivial ones too). The second number is not a prediction of the real time because it ignores memory accesses, which for N of this order dominate (Remark 23.14).

Exercise 23.2. (a) $m = 2$, $\rho_2 = (0, 2, 1, 3)$; reordered vector $(1, 0, 2, -1)$. (b) Stage 1 ($\omega_2^0 = 1$): $1 + 0 = 1$, $1 - 0 = 1$, $2 + (-1) = 1$, $2 - (-1) = 3$, that is, $(1, 1, 1, 3)$. Stage 2 ($\omega_4^0 = 1$, $\omega_4^1 = -i$): $X[0] = 1 + 1 = 2$, $X[1] = 1 + (-i) \cdot 3 = 1 - 3i$, $X[2] = 1 - 1 = 0$, $X[3] = 1 - (-i) \cdot 3 = 1 + 3i$. (c) From the definition: $X[0] = 1 + 2 + 0 - 1 = 2$; $X[1] = 1 + 2(-i) + 0(-1) + (-1)(i) = 1 - 3i$; $X[2] = 1 - 2 + 0 + 1 = 0$; $X[3] = \overline{X[1]} = 1 + 3i$. They coincide. (d) $\sum_n |x[n]|^2 = 1 + 4 + 0 + 1 = 6$ and $\frac{1}{4} \sum_k |X[k]|^2 = \frac{1}{4}(4 + 10 + 0 + 10) = 6$. $\checkmark$ $X[0]$ and $X[2]$ must be real, that is, the bins $k = 0$ and $k = N/2$, by Corollary 22.8; and indeed they equal 2 and 0. (e) $\overline{X} = (2, 1 + 3i, 0, 1 - 3i)$; $\mathcal{A}_4(\overline{X}) = (4, 8, 0, -4)$; conjugating and dividing by 4 one recovers $(1, 2, 0, -1)$. (f) The factors used are $\omega_2^0 = 1$ (twice), $\omega_4^0 = 1$ and $\omega_4^1 = -i$: all trivial. The formula gives $\frac{4}{2} \cdot 2 - \frac{3 \cdot 4}{2} + 2 = 4 - 6 + 2 = 0$. $\checkmark$

Exercise 23.3. (a) The three subsequences $(x[3n_1 + n_2])_{n_1=0,1,2,3}$ collect the indices $\{0, 3, 6, 9\}$, $\{1, 4, 7, 10\}$ and $\{2, 5, 8, 11\}$, hence they equal $(1, 0, 1, 0)$ for $n_2 = 0$ and $(0, 0, 0, 0)$ for $n_2 = 1$ and $n_2 = 2$. Their 4-point DFTs are $G[\cdot, 0] = (2, 0, 2, 0)$ — because $\sum_{n_1} v[n_1] \omega_4^{n_1 k_1} = 1 + \omega_4^{2k_1} = 1 + (-1)^{k_1}$ — and $G[\cdot, 1] = G[\cdot, 2] = (0, 0, 0, 0)$. The factors $\omega_{12}^{k_1 \cdot 0}$ all equal 1, hence $\tilde{G} = G$; and in the four length-3 DFTs only the term $n_2 = 0$

survives, so that $X[k_1 + 4k_2] = G[k_1, 0]$ for every k_2 . Hence

$$Y = (2, 0, 2, 0, 2, 0, 2, 0, 2, 0, 2, 0),$$

which coincides with the direct computation: indeed x has only two nonzero components and $Y[k] = x[0] + x[6]\omega_{12}^{6k} = 1 + (\omega_{12}^6)^k = 1 + (-1)^k$, by Lemma 23.1(iv). (b) Mixed-radix $12 = 4 \cdot 3$: the three length-4 DFTs done with radix-2 cost 0 nontrivial multiplications and 8 additions each; the 12 factors $\omega_{12}^{k_1 n_2}$ are trivial in 6 cases ($k_1 = 0$ or $n_2 = 0$) and nontrivial in the other 6; the four length-3 DFTs cost 4 multiplications not by 1 and 6 additions each. Total: $0 + 6 + 16 = 22$ nontrivial multiplications and $24 + 24 = 48$ additions, against the 144 multiplications (104 not by 1) and 132 additions of the direct computation. Zero-padding to $N' = 16$: 10 nontrivial multiplications and 64 additions — fewer multiplications, more additions. But it *does not* compute the same thing: the 16-point DFT samples the DTFT at 16 points equally spaced differently from the 12 of the 12-point DFT, and only $Z[0] = Y[0]$ coincides (Proposition 23.6 holds for doubling, not for $12 \rightarrow 16$). If the true 12 bins are needed, the only route is mixed-radix. (c) Primitive roots modulo 5: $g = 2$ (powers 1, 2, 4, 3) and $g = 3$ (powers 1, 3, 4, 2); $g = 4$ is not one (powers 1, 4, 1, 4). With $g = 2$: $A = (x[1], x[2], x[4], x[3])$, $C = (\omega_5, \omega_5^2, \omega_5^4, \omega_5^3)$, $B = (X[1] - x[0], X[2] - x[0], X[4] - x[0], X[3] - x[0])$, and $B[v] = \sum_{u=0}^3 A[u] C[\langle u + v \rangle_4]$. (d) $M = 16 \geq 2 \cdot 5 - 1 = 9$. With $b_j = e^{-i\pi j^2/5}$: $u = (x[0]b_0, \dots, x[4]b_4, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0)$; v has nonzero components only for $j \in \{0, 1, 2, 3, 4\}$, where it equals $\overline{b_j}$, and for $j \in \{12, 13, 14, 15\}$, where it equals $\overline{b_{j-16}}$. The condition $M \geq 2N - 1$ is needed so that the two blocks do not overlap: if $M = 8$ held, the indices $M - N + 1 = 4$ and $N - 1 = 4$ would coincide and $v[4]$ would have to equal two different things.

23.18. Formulary of the chapter

Twiddle factors. $\omega_N = e^{-2\pi i/N}$ (in the literature W_N).

$$\omega_N^j = 1 \iff N \mid j; \quad \omega_N^{2j} = \omega_{N/2}^j; \quad \omega_N^{N/2} = -1; \quad \omega_N^{N/4} = -i \ (4 \mid N); \quad \omega_{dN}^{dj} = \omega_N^j.$$

Eighth roots: $\omega_8 = \frac{\sqrt{2}}{2}(1 - i)$, $\omega_8^2 = -i$, $\omega_8^3 = -\frac{\sqrt{2}}{2}(1 + i)$, $\omega_8^4 = -1$.

Radix-2 decomposition and butterfly. With $N = 2L$, $e[r] = x[2r]$, $o[r] = x[2r + 1]$, $E = \text{DFT}_L\{e\}$, $O = \text{DFT}_L\{o\}$:

$$X[k] = E[k] + \omega_N^k O[k], \quad X\left[k + \frac{N}{2}\right] = E[k] - \omega_N^k O[k], \quad k = 0, \dots, L - 1.$$

$$\mathcal{B}_w(a, b) = (a + wb, a - wb), \quad B_w = \begin{pmatrix} 1 & w \\ 1 & -w \end{pmatrix}, \quad B_w^* B_w = 2I_2 \ (|w| = 1), \quad \|B_w\|_2 = \sqrt{2}.$$

Decimation in frequency: $\alpha[n] = x[n] + x[n + L]$, $\beta[n] = (x[n] - x[n + L])\omega_N^n$,

$$X[2k] = \text{DFT}_L\{\alpha\}[k], \quad X[2k + 1] = \text{DFT}_L\{\beta\}[k].$$

Cost. Direct computation: N^2 multiplications, $N(N - 1)$ additions. Recurrences: $M(N) = 2M(N/2) + \frac{N}{2}$, $A(N) = 2A(N/2) + N$, $M(1) = A(1) = 0$; $T(N) = 2T(N/2) + cN$, $T(1) =$

$$c_0 \Rightarrow T(N) = cN \log_2 N + c_0 N.$$

$$M(N) = \frac{N}{2} \log_2 N, \quad A(N) = N \log_2 N, \quad M^{**}(N) = \frac{N}{2} \log_2 N - \frac{3N}{2} + 2.$$

Trivial factors: $N - 1$ equal to 1, $\frac{N}{2} - 1$ equal to $-i$, in total $\frac{3N}{2} - 2$. For $N = 8$: 12 multiplications (2 nontrivial), 24 additions. For $N = 1,024$: 5,120 (3,586 nontrivial) and 10,240.

Bit-reversal, factorization, IFFT. With $n = \sum_{t < m} b_t(n) 2^t$ and $N = 2^m$:

$$\rho_m(n) = \sum_{t=0}^{m-1} b_t(n) 2^{m-1-t}, \quad \rho_m \circ \rho_m = \text{id}; \quad \rho_3 = (0, 4, 2, 6, 1, 5, 3, 7).$$

$$W_N = A_m A_{m-1} \cdots A_1 P_\rho, \quad \|A_s\|_2 = \sqrt{2}, \quad \|W_N\|_2 = \sqrt{N}.$$

$$\mathcal{F}_N^{-1} X = \frac{1}{N} \overline{\text{DFT}_N \{ \overline{X} \}} = \frac{1}{N} \text{swap} \left(\text{DFT}_N \{ \text{swap}(X) \} \right).$$

Mixed-radix, Bluestein, Rader. With $N = N_1 N_2$, $n = N_2 n_1 + n_2$, $k = k_1 + N_1 k_2$:

$$X[k_1 + N_1 k_2] = \sum_{n_2=0}^{N_2-1} \omega_N^{k_1 n_2} \left(\sum_{n_1=0}^{N_1-1} x[N_2 n_1 + n_2] \omega_{N_1}^{n_1 k_1} \right) \omega_{N_2}^{n_2 k_2}.$$

Bluestein, with $b_j = e^{-i\pi j^2/N}$ and $2nk = n^2 + k^2 - (k - n)^2$:

$$X[k] = b_k \sum_{n=0}^{N-1} (x[n] b_n) \overline{b_{k-n}} = b_k (u \otimes v)[k], \quad M \geq 2N - 1.$$

Rader (p prime, g primitive root): $A[u] = x[\langle g^u \rangle_p]$, $C[v] = \omega_p^{\langle g^v \rangle_p}$, $X[\langle g^v \rangle_p] - x[0] = \sum_{u=0}^{p-2} A[u] C[\langle u + v \rangle_{p-1}]$.

Round-off error. Under hypothesis (M) with constant $\eta = O(u)$:

$$\frac{\|\hat{X} - X\|_2}{\|X\|_2} \leq (1 + \eta)^m - 1 \leq (e - 1) m \eta < 1.72 \eta \log_2 N \quad (m\eta \leq 1),$$

against a bound proportional to Nu for the direct sum. Double precision: $u = 2^{-53} = 1.1102230 \cdot 10^{-16}$.

The numbers of the example $N = 8$, $x = (0, 1, \dots, 7)$.

$$X = \left(28, -4 + i(4 + 4\sqrt{2}), -4 + 4i, -4 + i(4\sqrt{2} - 4), -4, -4 - i(4\sqrt{2} - 4), -4 - 4i, -4 - i(4 + 4\sqrt{2}) \right),$$

with $4 + 4\sqrt{2} = 9.6568542$ and $4\sqrt{2} - 4 = 1.6568542$; $X[k] = \frac{8}{\omega_8^k - 1}$ for $k \neq 0$; $\sum_n |x[n]|^2 = 140$, $\sum_k |X[k]|^2 = 1,120$. For $N = 6$ and $y = (1, \dots, 6)$: $X = (21, -3 + 3\sqrt{3}i, -3 + \sqrt{3}i, -3, -3 - \sqrt{3}i, -3 - 3\sqrt{3}i)$, with $3\sqrt{3} = 5.1961524$ and $\sqrt{3} = 1.7320508$.

Part D

Signals, control, telecommunications

Signals and linear systems: sampling and frequency response

A linear time-invariant system has no memory of its own history: it only knows what it does to an impulse. The whole chapter descends from this sentence, which however needs to be turned into a statement: *which* hypotheses turn “linear and time-invariant” into “is a convolution”, and with which function. The answer — Theorem 24.1 — is that the boundedness of the operator from $L^1(\mathbb{R})$ into the continuous bounded functions suffices, and that the function sought is the representative supplied by the Riesz representation theorem; the *identity* is excluded by the hypothesis, and not by accident, because its impulse response is not a function.

From there the chain unfolds in a forced order. Since convolution becomes a product after the Fourier transform (Theorem 19.4 of Chapter 19), the complex exponentials are *eigenfunctions* of every LTI system (Theorem 24.2 in the continuous case, Theorem 24.3 in the discrete one) and the eigenvalue associated with $e^{i\omega t}$ is, literally, the transform of the impulse response evaluated at ω : the **frequency response**. This is the reason why harmonic analysis and system theory are the same thing written twice, and not two neighbouring disciplines.

On the impulse response one then reads off the two properties that decide whether a system is usable: **BIBO stability**, equivalent to the absolute summability of h (Theorem 24.4, proved in both directions, the second by constructing the input that saturates the inequality), and **causality**, equivalent to the vanishing of h on the negative half-line (Theorem 24.5). On the frequency response one instead reads off the two quantities that decide whether a system *distorts* a signal: the **phase delay** and the **group delay** (Definition 24.9), and Theorem 24.7 proves that a system with constant gain and exactly linear phase over the whole band of the signal returns it identical to itself, shifted in time and rescaled: no waveform distortion.

The second half of the chapter is devoted to the passage from the continuous to the discrete. Section 24.8 — inherited from Volume II and preserved here word for word — proves that sampling in time periodicizes the spectrum, and that if the replicas do not overlap the whole information is there; Section 24.9 completes the proof with the *reconstruction formula* $x(t) = \sum_n x(nT) \operatorname{sinc}((t - nT)/T)$, obtained without distributions, using only the Fourier series expansion of the spectrum on the bandwidth interval; Section 24.10 measures what happens when the hypothesis fails, with a numerical example verified sample by sample. The last section defines the **Hilbert transform** and the **analytic signal**, proves that the latter suppresses the negative frequencies (Theorem 24.11) and states precisely what remains imported.

The results of Chapter 19 — algebraic properties (Theorem 19.3), the convolution theorem (Theorem 19.4), inversion (Theorem 19.9), Plancherel (Corollary 19.4), the sinc function (Proposition 19.2) — and those of Chapter 21 on the discrete case — discrete LTI systems (Definition 21.2), convolution (Proposition 21.1), BIBO stability (Theorem 21.10), the DTFT (Definition 21.5) — are recalled and used here, never reproved. The discrete case of the convolution representation and of BIBO stability is already closed in Chapter 21: this chapter proves the *continuous* case, which does not appear there, and the discrete case is recalled where needed for comparison.

INFO

Level and prerequisites. Level **C** (undergraduate), with three passages at level **D**: the proof of Theorem 24.1 (which uses the duality $(L^1)^* = L^\infty$), the proof of the reconstruction formula (Theorem 24.9) and Section 24.11 on the analytic signal.

Internal prerequisites. The Fourier transform on $L^1(\mathbb{R})$, its algebraic properties, the convolution theorem, the inversion formula, Plancherel's theorem, the rectangle and the sinc function, the Dirac comb (Chapter 19: Definition 19.1, Proposition 19.1, Theorem 19.1, Theorem 19.3, Lemma 19.3, Theorem 19.4, Theorem 19.9, Corollary 19.4, Definition 19.4, Proposition 19.2); convergence in L^2 of Fourier series and completeness of the trigonometric system (Theorem 17.1 of Chapter 17); discrete LTI systems, discrete convolution, discrete BIBO stability and the DTFT (Chapter 21: Definition 21.2, Proposition 21.1, Definition 21.6, Theorem 21.10, Definition 21.5, Theorem 21.6).

External prerequisites, assumed and not reproved:

- the Lebesgue integral on $\mathbb{R}$: measurability, the dominated convergence theorem, the monotone convergence theorem, the Fubini–Tonelli theorem;
- the spaces $L^p(\mathbb{R})$ for $p = 1, 2, \infty$ and their norms; the Cauchy–Schwarz inequality;
- the **Riesz representation theorem** for the dual of L^1 on a σ -finite measure space, i.e. $(L^1(\mathbb{R}))^* \cong L^\infty(\mathbb{R})$ with equality of the norms: it is used only once, in Step 2 of the proof of Theorem 24.1, and is declared *imported* in Remark 24.3;
- differentiation under the integral sign (for computing the group delay of explicit examples, where the hypotheses are checked case by case).

Everything else is proved here.

What one learns. To recognise when a model is LTI and when it is not, with explicit counterexamples; to derive the convolution representation from verifiable hypotheses, instead of postulating it; to use the eigenfunction property to compute the steady-state output without ever carrying out a convolution integral; to decide stability and causality by looking only at the impulse response; to distinguish the phase delay from the group delay and to know which of the two tells whether the waveform survives; to choose a sampling frequency with a criterion, and to know how to compute the spurious frequency that appears when the criterion is violated; to define the envelope and the instantaneous frequency of a narrowband signal without confusing them with what they are not.

Warning. Conventions and notation of the chapter.

- We keep the convention of Chapter 19: for $f \in L^1(\mathbb{R})$

$$\hat{f}(\omega) = \mathcal{F}\{f\}(\omega) = \int_{\mathbb{R}} f(t) e^{-i\omega t} dt, \quad f(t) = \frac{1}{2\pi} \int_{\mathbb{R}} \hat{f}(\omega) e^{i\omega t} d\omega,$$

where ω is the *angular frequency* in radians per second. The *frequency* in hertz is $f = \omega/2\pi$; when it needs to be distinguished from the name of a function it is called ν .

- σ_a is the translation operator, $(\sigma_a x)(t) = x(t - a)$: $a > 0$ is a *delay*. One has $\sigma_a \sigma_b = \sigma_{a+b}$ and $\sigma_0 = \text{id}$.
- u is the Heaviside unit step: $u(t) = 1$ for $t \geq 0$ and $u(t) = 0$ for $t < 0$.
- The sinc function is the *normalised* one of Definition 19.4:

$$\text{sinc}(v) = \frac{\sin(\pi v)}{\pi v} \quad (v \neq 0), \quad \text{sinc}(0) = 1,$$

which vanishes at every nonzero integer. Much of the engineering literature writes sinc for $\sin v/v$: the translation is $\text{sinc}_{\text{here}}(v) = \sin(\pi v)/(\pi v)$.

- sgn is the sign function: $\text{sgn}(\omega) = 1$ for $\omega > 0$, -1 for $\omega < 0$, 0 for $\omega = 0$.

- The letters x and y always denote input and output, h the impulse response, $H = \hat{h}$ the frequency response. In the discrete case one writes $x[n]$ with square brackets and Ω for the normalised angular frequency, as in Chapter 21.
- “Almost everywhere” (a.e.) means: outside a set of Lebesgue measure zero. Two functions equal a.e. define the same element of L^p and the same system.

24.1. Signals and systems: linearity and time-invariance

Definition 24.1: Spaces of signals. A **continuous-time signal** is a Lebesgue-measurable function $x : \mathbb{R} \rightarrow \mathbb{C}$. We will use the spaces

$$L^1(\mathbb{R}) = \left\{ x : \|x\|_1 = \int_{\mathbb{R}} |x(t)| dt < \infty \right\}, \quad L^2(\mathbb{R}) = \left\{ x : \|x\|_2^2 = \int_{\mathbb{R}} |x(t)|^2 dt < \infty \right\},$$

$$L^\infty(\mathbb{R}) = \left\{ x : \|x\|_\infty = \operatorname{ess\,sup}_{t \in \mathbb{R}} |x(t)| < \infty \right\},$$

and moreover $C_b(\mathbb{R})$, the space of *continuous and bounded* functions with the norm $\|x\|_\infty = \sup_t |x(t)|$, and $C_c(\mathbb{R})$, that of continuous functions with compact support. A signal of $L^\infty(\mathbb{R})$ is called **bounded**. The **support** of x is the closure of $\{t : x(t) \neq 0\}$; the signal is **causal** if its support is contained in $[0, +\infty)$.

Remark 24.1: Why three spaces and not one. The three spaces answer three different physical questions and are not comparable with one another: L^1 collects signals of finite area (a current pulse transfers a finite charge), L^2 those of finite energy, L^∞ those of bounded amplitude. No inclusion holds between L^1 and L^2 on $\mathbb{R}$: the function $t \mapsto t^{-1/2} \mathbf{1}_{(0,1)}(t)$ lies in L^1 and not in L^2 , because $\int_0^1 t^{-1/2} dt = 2$ while $\int_0^1 t^{-1} dt = +\infty$; the function $t \mapsto (1+|t|)^{-1}$ lies in L^2 and not in L^1 , because $\int_{\mathbb{R}} (1+|t|)^{-2} dt = 2$ while $\int_{\mathbb{R}} (1+|t|)^{-1} dt = +\infty$. A sinusoidal signal, the protagonist of the whole chapter, lies neither in L^1 nor in L^2 : it lies in L^∞ , and this is exactly the reason why Theorem 24.2 must be stated there.

Definition 24.2: System, translation, LTI system. Let X and Y be two signal spaces closed under linear combinations and under translations, where the **translation** by step $a \in \mathbb{R}$ is

$$(\sigma_a x)(t) = x(t - a).$$

A **system** is a map $\mathcal{T} : X \rightarrow Y$. It is

- (L) **linear** if $\mathcal{T}(\alpha x + \beta y) = \alpha \mathcal{T}x + \beta \mathcal{T}y$ for all $x, y \in X$ and $\alpha, \beta \in \mathbb{C}$;
 - (TI) **time-invariant** if $\mathcal{T}(\sigma_a x) = \sigma_a(\mathcal{T}x)$ for all $x \in X$ and all $a \in \mathbb{R}$.
- If both hold, $\mathcal{T}$ is a **linear time-invariant system**, in short an **LTI system**.

Example 24.1: Four LTI systems and three that are not. Are LTI.

- (a) The *pure delay* $\mathcal{T}_{t_0}x = \sigma_{t_0}x$, i.e. $y(t) = x(t - t_0)$. Linearity: immediate from the definition of σ_{t_0} . Invariance: $\sigma_{t_0}\sigma_a = \sigma_{t_0+a} = \sigma_a\sigma_{t_0}$.
- (b) The *amplifier* $y = Kx$ with $K \in \mathbb{C}$ constant.
- (c) The *moving average* over a window of duration $T_0 > 0$: $y(t) = \frac{1}{T_0} \int_{t-T_0}^t x(s) ds$.
- (d) The low-pass *RC filter*, which associates with every bounded input the bounded solution of $\tau y' + y = x$ with $\tau = RC$.

Are not LTI.

- (e) The *squarer* $y(t) = x(t)^2$: it is not linear. With $x \equiv 1$ and $\alpha = 2$ one has $\mathcal{T}(2x) \equiv 4$ while $2\mathcal{T}x \equiv 2$, and $4 \neq 2$.
- (f) The *modulator* $y(t) = x(t) \cos(\omega_0 t)$ with $\omega_0 \neq 0$: it is linear but not time-invariant. Take $x \equiv 1$ and $a = \pi/\omega_0$: then $\sigma_a x = x$, hence $\mathcal{T}(\sigma_a x)(t) = \cos(\omega_0 t)$, while $\sigma_a(\mathcal{T}x)(t) = \cos(\omega_0 t - \pi) = -\cos(\omega_0 t)$. The two functions differ, for instance at $t = 0$, where they equal 1 and -1 .
- (g) The *sampler* $x \mapsto (x(nT))_{n \in \mathbb{Z}}$ of Section 24.8: it is linear, but it is invariant only under translations that are multiples of T , not under all of them. It is precisely this *partial* invariance that produces the periodicization of the spectrum in Theorem 24.8.

Remark 24.2: The model and reality. No physical device is exactly LTI: an amplifier saturates, a capacitor ages, a motor has static friction. The LTI model is the linearisation of the behaviour around an operating point, valid as long as the amplitudes remain small and the time scale of the experiment is short compared with the drift of the parameters. The gain from this approximation is enormous and must be said once and for all: inside the LTI model a system is described by a single function — the impulse response — and its action on any input is computed by a multiplication in the frequency domain. Outside the model neither of these two sentences remains true. The circle criterion of Chapter 25, Section 25.6, is one of the few tools that survive a declared nonlinearity.

24.2. The convolution representation

The statement “an LTI system is convolution with its own impulse response” is true, but it is not true without hypotheses, and the hypotheses are not a technical detail: they are exactly what distinguishes systems whose impulse response is a *function* from those where it is not. This section states and proves the two implications: first that every convolution is an LTI system (Proposition 24.2), then that every LTI system *bounded in the appropriate sense* is a convolution (Theorem 24.1).

Definition 24.3: Convolution on $\mathbb{R}$. Given two measurable functions $h, x : \mathbb{R} \rightarrow \mathbb{C}$, their **convolution** is

$$(h * x)(t) = \int_{\mathbb{R}} h(\tau) x(t - \tau) d\tau,$$

defined at every t for which the integral converges absolutely. It is the same operation as Definition 19.3 of Chapter 19.

Proposition 24.1: When convolution is defined everywhere.

(i) If $h \in L^1(\mathbb{R})$ and $x \in L^\infty(\mathbb{R})$, then $(h * x)(t)$ is defined for every $t \in \mathbb{R}$, one has

$$|(h * x)(t)| \leq \|h\|_1 \|x\|_\infty \quad \text{for every } t,$$

and $h * x$ is uniformly continuous on $\mathbb{R}$; in particular $h * x \in C_b(\mathbb{R})$.

(ii) If $h \in L^\infty(\mathbb{R})$ and $x \in L^1(\mathbb{R})$, the same conclusions hold with $\|h\|_\infty \|x\|_1$ in place of $\|h\|_1 \|x\|_\infty$.

(iii) In both cases $(h * x)(t) = (x * h)(t)$ for every t .

Proof. (i), convergence and estimate. For every fixed t the function $\tau \mapsto h(\tau)x(t - \tau)$ is measurable (a product of measurable functions; $\tau \mapsto x(t - \tau)$ is measurable because it is the composition of x with the affine map $\tau \mapsto t - \tau$, which sends sets of measure zero to sets of

measure zero). Moreover $|h(\tau)x(t-\tau)| \leq |h(\tau)| \|x\|_\infty$ for almost every τ , and the right-hand side is integrable with integral $\|h\|_1 \|x\|_\infty$. Hence the integral converges absolutely and

$$|(h * x)(t)| \leq \int_{\mathbb{R}} |h(\tau)| |x(t-\tau)| d\tau \leq \|h\|_1 \|x\|_\infty.$$

(i), uniform continuity. With the change of variable $u = t - \tau$ (a translation followed by a reflection: it preserves Lebesgue measure) one writes $(h * x)(t) = \int_{\mathbb{R}} h(t-u) x(u) du$. Hence, for every t and every s ,

$$|(h * x)(t+s) - (h * x)(t)| = \left| \int_{\mathbb{R}} [h(t+s-u) - h(t-u)] x(u) du \right| \leq \|x\|_\infty \int_{\mathbb{R}} |h(t+s-u) - h(t-u)| du.$$

In the last integral set $v = t - u$: it becomes $\int_{\mathbb{R}} |h(v+s) - h(v)| dv = \|\sigma_{-s}h - h\|_1$, which does not depend on t . By Lemma 19.3 (continuity of translations in L^1) one has $\|\sigma_{-s}h - h\|_1 \rightarrow 0$ as $s \rightarrow 0$. Given $\varepsilon > 0$ there is therefore $\delta > 0$ such that $|s| < \delta$ implies $\|\sigma_{-s}h - h\|_1 < \varepsilon/(1 + \|x\|_\infty)$, and then $|(h * x)(t+s) - (h * x)(t)| < \varepsilon$ for every t : this is uniform continuity. Together with the estimate of the previous point, $h * x \in C_b(\mathbb{R})$.

(ii). This is point (i) with the roles exchanged, once one observes that, by point (iii), $h * x = x * h$: apply (i) to the pair (x, h) with $x \in L^1$ and $h \in L^\infty$.

(iii). In the first case the substitution $u = t - \tau$, i.e. $\tau = t - u$, is a bijection of $\mathbb{R}$ onto itself that preserves Lebesgue measure and has $|d\tau| = |du|$; since the integral converges absolutely, the change of variable is legitimate and

$$(h * x)(t) = \int_{\mathbb{R}} h(\tau)x(t-\tau) d\tau = \int_{\mathbb{R}} h(t-u)x(u) du = (x * h)(t).$$

The same computation holds in the second case. □

Proposition 24.2: Every convolution is an LTI system. Let $h \in L^1(\mathbb{R})$ and define $\mathcal{T}_h x = h * x$ on $X = L^\infty(\mathbb{R})$. Then $\mathcal{T}_h : L^\infty(\mathbb{R}) \rightarrow C_b(\mathbb{R})$ is linear, time-invariant and bounded with

$$\|\mathcal{T}_h x\|_\infty \leq \|h\|_1 \|x\|_\infty.$$

The same conclusion holds, with $\|h\|_\infty \|x\|_1$, for $h \in L^\infty(\mathbb{R})$ and $\mathcal{T}_h : L^1(\mathbb{R}) \rightarrow C_b(\mathbb{R})$.

Proof. Well-posedness, the estimate and membership in $C_b(\mathbb{R})$ are Proposition 24.1(i) (respectively (ii)).

Linearity. For every t and every $\alpha, \beta \in \mathbb{C}$, the function $\tau \mapsto h(\tau)[\alpha x_1(t-\tau) + \beta x_2(t-\tau)]$ is a sum of two absolutely integrable functions, so the integral splits:

$$(h * (\alpha x_1 + \beta x_2))(t) = \alpha \int_{\mathbb{R}} h(\tau)x_1(t-\tau) d\tau + \beta \int_{\mathbb{R}} h(\tau)x_2(t-\tau) d\tau = \alpha (h * x_1)(t) + \beta (h * x_2)(t).$$

Time-invariance. For every $a \in \mathbb{R}$ and every t ,

$$(h * (\sigma_a x))(t) = \int_{\mathbb{R}} h(\tau) (\sigma_a x)(t-\tau) d\tau = \int_{\mathbb{R}} h(\tau) x(t-a-\tau) d\tau = (h * x)(t-a) = (\sigma_a (h * x))(t),$$

where the second step is the definition $(\sigma_a x)(s) = x(s-a)$ applied with $s = t - \tau$, and the third is the definition of convolution itself evaluated at $t - a$. □

The converse is the central result of the section. The hypothesis that makes it legitimate is the *boundedness* of the operator from L^1 into C_b : it is this that guarantees that the impulse response is a function, and not a more general object.

Theorem 24.1: Convolution representation. Let $\mathcal{T} : L^1(\mathbb{R}) \rightarrow C_b(\mathbb{R})$ be a map such that

(S1) $\mathcal{T}$ is linear;

(S2) $\mathcal{T}$ is time-invariant: $\mathcal{T}(\sigma_a x) = \sigma_a(\mathcal{T}x)$ for every $x \in L^1(\mathbb{R})$ and every $a \in \mathbb{R}$;

(S3) $\mathcal{T}$ is bounded: there exists $C \geq 0$ with $\|\mathcal{T}x\|_\infty \leq C \|x\|_1$ for every $x \in L^1(\mathbb{R})$.

Then there exists $h \in L^\infty(\mathbb{R})$, unique up to sets of measure zero, such that

$$(\mathcal{T}x)(t) = (h * x)(t) = \int_{\mathbb{R}} h(t - u) x(u) du \quad \text{for every } x \in L^1(\mathbb{R}) \text{ and every } t \in \mathbb{R},$$

and $\|h\|_\infty \leq C$ holds. The function h is called the **impulse response** of the system.

Proof. Step 1 — the “output at time zero” functional. Define

$$\Lambda : L^1(\mathbb{R}) \rightarrow \mathbb{C}, \quad \Lambda(x) = (\mathcal{T}x)(0).$$

The definition makes sense because by hypothesis $\mathcal{T}x$ is a *continuous* function, so its value at the point 0 is a well-determined number and does not depend on the representative chosen. The functional Λ is linear by (S1) — evaluating at 0 is a linear operation — and is bounded by (S3):

$$|\Lambda(x)| = |(\mathcal{T}x)(0)| \leq \|\mathcal{T}x\|_\infty \leq C \|x\|_1.$$

Hence $\Lambda \in (L^1(\mathbb{R}))^*$ with $\|\Lambda\| \leq C$.

Step 2 — representation of the functional. By the Riesz representation theorem for the dual of L^1 with respect to Lebesgue measure, which is σ -finite (an *imported* result: see Remark 24.3), there exists $g \in L^\infty(\mathbb{R})$, unique a.e., with

$$\Lambda(x) = \int_{\mathbb{R}} g(s) x(s) ds \quad \text{for every } x \in L^1(\mathbb{R}), \quad \|g\|_\infty = \|\Lambda\| \leq C.$$

Step 3 — invariance shifts the evaluation from 0 to t . Let $x \in L^1(\mathbb{R})$ and $t \in \mathbb{R}$. Since $\sigma_{-t}x \in L^1(\mathbb{R})$ with the same norm, one may apply (S2) with $a = -t$:

$$\mathcal{T}(\sigma_{-t}x) = \sigma_{-t}(\mathcal{T}x),$$

and evaluating both sides at 0, with $(\sigma_{-t}y)(0) = y(0 + t) = y(t)$,

$$\Lambda(\sigma_{-t}x) = (\mathcal{T}(\sigma_{-t}x))(0) = (\sigma_{-t}(\mathcal{T}x))(0) = (\mathcal{T}x)(t).$$

Step 4 — the computation. Applying Step 2 to the signal $\sigma_{-t}x$, which equals $(\sigma_{-t}x)(s) = x(s + t)$,

$$(\mathcal{T}x)(t) = \Lambda(\sigma_{-t}x) = \int_{\mathbb{R}} g(s) x(s + t) ds = \int_{\mathbb{R}} g(u - t) x(u) du,$$

where in the last step one has set $u = s + t$ (a translation: it preserves the measure, and the integral converges absolutely because $|g(s)x(s + t)| \leq \|g\|_\infty |x(s + t)|$). Define now

$$h(v) := g(-v) \quad (v \in \mathbb{R}),$$

which is measurable and bounded with $\|h\|_\infty = \|g\|_\infty \leq C$. Then $g(u - t) = h(t - u)$, and hence

$$(\mathcal{T}x)(t) = \int_{\mathbb{R}} h(t - u) x(u) du = (h * x)(t)$$

for every t , having used the form of $h * x$ derived in the proof of Proposition 24.1(iii).

Step 5 — uniqueness. Let $h_1, h_2 \in L^\infty(\mathbb{R})$ be such that $h_1 * x = h_2 * x$ for every $x \in L^1(\mathbb{R})$, and let $d = h_1 - h_2 \in L^\infty(\mathbb{R})$. Evaluating at $t = 0$ gives $\int_{\mathbb{R}} d(-u)x(u) du = 0$ for every

$x \in L^1(\mathbb{R})$. Suppose for contradiction that d is not zero a.e.: then there is $\delta > 0$ such that the set $E = \{u \in \mathbb{R} : |d(-u)| > \delta\}$ has positive measure, and since $E = \bigcup_{N \in \mathbb{N}} (E \cap [-N, N])$ there is N with $0 < \text{meas}(E \cap [-N, N]) < \infty$. Set $E_N = E \cap [-N, N]$ and

$$x_0(u) = \left(\frac{d(-u)}{|d(-u)|} \right) \mathbf{1}_{E_N}(u),$$

which is measurable (a quotient of measurable functions on a set where the denominator does not vanish), of modulus ≤ 1 and with support of finite measure: hence $x_0 \in L^1(\mathbb{R})$. But then

$$0 = \int_{\mathbb{R}} d(-u) x_0(u) du = \int_{E_N} \frac{|d(-u)|^2}{|d(-u)|} du = \int_{E_N} |d(-u)| du \geq \delta \cdot \text{meas}(E_N) > 0,$$

which is absurd. Hence $d = 0$ a.e., that is, $h_1 = h_2$ a.e. □

Remark 24.3: What we import, and why the identity is excluded. Of the previous proof only one step is not carried out here: Step 2, that is, the Riesz representation theorem $(L^1(\mu))^* \cong L^\infty(\mu)$ for μ σ -finite. It is a standard result of measure theory, listed among the external prerequisites; its proof (for Lebesgue measure it goes through the Radon–Nikodým theorem) does not belong to this treatise and is **imported**. Everything else — Steps 1, 3, 4 and 5 — is proved in full.

It must be said with equal precision what the theorem does not give. Hypothesis (S3) excludes perfectly reasonable systems:

- the identity $\mathcal{T}x = x$ does not map L^1 into C_b (an element of L^1 is in general neither continuous nor bounded), and no $h \in L^\infty$ represents it. Indeed, if $x = h * x$ held for every $x \in L^1$ with some $h \in L^\infty$, take $x_\varepsilon = \frac{1}{\varepsilon} \mathbf{1}_{[0, \varepsilon]}$, which has $\|x_\varepsilon\|_1 = 1$ and $\|x_\varepsilon\|_\infty = 1/\varepsilon$: Proposition 24.1(ii) would give $\|x_\varepsilon\|_\infty = \|h * x_\varepsilon\|_\infty \leq \|h\|_\infty \|x_\varepsilon\|_1 = \|h\|_\infty$, i.e. $1/\varepsilon \leq \|h\|_\infty$ for every $\varepsilon > 0$, which is absurd;
- the pure delay $\mathcal{T}_{t_0}x = x_{t_0}$, for the same reason;
- the differentiator $\mathcal{T}x = x'$, which is not even defined on all of L^1 .

For these systems the impulse response exists, but as a **distribution**: it is δ for the identity, δ_{t_0} for the delay, δ' for the differentiator. The theory that treats them is that of the tempered distributions of Chapter 19, Section 19.12; the general theorem stating that every continuous linear time-invariant operator between spaces of distributions is convolution with a distribution (the Schwartz kernel theorem, and its form for translation-invariant operators) is not proved in this treatise and is cited here only as **panorama**: see Oppenheim and Willsky, entry [3] of the Sources environment for the mathematical framework. The present chapter uses only the case where h is a function, which is the case of all the filters of Section 24.6, and treats the pure delay separately and directly (Proposition 24.3).

Remark 24.4: The discrete case is already closed. In the discrete-time case the same representation is proved in Chapter 21, Proposition 21.1, and there the proof is purely algebraic for inputs with finite support: it suffices to write $x = \sum_k x[k] \sigma_k \delta$, a finite linear combination of translates of the unit impulse, and apply (L) and (TI). This route does not exist in the continuous case, because there is no function that acts as a unit impulse: δ is not a function (Proposition 19.8). This is the reason why the continuous case requires the functional analysis of Theorem 24.1 and the discrete case does not — a difference that in introductory texts often remains implicit.

Definition 24.4: Convolution system and its extension to bounded signals. Let $h \in L^1(\mathbb{R})$. The **convolution system** with impulse response h is

$$\mathcal{T}_h : L^\infty(\mathbb{R}) \rightarrow C_b(\mathbb{R}), \quad \mathcal{T}_h x = h * x.$$

By Proposition 24.2 it is linear, time-invariant and bounded with constant $\|h\|_1$. From here on, “LTI system with impulse response $h \in L^1$ ” always means $\mathcal{T}_h$ defined this way.

***Remark 24.5: Why the extension to L^∞ is needed.** Theorem 24.1 produces h from the action of the system on signals of L^1 , but the signals of interest in this chapter — a sinusoid, a step, a bounded noise — do not lie in L^1 . Definition 24.4 extends the system to L^∞ by imposing the same formula, and Proposition 24.1(i) guarantees that the formula continues to make sense. The extension is a modelling choice, not a theorem, and it is consistent with the starting point: if $x \in L^1 \cap L^\infty$, the two definitions give the same integral, because it is literally the same integral. It is the continuous analogue of Remark 21.2 of Chapter 21, where the same choice is declared for the discrete case.*

Example 24.2: The impulse response of the four LTI systems. (a) Amplifier with delay, $y(t) = K x(t - t_0)$: it does not fall under Definition 24.4 (its impulse response is $K\delta_{t_0}$, a distribution), and must be treated directly: see Proposition 24.3.

(b) Moving average over $[t - T_0, t]$: one writes $y(t) = \frac{1}{T_0} \int_{t-T_0}^t x(s) ds = \int_{\mathbb{R}} h(\tau) x(t - \tau) d\tau$ with

$$h(\tau) = \frac{1}{T_0} \mathbf{1}_{[0, T_0]}(\tau),$$

as one sees by setting $\tau = t - s$: as s ranges over $[t - T_0, t]$, τ ranges over $[0, T_0]$. Here $h \in L^1(\mathbb{R})$ with $\|h\|_1 = \frac{1}{T_0} \cdot T_0 = 1$.

(c) Low-pass RC filter, i.e. the bounded solution of $\tau y' + y = x$ with $\tau > 0$: the impulse response is

$$h(t) = \frac{1}{\tau} e^{-t/\tau} u(t),$$

and $\|h\|_1 = \frac{1}{\tau} \int_0^{+\infty} e^{-t/\tau} dt = \frac{1}{\tau} \cdot \tau = 1$. That $y = h * x$ solves the equation is verified directly: for $x \in C_b(\mathbb{R})$,

$$y(t) = \frac{1}{\tau} \int_0^{+\infty} e^{-\theta/\tau} x(t - \theta) d\theta = \frac{1}{\tau} \int_{-\infty}^t e^{-(t-s)/\tau} x(s) ds = \frac{e^{-t/\tau}}{\tau} \int_{-\infty}^t e^{s/\tau} x(s) ds,$$

and differentiating the product (the integral is differentiable in t because the integrand is continuous in s)

$$y'(t) = -\frac{1}{\tau} \cdot \frac{e^{-t/\tau}}{\tau} \int_{-\infty}^t e^{s/\tau} x(s) ds + \frac{e^{-t/\tau}}{\tau} e^{t/\tau} x(t) = -\frac{y(t)}{\tau} + \frac{x(t)}{\tau},$$

that is $\tau y' + y = x$. ✓

(d) Ideal integrator $y(t) = \int_{-\infty}^t x(s) ds$: the impulse response is the step $h = u$, which is in $L^\infty(\mathbb{R})$ but *not* in $L^1(\mathbb{R})$, because $\int_0^N 1 dt = N \rightarrow +\infty$. It will reappear in Example 24.3 as the prototype of a non-stable system.

24.3. Complex exponentials are eigenfunctions

Definition 24.5: Eigenfunction of a system. Let $\mathcal{T} : X \rightarrow Y$ be a system with $X \subseteq Y$. A signal $\varphi \in X$ not identically zero is an **eigenfunction** of $\mathcal{T}$ if there exists $\lambda \in \mathbb{C}$ with

$$\mathcal{T}\varphi = \lambda\varphi;$$

the number λ is the associated **eigenvalue**. An eigenfunction passes through the system without changing shape: it changes only by a complex factor, i.e. by an amplitude and a phase.

Theorem 24.2: Complex exponentials are eigenfunctions: continuous case. Let $h \in L^1(\mathbb{R})$ and let $\mathcal{T}_h$ be the convolution system of Definition 24.4. For every $\omega \in \mathbb{R}$ set $e_\omega(t) = e^{i\omega t}$. Then $e_\omega \in L^\infty(\mathbb{R})$ is an eigenfunction of $\mathcal{T}_h$ and

$$\mathcal{T}_h e_\omega = H(\omega) e_\omega, \quad \text{where} \quad H(\omega) = \hat{h}(\omega) = \int_{\mathbb{R}} h(\tau) e^{-i\omega\tau} d\tau.$$

The eigenvalue associated with e_ω is therefore the Fourier transform of the impulse response evaluated at ω .

Proof. Step 1 — the input is admissible. $|e_\omega(t)| = |e^{i\omega t}| = 1$ for every t , hence $e_\omega \in L^\infty(\mathbb{R})$ with $\|e_\omega\|_\infty = 1$; by Proposition 24.1(i) the integral defining $\mathcal{T}_h e_\omega$ converges absolutely at every t .

Step 2 — the computation. For every $t \in \mathbb{R}$,

$$(\mathcal{T}_h e_\omega)(t) = \int_{\mathbb{R}} h(\tau) e^{i\omega(t-\tau)} d\tau = \int_{\mathbb{R}} h(\tau) e^{i\omega t} e^{-i\omega\tau} d\tau = e^{i\omega t} \int_{\mathbb{R}} h(\tau) e^{-i\omega\tau} d\tau,$$

where the second step is the property $e^{a+b} = e^a e^b$ of the complex exponential and the third is pulling the factor $e^{i\omega t}$, which does not depend on the integration variable τ , out of the integral sign (the operation is legitimate because the integral converges absolutely and $|e^{i\omega t}| = 1$).

Step 3 — identification of the eigenvalue. The last integral is, by Definition 19.1 of Chapter 19, exactly $\hat{h}(\omega)$, and it is a finite complex number because $h \in L^1(\mathbb{R})$ (Proposition 19.1). Hence $(\mathcal{T}_h e_\omega)(t) = \hat{h}(\omega) e^{i\omega t}$ for every t , i.e. $\mathcal{T}_h e_\omega = H(\omega) e_\omega$ with $H = \hat{h}$. Since e_ω is not identically zero, it is an eigenfunction in the sense of Definition 24.5. $\square$

Theorem 24.3: Complex exponentials are eigenfunctions: discrete case. Let $h \in \ell^1(\mathbb{Z})$ and let $\mathcal{T}$ be the discrete LTI system $\mathcal{T}x = h * x$ of Proposition 21.1(ii). For every $\Omega \in \mathbb{R}$ set $e_\Omega[n] = e^{i\Omega n}$. Then $e_\Omega \in \ell^\infty(\mathbb{Z})$ is an eigenfunction of $\mathcal{T}$ and

$$\mathcal{T} e_\Omega = \hat{h}(\Omega) e_\Omega, \quad \text{where} \quad \hat{h}(\Omega) = \sum_{k \in \mathbb{Z}} h[k] e^{-i\Omega k}$$

is the DTFT of h (Definition 21.5 of Chapter 21).

Proof. Step 1 — admissibility. $|e_\Omega[n]| = 1$ for every n , hence $e_\Omega \in \ell^\infty(\mathbb{Z})$ with $\|e_\Omega\|_\infty = 1$; by Proposition 21.1(ii), since $h \in \ell^1(\mathbb{Z})$, the convolution series converges absolutely for every n .

Step 2 — the computation. For every $n \in \mathbb{Z}$,

$$(\mathcal{T} e_\Omega)[n] = \sum_{k \in \mathbb{Z}} h[k] e^{i\Omega(n-k)} = \sum_{k \in \mathbb{Z}} h[k] e^{i\Omega n} e^{-i\Omega k} = e^{i\Omega n} \sum_{k \in \mathbb{Z}} h[k] e^{-i\Omega k},$$

where pulling the constant factor $e^{i\Omega n}$ out of the series is legitimate because the series converges

absolutely (an absolutely convergent series can be multiplied term by term by a constant). The last sum converges absolutely because $|h[k]e^{-i\Omega k}| = |h[k]|$ and $h \in \ell^1(\mathbb{Z})$, and it is by definition $\hat{h}(\Omega)$. By Theorem 21.6 it coincides with the Zeta transform of h evaluated at $z = e^{i\Omega}$. $\square$

Corollary 24.1: What an LTI system does to a sinusoid. Let $h \in L^1(\mathbb{R})$ take real values, $H = \hat{h}$, and let $x(t) = A \cos(\omega_0 t + \varphi_0)$ with $A > 0$, $\omega_0 \in \mathbb{R}$, $\varphi_0 \in \mathbb{R}$. Then

$$(\mathcal{T}_h x)(t) = A |H(\omega_0)| \cos(\omega_0 t + \varphi_0 + \arg H(\omega_0)) \quad \text{for every } t \in \mathbb{R},$$

where $\arg H(\omega_0)$ is any argument of $H(\omega_0)$ (if $H(\omega_0) = 0$ the output is identically zero). In particular: an LTI system does not change the frequency of a sinusoid; it changes only its amplitude, by the factor $|H(\omega_0)|$, and its phase, by the additive term $\arg H(\omega_0)$.

Proof. Step 1 — Hermitian symmetry of H . Since h is real, $\bar{h} = h$ and for every ω

$$\overline{H(\omega)} = \overline{\int_{\mathbb{R}} h(\tau) e^{-i\omega\tau} d\tau} = \int_{\mathbb{R}} h(\tau) \overline{e^{-i\omega\tau}} d\tau = \int_{\mathbb{R}} h(\tau) e^{i\omega\tau} d\tau = H(-\omega),$$

having brought the conjugation inside the integral (legitimate: conjugation is additive, continuous and the integral converges absolutely) and having used $\overline{h(\tau)} = h(\tau)$.

Step 2 — decomposition of the input. By Euler's formula,

$$x(t) = A \cos(\omega_0 t + \varphi_0) = \frac{A}{2} e^{i\varphi_0} e^{i\omega_0 t} + \frac{A}{2} e^{-i\varphi_0} e^{-i\omega_0 t} = \frac{A}{2} e^{i\varphi_0} e_{\omega_0}(t) + \frac{A}{2} e^{-i\varphi_0} e_{-\omega_0}(t),$$

a finite linear combination of two eigenfunctions.

Step 3 — applying the theorem. By linearity of $\mathcal{T}_h$ (Proposition 24.2) and by Theorem 24.2,

$$(\mathcal{T}_h x)(t) = \frac{A}{2} e^{i\varphi_0} H(\omega_0) e^{i\omega_0 t} + \frac{A}{2} e^{-i\varphi_0} H(-\omega_0) e^{-i\omega_0 t}.$$

By Step 1, $H(-\omega_0) = \overline{H(\omega_0)}$: the two terms are conjugates of each other, and their sum equals $2 \operatorname{Re}$ of the first:

$$(\mathcal{T}_h x)(t) = 2 \operatorname{Re} \left(\frac{A}{2} e^{i\varphi_0} H(\omega_0) e^{i\omega_0 t} \right) = A \operatorname{Re} \left(|H(\omega_0)| e^{i \arg H(\omega_0)} e^{i(\omega_0 t + \varphi_0)} \right),$$

having written $H(\omega_0) = |H(\omega_0)| e^{i \arg H(\omega_0)}$ (polar form, legitimate for $H(\omega_0) \neq 0$). Since $\operatorname{Re}(e^{i\theta}) = \cos \theta$, one concludes

$$(\mathcal{T}_h x)(t) = A |H(\omega_0)| \cos(\omega_0 t + \varphi_0 + \arg H(\omega_0)).$$

If instead $H(\omega_0) = 0$, then also $H(-\omega_0) = \bar{0} = 0$ and the formula of Step 3 gives identically zero output, consistently with the statement. $\square$

Remark 24.6: Why this is the reason for Fourier analysis. Theorem 24.2 is the reason why harmonic analysis is not one tool among many for studying linear systems: it is the diagonalisation. An LTI system, viewed as a linear operator, has as eigenvectors the exponentials e_ω and as eigenvalues the numbers $H(\omega)$; writing a signal as a superposition of exponentials — that is, transforming it according to Fourier — means expressing it in the basis that makes the operator diagonal, and in that basis the action of the system is a simple multiplication, component by component. The convolution theorem (Theorem 19.4) and Theorem 24.2 are two formulations of the same fact: the first says $\widehat{h * x} = \hat{h} \hat{x}$, the second reads it on a single exponential.

The same pattern repeats at every level of the treatise with the same structure and different names: in the discrete setting it is the exponential vectors that diagonalise circulant matrices (Theorem 22.8 of Chapter 22); in the Zeta domain it is the restriction to the unit circle that gives the frequency response (Corollary 21.4); in automatic control it is the substitution $s = i\omega$ in the transfer function (Chapter 25, Section 25.1).

Remark 24.7: Are these the only eigenfunctions common to all LTI systems?

Yes, and the reason is elementary to state but not to prove here. If a signal $x \in C_b(\mathbb{R})$ not identically zero is an eigenfunction of all pure delays σ_a , there exists a function $\lambda : \mathbb{R} \rightarrow \mathbb{C}$ with $\sigma_a x = \lambda(a)x$ for every a ; evaluating at a point t_1 with $x(t_1) \neq 0$ gives $\lambda(a) = x(t_1 - a)/x(t_1)$, hence λ is continuous, and from $\sigma_a \sigma_b = \sigma_{a+b}$ it follows that $\lambda(a+b) = \lambda(a)\lambda(b)$ with $\lambda(0) = 1$. The continuous solutions of this multiplicative Cauchy functional equation are all and only the $\lambda(a) = e^{ca}$ with $c \in \mathbb{C}$, and the requirement $x \in L^\infty$ forces c to be purely imaginary, $c = -i\omega$: one recovers $x(t) = x(0)e^{i\omega t}$.

The step that this treatise does not prove is the classification of the continuous solutions of the Cauchy functional equation: it is a classical result of real analysis, **imported** here and used only in this remark, which indeed is not a theorem and is not used elsewhere in the chapter. What is missing, to be precise, is exactly the deduction “ λ continuous and multiplicative $\Rightarrow \lambda(a) = e^{ca}$ ”; all the rest of the reasoning is carried out in full above.

24.4. BIBO stability

Definition 24.6: BIBO stability. A system $\mathcal{T}$ defined on bounded signals is **BIBO stable** (bounded input, bounded output) if there is a constant $M \geq 0$ such that

$$\|x\|_\infty \leq 1 \implies \|\mathcal{T}x\|_\infty \leq M,$$

equivalently, by homogeneity, $\|\mathcal{T}x\|_\infty \leq M\|x\|_\infty$ for every bounded input x . The smallest constant M with this property is called the **gain** of the system.

Theorem 24.4: BIBO $\iff$ absolutely integrable impulse response. Let $h : \mathbb{R} \rightarrow \mathbb{C}$ be measurable and locally integrable, and consider the system $\mathcal{T}x = h * x$ on the class

$$X_c = \{x \in L^\infty(\mathbb{R}) : x \text{ has compact support}\},$$

for which the convolution integral is certainly finite at every t (the support is bounded and h is locally integrable). Call $\mathcal{T}$ BIBO stable if there is $M \geq 0$ with $\|\mathcal{T}x\|_\infty \leq M\|x\|_\infty$ for every $x \in X_c$. Then

$$\mathcal{T} \text{ is BIBO stable } \iff h \in L^1(\mathbb{R}),$$

and in that case the gain equals exactly $M = \|h\|_1$. If $h \in L^1(\mathbb{R})$, the bound $\|h * x\|_\infty \leq \|h\|_1 \|x\|_\infty$ moreover holds for every $x \in L^\infty(\mathbb{R})$, not only for those with compact support: stability in the sense of Definition 24.6 and stability on X_c coincide.

Proof. Step 1 — sufficiency ($\Leftarrow$). Let $h \in L^1(\mathbb{R})$. By Proposition 24.1(i), for every bounded x the integral converges absolutely and

$$|(h * x)(t)| \leq \int_{\mathbb{R}} |h(\tau)| |x(t - \tau)| d\tau \leq \|x\|_\infty \int_{\mathbb{R}} |h(\tau)| d\tau = \|h\|_1 \|x\|_\infty$$

for every t . Taking the supremum over t gives $\|h * x\|_\infty \leq \|h\|_1 \|x\|_\infty$: the system is BIBO

stable with admissible constant $M = \|h\|_1$.

Step 2 — necessity ($\Rightarrow$): construction of the input that saturates the inequality. Suppose $\mathcal{T}$ is BIBO stable with constant M . Fix $N > 0$ and define

$$x_N(t) = \begin{cases} \frac{\overline{h(-t)}}{|h(-t)|}, & |t| \leq N \text{ and } h(-t) \neq 0, \\ 0, & \text{otherwise.} \end{cases}$$

This function is measurable: the set $A_N = \{t : |t| \leq N, h(-t) \neq 0\}$ is measurable because h is and $t \mapsto h(-t)$ is measurable; on A_N the quotient $\overline{h(-t)}/|h(-t)|$ is measurable because it is a quotient of measurable functions with denominator never zero. Moreover $|x_N(t)| = 1$ on A_N and 0 outside, hence $\|x_N\|_\infty \leq 1$ and x_N has support contained in $[-N, N]$, compact. By the stability hypothesis, $\|\mathcal{T}x_N\|_\infty \leq M$.

Step 3 — evaluating the output at time 0. One computes $(\mathcal{T}x_N)(0) = (h * x_N)(0) = \int_{\mathbb{R}} h(\tau) x_N(-\tau) d\tau$. Now $x_N(-\tau)$ equals $\overline{h(\tau)}/|h(\tau)|$ when $|\tau| \leq N$ and $h(\tau) \neq 0$, and 0 otherwise; hence

$$(\mathcal{T}x_N)(0) = \int_{\{|\tau| \leq N, h(\tau) \neq 0\}} h(\tau) \frac{\overline{h(\tau)}}{|h(\tau)|} d\tau = \int_{\{|\tau| \leq N, h(\tau) \neq 0\}} \frac{|h(\tau)|^2}{|h(\tau)|} d\tau = \int_{-N}^N |h(\tau)| d\tau,$$

where $z\bar{z} = |z|^2$ was used and, in the last step, the points with $h(\tau) = 0$ were put back in, contributing a zero integrand. The integral is finite because h is locally integrable.

Step 4 — conclusion. The number just computed is real, nonnegative, and does not exceed M by hypothesis:

$$\int_{-N}^N |h(\tau)| d\tau = (\mathcal{T}x_N)(0) \leq \|\mathcal{T}x_N\|_\infty \leq M \quad \text{for every } N > 0.$$

The function $N \mapsto \int_{-N}^N |h|$ is nondecreasing and bounded by M ; by the monotone convergence theorem applied to $|h|\mathbf{1}_{[-N, N]} \uparrow |h|$,

$$\|h\|_1 = \int_{\mathbb{R}} |h(\tau)| d\tau = \lim_{N \rightarrow +\infty} \int_{-N}^N |h(\tau)| d\tau \leq M < \infty,$$

that is, $h \in L^1(\mathbb{R})$ and $\|h\|_1 \leq M$.

Step 5 — optimality of the constant. Step 1 shows that $\|h\|_1$ is an admissible constant; Step 4 shows that every admissible constant M satisfies $\|h\|_1 \leq M$. The minimum of the admissible constants is therefore exactly $\|h\|_1$: it is the gain of the system. $\square$

Remark 24.8: The signal of Step 2, read in engineering terms. When h is real, the quotient $\overline{h(-t)}/|h(-t)|$ reduces to $\text{sgn}(h(-t))$: the critical input is a unit-amplitude square wave that changes sign exactly where the time-reversed impulse response changes sign. Its effect is that, in the convolution integral at time 0, all the elementary contributions $h(\tau)x_N(-\tau)$ turn out to be aligned: there is no longer any cancellation, and the output reaches the maximum possible value $\int |h|$. This is the most economical way of saying that $\|h\|_1$ is not a pessimistic bound, but a value actually attained (in the limit): there is a bounded disturbance that drives the output that far. A designer who checks stability only with sinusoidal inputs will never see this, because a sinusoid produces $|H(\omega)| \leq \|h\|_1$, with strict inequality in general.

Example 24.3: Three systems, three outcomes. (a) RC filter, $h(t) = \frac{1}{\tau}e^{-t/\tau}u(t)$ **with** $\tau > 0$. In closed form

$$\|h\|_1 = \frac{1}{\tau} \int_0^{+\infty} e^{-t/\tau} dt = \frac{1}{\tau} \left[-\tau e^{-t/\tau} \right]_0^{+\infty} = \frac{1}{\tau} \cdot \tau = 1.$$

The system is BIBO stable with gain exactly 1: no input of amplitude ≤ 1 can produce an output of amplitude > 1 , and a unit step reaches it asymptotically. *Independent check:* Simpson's quadrature of $|h|$ on $[0, 40\tau]$ with $4 \cdot 10^5$ subintervals, for $\tau = 1$ ms, gives 0.999 999 999 999 56, which differs from the closed value 1 by $4.40 \cdot 10^{-13}$ (the theoretical residual of the tail beyond 40τ is $e^{-40} = 4.25 \cdot 10^{-18}$, well below the quadrature error). ✓

(b) Ideal integrator, $h = u$. The partial sums of Step 4 equal $\int_0^N 1 d\tau = N$, which grows without bound: by Theorem 24.4 the system is *not* BIBO stable. The direct check is instructive: the constant input $x \equiv 1$, of amplitude 1, produces $y(t) = \int_{-\infty}^t 1 ds = +\infty$, and already the input $x = \mathbf{1}_{[0,+\infty)}$ produces $y(t) = t$ for $t \geq 0$, unbounded.

(c) Moving average, $h = \frac{1}{T_0} \mathbf{1}_{[0, T_0]}$. Here $\|h\|_1 = \frac{1}{T_0} \cdot T_0 = 1$: BIBO stable with gain 1. The critical input of Step 2 is, in this case, the constant input $x \equiv 1$, because $h \geq 0$ and hence $\text{sgn}(h(-t)) = 1$ over the whole support; and indeed $y \equiv 1$.

Remark 24.9: The discrete case, and the bridge with poles. The corresponding discrete statement — BIBO stable $\iff h \in \ell^1(\mathbb{Z})$, with gain $\|h\|_1$ — is Theorem 21.10 of Chapter 21, proved there with the same five-step strategy and with the critical input $x_N[n] = \overline{h[-n]}/|h[-n]|$: the two proofs are deliberately parallel, and comparing the two Step 3's shows that the only technical difference is the substitution of the sum for the integral and of the comparison criterion for the monotone convergence theorem.

From there Chapter 21 goes on to translate the condition into geometry: for a causal rational system stability is equivalent to all poles lying inside the unit circle (Theorem 21.12), and the unit circle must lie in the annulus of convergence (Corollary 21.4). The continuous analogue — poles in the left half-plane — is the content of Chapter 20 and of the Nyquist criterion of Chapter 25, Section 25.3.

24.5. Causality

Definition 24.7: Causal system. A system $\mathcal{T}$ is **causal** if, for every $t_0 \in \mathbb{R}$ and every pair of admissible inputs x_1, x_2 ,

$$x_1(t) = x_2(t) \text{ for every } t \leq t_0 \implies (\mathcal{T}x_1)(t) = (\mathcal{T}x_2)(t) \text{ for every } t \leq t_0.$$

In words: the output at time t_0 does not depend on the values of the input after t_0 . A non-causal system is called **anticipative**.

Remark 24.10: The equivalent form for linear systems. If $\mathcal{T}$ is linear, Definition 24.7 is equivalent to the apparently weaker condition

$$x(t) = 0 \text{ for every } t \leq t_0 \implies (\mathcal{T}x)(t) = 0 \text{ for every } t \leq t_0.$$

That the first implies the second is immediate ($x_2 = 0$, $x_1 = x$, and $\mathcal{T}0 = 0$ by linearity). Conversely, if the second holds and $x_1 = x_2$ on $(-\infty, t_0]$, apply the second to $x = x_1 - x_2$: one gets $\mathcal{T}x_1 - \mathcal{T}x_2 = \mathcal{T}(x_1 - x_2) = 0$ on $(-\infty, t_0]$, which is the first. In what follows either form will be used indifferently.

Theorem 24.5: Causality $\iff$ causal impulse response. Let $h \in L^1(\mathbb{R})$ and let $\mathcal{T}_h$ be the convolution system of Definition 24.4. Then

$$\mathcal{T}_h \text{ is causal} \iff h(t) = 0 \text{ for almost every } t < 0.$$

In that case, for every bounded input,

$$y(t) = \int_0^{+\infty} h(\tau) x(t - \tau) d\tau = \int_{-\infty}^t h(t - u) x(u) du :$$

the output at time t is a weighted average of the past of the input only.

Proof. Step 1 — sufficiency ($\Leftarrow$). Let $h = 0$ a.e. on $(-\infty, 0)$. By the form of the convolution derived in Proposition 24.1(iii),

$$y(t) = \int_{\mathbb{R}} h(t - u) x(u) du.$$

For $u > t$ one has $t - u < 0$, hence $h(t - u) = 0$ for almost every such u , and the integrand vanishes a.e. on $(t, +\infty)$: the integral reduces to $\int_{-\infty}^t h(t - u)x(u) du$, which depends only on the values $x(u)$ with $u \leq t$. Hence, if $x = 0$ on $(-\infty, t_0]$, for every $t \leq t_0$ the integrand vanishes a.e. and $y(t) = 0$: the system is causal by Remark 24.10. The second form of the statement is obtained from the first by the substitution $\tau = t - u$.

Step 2 — necessity ($\Rightarrow$): reduction. Let $\mathcal{T}_h$ be causal. Fix $t < 0$ and show that $h(s) = 0$ for almost every $s < t$; since $(-\infty, 0) = \bigcup_{n \geq 1} (-\infty, -1/n)$ is a *countable* union and a countable union of sets of measure zero has measure zero, this will suffice to conclude that $h = 0$ a.e. on $(-\infty, 0)$.

Step 3 — the family of test inputs. Fix $t < 0$ and $N > 0$, and let

$$x_N(u) = \begin{cases} \frac{\overline{h(t-u)}}{|h(t-u)|}, & 0 \leq u \leq N \text{ and } h(t-u) \neq 0, \\ 0, & \text{otherwise,} \end{cases}$$

measurable by the same argument as in Step 2 of the proof of Theorem 24.4, with $|x_N| \leq 1$ and support contained in $[0, N]$. In particular $x_N(u) = 0$ for every $u \leq 0$, hence for every $u \leq t_0 := 0$; by causality and by Remark 24.10, $y_N = \mathcal{T}_h x_N$ vanishes on $(-\infty, 0]$, and in particular $y_N(t) = 0$, since $t < 0$.

Step 4 — computing $y_N(t)$. By the form of the convolution,

$$0 = y_N(t) = \int_{\mathbb{R}} h(t-u) x_N(u) du = \int_{\{0 \leq u \leq N, h(t-u) \neq 0\}} h(t-u) \frac{\overline{h(t-u)}}{|h(t-u)|} du = \int_0^N |h(t-u)| du,$$

where, as in Step 3 of the proof of Theorem 24.4, one has used $z\bar{z} = |z|^2$ and put back the points with $h(t-u) = 0$, which contribute a zero integrand.

Step 5 — conclusion. A vanishing integral of a nonnegative function forces the function to be zero a.e.: hence $|h(t-u)| = 0$ for almost every $u \in [0, N]$, i.e. $h(s) = 0$ for almost every $s \in [t-N, t]$ (substitution $s = t-u$, which preserves the measure). Letting N grow along the integers and again using that a countable union of sets of measure zero has measure zero, one obtains $h(s) = 0$ for almost every $s < t$. By Step 2 the claim follows. $\square$

Corollary 24.2: Causality of the three examples. With the impulse responses of Example 24.2: the RC filter $h(t) = \frac{1}{\tau} e^{-t/\tau} u(t)$ and the moving average $h = \frac{1}{T_0} \mathbf{1}_{[0, T_0]}$ are causal,

because both functions vanish on $(-\infty, 0)$ by construction. The ideal low-pass filter, with frequency response $\mathbf{1}_{[-\Omega, \Omega]}$, is not: its impulse response is $h(t) = \frac{\Omega}{\pi} \text{sinc}(\Omega t/\pi)$, which by Proposition 19.2 is the inverse transform of the rectangle, and is different from zero over all of $\mathbb{R}$ — in particular on $(-\infty, 0)$, where it is not zero even a.e., because it vanishes only at the isolated points $t = k\pi/\Omega$, $k \in \mathbb{Z}$, $k \neq 0$.

Proof. For the first two the conclusion is the direct reading of Theorem 24.5: $\frac{1}{\tau}e^{-t/\tau}u(t) = 0$ for $t < 0$ because $u(t) = 0$ there, and $\mathbf{1}_{[0, T_0]}(t) = 0$ for $t < 0$ because $t \notin [0, T_0]$.

For the third: Proposition 19.2 of Chapter 19 computes the transform of the rectangle; applying the inversion formula (Theorem 19.9) to the function $\mathbf{1}_{[-\Omega, \Omega]}$, which lies in $L^1(\mathbb{R})$, one obtains

$$h(t) = \frac{1}{2\pi} \int_{-\Omega}^{\Omega} e^{i\omega t} d\omega = \frac{1}{2\pi} \cdot \frac{e^{i\Omega t} - e^{-i\Omega t}}{it} = \frac{\sin(\Omega t)}{\pi t} = \frac{\Omega}{\pi} \text{sinc}\left(\frac{\Omega t}{\pi}\right),$$

for $t \neq 0$, with $h(0) = \Omega/\pi$ by continuity. The zeros of $\sin(\Omega t)$ are the points $t = k\pi/\Omega$ with $k \in \mathbb{Z}$: a countable set, hence of measure zero. Hence h is not zero a.e. on $(-\infty, 0)$, and by Theorem 24.5 the system is not causal. This is the reason why the ideal low-pass filter that appears in the proof of Theorem 24.8 is not realisable in real time, as already observed in Remark 24.17. $\square$

Remark 24.11: What causality imposes on the frequency response. A causal and stable system cannot have an arbitrary frequency response: magnitude and phase are linked. The precise formulation of this link is twofold.

- Holomorphic extension. If $h \in L^1(\mathbb{R})$ is causal, the integral $\int_0^{+\infty} h(t)e^{-st} dt$ converges absolutely for every s with $\text{Re } s \geq 0$, because $|e^{-st}| = e^{-t\text{Re } s} \leq 1$ for $t \geq 0$: the frequency response therefore extends to a function defined on the whole closed right half-plane, and it is the Laplace transform of Chapter 20, restricted to the imaginary axis. This passage is proved here in full.
- Kramers–Kronig relations and the Paley–Wiener theorem. That the real and imaginary parts of H are linked by a Hilbert transform (Section 24.11), and that a given function $|H|$ is the magnitude of the frequency response of a causal system if and only if $\int_{\mathbb{R}} \frac{|\log |H(\omega)||}{1+\omega^2} d\omega < \infty$ (Paley–Wiener condition), are results that this treatise **does not prove**: the theory of Hardy spaces on the half-plane, which is not developed here, is missing. They are cited here as **panorama**, and their source is entry [4] of the Sources environment (Oppenheim and Schaffer). An immediate consequence, which is elementary, is that no causal and stable system can have $|H|$ identically zero on a non-degenerate interval of frequencies, because there $\log |H| = -\infty$ and the integral diverges: the ideal low-pass filter of Corollary 24.2 is excluded twice over.

24.6. Frequency response: magnitude and phase

Definition 24.8: Frequency response, gain, phase. Let $h \in L^1(\mathbb{R})$ be the impulse response of an LTI system. Its **frequency response** is

$$H(\omega) = \hat{h}(\omega) = \int_{\mathbb{R}} h(t) e^{-i\omega t} dt, \quad \omega \in \mathbb{R}.$$

The number $|H(\omega)| \geq 0$ is the **gain** at angular frequency ω , and it is often expressed in **decibels**:

$$|H(\omega)|_{\text{dB}} = 20 \log_{10} |H(\omega)|.$$

On any interval where H does not vanish, a continuous function $\phi : I \rightarrow \mathbb{R}$ with $H(\omega) = |H(\omega)|e^{i\phi(\omega)}$ for $\omega \in I$ is called a **phase** (or *continuous phase*, in English *unwrapped phase*) of the system on I ; it is determined up to a constant integer multiple of 2π .

Theorem 24.6: Elementary properties of the frequency response. Let $h \in L^1(\mathbb{R})$ and $H = \hat{h}$. Then

- (i) H is uniformly continuous on $\mathbb{R}$ and $|H(\omega)| \leq \|h\|_1$ for every ω ;
- (ii) $H(0) = \int_{\mathbb{R}} h(t) dt$ is the DC gain, and $|H(\omega)| \rightarrow 0$ as $|\omega| \rightarrow \infty$;
- (iii) if h is real-valued, $H(-\omega) = \overline{H(\omega)}$ for every ω ; consequently $|H|$ is even and any phase can be chosen odd;
- (iv) the gain of the system (Definition 24.6) is $\|h\|_1$, and $\sup_{\omega} |H(\omega)| \leq \|h\|_1$, with strict inequality in general.

Proof. (i). This is Theorem 19.1 (uniform continuity of the transform) together with Proposition 19.1 of Chapter 19, according to which $|\hat{h}(\omega)| \leq \int_{\mathbb{R}} |h(t)| |e^{-i\omega t}| dt = \|h\|_1$.

(ii). The first statement is the definition with $\omega = 0$, since $e^0 = 1$. The second is the Riemann–Lebesgue lemma, Theorem 19.5.

(iii). This is Step 1 of the proof of Corollary 24.1, where it is carried out in full. From $H(-\omega) = \overline{H(\omega)}$ it follows that $|H(-\omega)| = |\overline{H(\omega)}| = |H(\omega)|$, i.e. the evenness of the magnitude; and if $H(\omega) \neq 0$, the arguments of $H(-\omega)$ and of $H(\omega)$ are opposite modulo 2π , so that on a symmetric interval free of zeros one can choose the continuous odd determination.

(iv). The value $\|h\|_1$ is Theorem 24.4, Step 5. The inequality $\sup_{\omega} |H| \leq \|h\|_1$ is point (i). That it can be strict is seen on the example $h = \mathbf{1}_{[0,1]} - \mathbf{1}_{[1,2]}$: here $\|h\|_1 = 2$, while $H(0) = \int_0^1 1 dt - \int_1^2 1 dt = 0$ and in general

$$H(\omega) = \int_0^1 e^{-i\omega t} dt - \int_1^2 e^{-i\omega t} dt = \frac{1 - e^{-i\omega}}{i\omega} - \frac{e^{-i\omega} - e^{-2i\omega}}{i\omega} = \frac{(1 - e^{-i\omega})^2}{i\omega},$$

whose modulus is $|1 - e^{-i\omega}|^2/|\omega| = 4 \sin^2(\omega/2)/|\omega|$, having used $|1 - e^{-i\omega}|^2 = (1 - \cos \omega)^2 + \sin^2 \omega = 2 - 2 \cos \omega = 4 \sin^2(\omega/2)$. That the supremum of this function is strictly less than $2 = \|h\|_1$ is seen in two steps. For $|\omega| \geq 5/2$ one has $4 \sin^2(\omega/2)/|\omega| \leq 4/|\omega| \leq 8/5 = 1.6 < 2$, because $\sin^2 \leq 1$. On $[-5/2, 5/2]$ the function $|H|$ is continuous (at $\omega = 0$ it equals 0, as read from $H(0) = 0$), so by the Weierstrass theorem it attains a maximum there; and this maximum is < 2 , because at every point $\omega \neq 0$ of the interval the strict inequality $4 \sin^2(\omega/2)/|\omega| < 4(\omega/2)^2/|\omega| = |\omega| \leq 5/2$ holds, which together with $\sin v < v$ for $v > 0$ and the bound $4/|\omega|$ for $|\omega| \geq 2$ gives in any case a value < 2 . The actual maximum, computed numerically, equals 1.449 222 707 6 and is attained at $\omega^* = 2.331 122 3$, a root of the stationarity equation $\tan(\omega/2) = \omega$: two independent computations (exhaustive search with step 10^{-6} and subsequent ternary search) give the same value, and $\tan(\omega^*/2) = 2.331 122 3$ confirms the stationarity condition. ✓ Hence $\sup_{\omega} |H(\omega)| = 1.449 \dots < 2 = \|h\|_1$. $\square$

Example 24.4: The RC filter: gain and phase, with the numbers. Consider the RC filter of Example 24.2(c), with $h(t) = \frac{1}{\tau} e^{-t/\tau} u(t)$ and $\tau = RC = 1$ ms.

Closed form. For every $\omega \in \mathbb{R}$,

$$H(\omega) = \frac{1}{\tau} \int_0^{+\infty} e^{-t/\tau} e^{-i\omega t} dt = \frac{1}{\tau} \int_0^{+\infty} e^{-(1/\tau + i\omega)t} dt = \frac{1}{\tau} \cdot \frac{1}{1/\tau + i\omega} = \frac{1}{1 + i\omega\tau},$$

where the integral converges because $\operatorname{Re}(1/\tau + i\omega) = 1/\tau > 0$ and equals $[-e^{-(1/\tau + i\omega)t}]/(1/\tau + i\omega)$.

$i\omega)]_0^{+\infty} = 1/(1/\tau + i\omega)$. Hence

$$|H(\omega)| = \frac{1}{\sqrt{1 + \omega^2\tau^2}}, \quad \phi(\omega) = -\arctan(\omega\tau).$$

At the cutoff angular frequency $\omega = 1/\tau = 1000 \text{ rad/s}$ (i.e. $\nu = 1/(2\pi\tau) = 159.154943 \text{ Hz}$):

$$H = \frac{1}{1+i} = \frac{1-i}{2} = 0.5 - 0.5i, \quad |H| = \frac{1}{\sqrt{2}} = 0.7071067812,$$

$$|H|_{\text{dB}} = 20 \log_{10} \frac{1}{\sqrt{2}} = -10 \log_{10} 2 = -3.010299957 \text{ dB}, \quad \phi = -\arctan 1 = -\frac{\pi}{4} = -45^\circ.$$

Independent check (Python script executed). Computing $H(\omega)$ by Simpson's quadrature of the integral $\int_0^{60\tau} h(t)e^{-i\omega t} dt$ with $6 \cdot 10^5$ subintervals gives, for $\omega\tau = 1$, $0.499999999999899 - 0.500000000000189i$, which differs from the closed value $0.5 - 0.5i$ by $2.14 \cdot 10^{-13}$; for $\omega\tau = 3$ one obtains $0.100000000000014 - 0.299999999999999i$ against the closed value $0.1 - 0.3i$, with gap $1.36 \cdot 10^{-14}$. ✓

Reading. At the cutoff angular frequency the signal comes out with 70.7% of the amplitude (half the power, whence the name “−3 dB frequency”) and delayed by one eighth of a period, because 45° is one eighth of a turn. By Corollary 24.1, an input $\cos(1000t)$ produces the output $0.7071067812 \cos(1000t - \pi/4)$.

Figure 24.1: Frequency response of the RC filter of Example 24.4, on a logarithmic scale of angular frequencies. The coordinates of the thirteen points of each curve were computed from the closed formulas $|H|_{\text{dB}} = -10 \log_{10}(1 + \omega^2\tau^2)$ and $\phi = -\arctan(\omega\tau)$ and re-checked with a script: for instance at $\omega\tau = 1$ one has -3.01030 dB and -45° , at $\omega\tau = 10$ one has -20.04321 dB and -84.28941° . The dashed lines are the asymptotes 0 dB and -20 dB/decade , which meet exactly at the cutoff angular frequency.

Example 24.5: The moving average: an exact zero and an exactly linear phase.

For $h = \frac{1}{T_0} \mathbf{1}_{[0, T_0]}$ and $\omega \neq 0$,

$$H(\omega) = \frac{1}{T_0} \int_0^{T_0} e^{-i\omega t} dt = \frac{1}{T_0} \cdot \frac{1 - e^{-i\omega T_0}}{i\omega} = e^{-i\omega T_0/2} \cdot \frac{e^{i\omega T_0/2} - e^{-i\omega T_0/2}}{i\omega T_0} = e^{-i\omega T_0/2} \frac{\sin(\omega T_0/2)}{\omega T_0/2},$$

having collected $e^{-i\omega T_0/2}$ and used $e^{i\theta} - e^{-i\theta} = 2i \sin \theta$ with $\theta = \omega T_0/2$; for $\omega = 0$ one has $H(0) = 1$, consistent with the limit. Hence

$$|H(\omega)| = \left| \frac{\sin(\omega T_0/2)}{\omega T_0/2} \right|, \quad H(\omega) = e^{-i\omega T_0/2} \operatorname{sinc}\left(\frac{\omega T_0}{2\pi}\right),$$

and the gain vanishes exactly at the angular frequencies $\omega = 2\pi k/T_0$, $k \in \mathbb{Z}$, $k \neq 0$, i.e. at the frequencies $\nu = k/T_0$.

Numbers, with $T_0 = 2$ ms. The zeros fall at $\nu = 500, 1\,000, 1\,500$ Hz. At $\omega = 1\,000$ rad/s the closed formula gives $0.454\,648\,713\,412\,84 - 0.708\,073\,418\,273\,57i$; the same quantity computed from the uncollected expression $(1 - e^{-i\omega T_0})/(i\omega T_0)$ gives the same number with gap $5.55 \cdot 10^{-17}$, and Simpson's quadrature of the integral with $2 \cdot 10^5$ subintervals gives gap $1.84 \cdot 10^{-14}$. ✓ At the first zero angular frequency, $\omega = 2\pi/T_0 = 3\,141.592\,653\,6$ rad/s, the computed gain equals $3.90 \cdot 10^{-17}$, i.e. zero within machine error. ✓

What matters. The factor $e^{-i\omega T_0/2}$ is a phase *exactly linear* in ω : it is the seed of Theorem 24.7, and it already says that this filter delays all components by the same time $T_0/2$, i.e. by half the window — which is reasonable, because an average over $[t - T_0, t]$ is “centred” at $t - T_0/2$.

24.7. Phase delay and group delay

Corollary 24.1 says that a sinusoid of angular frequency ω_0 comes out phase-shifted by $\phi(\omega_0)$. A phase shift, however, is not a delay: to translate it into seconds one must divide it by the angular frequency, and the result depends in general on ω_0 . When it really does depend, different components of the same signal come out delayed by different times and the waveform changes. This section defines the two quantities that measure the phenomenon and proves exactly when it does not occur.

Definition 24.9: Phase delay and group delay. Let H be the frequency response of an LTI system and let ϕ be a continuous phase on an interval I on which H does not vanish (Definition 24.8). For $\omega \in I$, $\omega \neq 0$, the number

$$\tau_p(\omega) = -\frac{\phi(\omega)}{\omega}$$

is called the **phase delay**, and, if ϕ is differentiable at ω , the number

$$\tau_g(\omega) = -\frac{d\phi}{d\omega}(\omega)$$

is called the **group delay**. Both are measured in seconds. The first is the time delay suffered by the *single* sinusoid of angular frequency ω ; the second, as Theorem 24.7 shows, is the delay suffered by the *envelope* of a group of components concentrated around ω .

Remark 24.12: Why two delays and not one. The phase delay is the quotient $-\phi/\omega$, the group delay is the derivative $-\phi'$: geometrically, the first is the slope of the secant joining

the origin to the point $(\omega, \phi(\omega))$ of the graph of the phase, with the sign changed; the second is the slope of the tangent at that point, with the sign changed. The two coincide for every ω if and only if the phase is exactly linear and passes through the origin, $\phi(\omega) = -t_0\omega$: and this is precisely the no-distortion case of Theorem 24.7. The difference between secant and tangent thus measures, in a completely elementary way, how far a system is from the no-distortion condition.

Proposition 24.3: The pure delay. Let $t_0 \in \mathbb{R}$ and $\mathcal{T}_{t_0}x = \sigma_{t_0}x$, i.e. $y(t) = x(t - t_0)$, defined on $L^\infty(\mathbb{R})$. Then:

- (i) $\mathcal{T}_{t_0}$ is linear and time-invariant;
- (ii) every e_ω is an eigenfunction of it, with eigenvalue $H(\omega) = e^{-i\omega t_0}$;
- (iii) $|H(\omega)| = 1$ for every ω , the continuous phase is $\phi(\omega) = -\omega t_0$, and

$$\tau_p(\omega) = \tau_g(\omega) = t_0 \quad \text{for every } \omega \neq 0.$$

Proof. (i). Linearity is immediate: $\sigma_{t_0}(\alpha x_1 + \beta x_2)(t) = (\alpha x_1 + \beta x_2)(t - t_0) = \alpha x_1(t - t_0) + \beta x_2(t - t_0)$. Invariance follows from $\sigma_{t_0}\sigma_a = \sigma_{t_0+a} = \sigma_a\sigma_{t_0}$, which is checked by evaluating at t : $(\sigma_{t_0}\sigma_a x)(t) = (\sigma_a x)(t - t_0) = x(t - t_0 - a)$, symmetric in the two indices.

(ii). For every t ,

$$(\mathcal{T}_{t_0}e_\omega)(t) = e^{i\omega(t-t_0)} = e^{-i\omega t_0}e^{i\omega t} = e^{-i\omega t_0}e_\omega(t),$$

using $e^{a+b} = e^ae^b$. Since e_ω is not identically zero, it is an eigenfunction with eigenvalue $e^{-i\omega t_0}$. Note that this system does *not* fall under Definition 24.4, because its impulse response is not a function of L^1 (Remark 24.3): the computation just carried out is direct and does not use Theorem 24.2.

(iii). $|e^{-i\omega t_0}| = 1$ because $\omega t_0 \in \mathbb{R}$. The function $\omega \mapsto -\omega t_0$ is continuous on all of $\mathbb{R}$ and satisfies $H(\omega) = 1 \cdot e^{i(-\omega t_0)}$: it is therefore a continuous phase in the sense of Definition 24.8. Finally

$$\tau_p(\omega) = -\frac{-\omega t_0}{\omega} = t_0, \quad \tau_g(\omega) = -\frac{d}{d\omega}(-\omega t_0) = t_0.$$

□

Theorem 24.7: A linear-phase system does not distort the waveform. Let $x \in L^1(\mathbb{R})$ with $\hat{x} \in L^1(\mathbb{R})$ and $\hat{x}(\omega) = 0$ for $|\omega| > \Omega$ (a signal band-limited to $\Omega > 0$). Let $h \in L^1(\mathbb{R})$ be the impulse response of an LTI system whose frequency response satisfies

$$H(\omega) = A e^{-i\omega t_0} \quad \text{for every } |\omega| \leq \Omega,$$

with $A > 0$ and $t_0 \in \mathbb{R}$ constants (constant gain and exactly linear phase over the band of the signal; outside the band H is arbitrary). Then

$$y(t) = (h * x)(t) = A x(t - t_0) \quad \text{for every } t \in \mathbb{R} :$$

the output is the input rescaled by A and delayed by t_0 , with no alteration of the waveform. In this case $\tau_p(\omega) = \tau_g(\omega) = t_0$ throughout the band.

Proof. Step 1 — the spectrum of the output. Since $h, x \in L^1(\mathbb{R})$, also $y = h * x \in L^1(\mathbb{R})$ and by Theorem 19.4 (the convolution theorem) of Chapter 19

$$\hat{y}(\omega) = \hat{h}(\omega) \hat{x}(\omega) = H(\omega) \hat{x}(\omega) \quad \text{for every } \omega \in \mathbb{R}.$$

Step 2 — the band hypothesis eliminates the out-of-band behaviour. For $|\omega| > \Omega$ one has $\hat{x}(\omega) = 0$, hence $\hat{y}(\omega) = H(\omega) \cdot 0 = 0$ whatever H is there. For $|\omega| \leq \Omega$ one uses the

hypothesis on H :

$$\hat{y}(\omega) = A e^{-i\omega t_0} \hat{x}(\omega).$$

Putting the two cases together, and noting that for $|\omega| > \Omega$ also $A e^{-i\omega t_0} \hat{x}(\omega) = 0$, one obtains the identity valid on all of $\mathbb{R}$:

$$\hat{y}(\omega) = A e^{-i\omega t_0} \hat{x}(\omega) \quad \text{for every } \omega \in \mathbb{R}.$$

Step 3 — recognising the right-hand side. Let $z(t) = A x(t - t_0)$. Then $z \in L^1(\mathbb{R})$ and, by the translation property of Theorem 19.3,

$$\hat{z}(\omega) = A \widehat{\sigma_{t_0} x}(\omega) = A e^{-i\omega t_0} \hat{x}(\omega).$$

Hence $\hat{y} = \hat{z}$ on all of $\mathbb{R}$.

Step 4 — from equality of the spectra to equality of the signals. The two functions y and z lie in $L^1(\mathbb{R})$ and have the same transform; by linearity $\widehat{y - z} \equiv 0$, and since $\widehat{y - z} = 0 \in L^1(\mathbb{R})$ one can apply the inversion formula in L^1 (Theorem 19.9) to the function $y - z$:

$$(y - z)(t) = \frac{1}{2\pi} \int_{\mathbb{R}} \widehat{y - z}(\omega) e^{i\omega t} d\omega = 0$$

for almost every t . It remains to promote “almost every” to “every”: $\hat{y} = \hat{z} \in L^1(\mathbb{R})$ — indeed $|\hat{z}(\omega)| = A|\hat{x}(\omega)|$ and $\hat{x} \in L^1(\mathbb{R})$ by hypothesis — hence, again by Theorem 19.9, both y and z coincide a.e. with *continuous* functions, and two continuous functions equal a.e. are equal everywhere. Hence $y(t) = A x(t - t_0)$ for every t .

Step 5 — the two delays. On $|\omega| \leq \Omega$ one has $|H(\omega)| = A > 0$ and $\phi(\omega) = -\omega t_0$ is a continuous phase; the computation of the two delays is that of point (iii) of Proposition 24.3 and gives $\tau_p = \tau_g = t_0$. $\square$

Corollary 24.3: The no-distortion condition, and its practical reading. Let $h \in L^1(\mathbb{R})$ be real-valued, with $H = \hat{h}$ never zero on $[-\Omega, \Omega]$ and $H(0) > 0$. The following are equivalent:

- (a) there exist $A > 0$ and $t_0 \in \mathbb{R}$ such that $y = A x(\cdot - t_0)$ for every signal x under the hypotheses of Theorem 24.7 with band Ω ;
- (b) on $[-\Omega, \Omega]$ the gain $|H(\omega)|$ is constant and the group delay $\tau_g(\omega)$ is constant.

Proof. (b) $\Rightarrow$ (a). Let $|H| \equiv A$ on $[-\Omega, \Omega]$ and $\tau_g = -\phi' \equiv t_0$. Since H does not vanish on the band, a continuous phase ϕ exists there (Definition 24.8); integrating $\phi' \equiv -t_0$ over the connected interval $[-\Omega, \Omega]$ gives $\phi(\omega) = -t_0\omega + c$ with c constant. Since h is real, $H(0) = \int_{\mathbb{R}} h$ is real, and is > 0 by hypothesis: hence $A = |H(0)| = H(0)$ and $e^{i\phi(0)} = H(0)/|H(0)| = 1$, i.e. $c = \phi(0) \in 2\pi\mathbb{Z}$; choosing the determination with $c = 0$ (legitimate: the continuous phase is defined up to a constant multiple of 2π) one has $H(\omega) = A e^{-i\omega t_0}$ over the whole band, and one applies Theorem 24.7.

(a) $\Rightarrow$ (b). Choose an explicit test signal whose transform does not vanish *inside* the band: let $\hat{x}(\omega) = (1 - |\omega|/\Omega)^+$ be the triangle of base $[-\Omega, \Omega]$, which is continuous, has support in $[-\Omega, \Omega]$ and lies in $L^1(\mathbb{R})$ (it is the function of Proposition 19.3 of Chapter 19, rescaled). The corresponding x is computed from the inversion formula: since the integrand is even in its real part and odd in its imaginary part,

$$x(t) = \frac{1}{2\pi} \int_{-\Omega}^{\Omega} \left(1 - \frac{|\omega|}{\Omega}\right) e^{i\omega t} d\omega = \frac{1}{\pi} \int_0^{\Omega} \left(1 - \frac{\omega}{\Omega}\right) \cos(\omega t) d\omega = \frac{1 - \cos(\Omega t)}{\pi \Omega t^2} = \frac{\Omega}{2\pi} \left(\frac{\sin(\Omega t/2)}{\Omega t/2}\right)^2,$$

where the integral was computed by parts — $\int_0^{\Omega} \cos(\omega t) d\omega = \sin(\Omega t)/t$ and $\frac{1}{\Omega} \int_0^{\Omega} \omega \cos(\omega t) d\omega = \sin(\Omega t)/t - (1 - \cos(\Omega t))/(\Omega t^2)$, whose difference is $(1 - \cos(\Omega t))/(\Omega t^2)$ — and the last

equality is $1 - \cos v = 2 \sin^2(v/2)$ with $v = \Omega t$. This x lies in $L^1(\mathbb{R})$ because $|x(t)| \leq \frac{\Omega}{2\pi} \min\{1, 4/(\Omega t)^2\}$ — using $|\sin u/u| \leq 1$ for the first bound and $|\sin u| \leq 1$ for the second — and $\int_{\mathbb{R}} \min\{1, 4/(\Omega t)^2\} dt = \frac{4}{\Omega} + 2 \int_{2/\Omega}^{+\infty} \frac{4}{\Omega^2 t^2} dt = \frac{4}{\Omega} + \frac{4}{\Omega} = \frac{8}{\Omega} < \infty$. The hypotheses of Theorem 24.7 are therefore satisfied by this x . If (a) holds, then $y = Ax(\cdot - t_0)$; taking transforms and using Step 1 and Step 3 of the previous proof,

$$H(\omega) \hat{x}(\omega) = A e^{-i\omega t_0} \hat{x}(\omega) \quad \text{for every } \omega \in \mathbb{R}.$$

For $|\omega| < \Omega$ one has $\hat{x}(\omega) = 1 - |\omega|/\Omega > 0$, so one can divide: $H(\omega) = A e^{-i\omega t_0}$ on $(-\Omega, \Omega)$, and by continuity of H (Theorem 24.6(i)) also at the two endpoints. From this $|H| \equiv A$ and $\phi(\omega) = -t_0\omega$ over the whole band, hence $\tau_g \equiv t_0$ constant. $\square$

Example 24.6: The RC filter distorts: the two delays, with the numbers. For the RC filter of Example 24.4, with $\phi(\omega) = -\arctan(\omega\tau)$:

$$\tau_p(\omega) = \frac{\arctan(\omega\tau)}{\omega}, \quad \tau_g(\omega) = -\frac{d}{d\omega}(-\arctan(\omega\tau)) = \frac{\tau}{1 + \omega^2\tau^2},$$

having used $\frac{d}{dv} \arctan v = \frac{1}{1+v^2}$ and the chain rule with $v = \omega\tau$. The two delays do *not* coincide and are *not* constant: the system distorts.

Numbers with $\tau = 1$ ms. The table reports, for four values of $\omega\tau$, the gain, the phase, and the two delays in milliseconds.

$\omega\tau$	$ H $	ϕ (degrees)	τ_p (ms)	τ_g (ms)
0.5	0.894 427 191	-26.565 051	0.927 295 218	0.8
1	0.707 106 781	-45.000 000	0.785 398 163	0.5
2	0.447 213 595	-63.434 949	0.553 574 359	0.2
5	0.196 116 135	-78.690 068	0.274 680 153	0.038 461 538

Independent check. The group delay computed by centred differences, $-(\phi(\omega + d) - \phi(\omega - d))/(2d)$ with $d = 10^{-6}$, gives 0.499 999 985 9 ms at $\omega\tau = 1$ (closed formula 0.5 ms, gap $1.41 \cdot 10^{-11}$ ms) and 0.100 000 008 3 ms at $\omega\tau = 3$ (closed formula 0.1 ms, gap $8.27 \cdot 10^{-12}$ ms). ✓ Moreover $\tau_p(1/\tau) = \arctan(1)/(1/\tau) = (\pi/4)\tau = 0.785 398 163 4$ ms coincides with $\pi/4$ milliseconds computed separately. ✓

Interpretation. Between $\omega\tau = 1$ and $\omega\tau = 3$ the group delay goes from 0.5 to 0.1 ms: an exact factor of 5, because $\tau_g(1/\tau)/\tau_g(3/\tau) = \frac{\tau/2}{\tau/10} = 5$. Two components of the same signal, one at $\omega = 1/\tau$ and the other at $\omega = 3/\tau$, come out of the filter phase-shifted relative to each other differently from how they went in: the resulting waveform is not the translate of the original. Compared with the moving average of Example 24.5, which has constant $\tau_g \equiv T_0/2$, the difference is stark — and it is the reason why linear-phase filters are preferred whenever the shape of the waveform matters (electrocardiography, peak measurements, seismology) and not only its spectral content.

Remark 24.13: Minimum-phase systems: panorama. Among all causal and stable systems that have the same gain $|H(\omega)|$, there is a privileged one, called **minimum-phase**: the one whose frequency response, extended to the right half-plane as in Remark 24.11, has no zeros there. One shows about it — in a theory that this treatise does not develop — that, among all those of equal gain, it has the phase of minimum magnitude, the minimum group delay, and the energy of the impulse response concentrated as close as possible to the origin; and that every causal and stable system factors uniquely as “minimum-phase system $\times$ all-pass system”, where an all-pass system has $|H| \equiv 1$ and therefore acts only on the phase. The central fact is that a minimum-phase system has a causal and stable inverse,

Figure 24.2: Normalised group delay. For the *RC* filter one has $\tau_g/\tau = 1/(1 + \omega^2\tau^2)$ and it decreases from 1 to 0: the slow components come out delayed by τ , the fast ones almost immediately, and the waveform is deformed. For the moving average with window $T_0 = \tau$, instead, $\tau_g = T_0/2 = \tau/2$ for every ω , i.e. $\tau_g/\tau = 0.5$: this is the dashed horizontal line, and by Theorem 24.7 it means no waveform distortion within the band where the gain stays constant. The eleven coordinates of the blue curve are computed from the closed formula and checked: at $\omega\tau = 1$ it equals 0.5, at $\omega\tau = 3$ it equals 0.1, at $\omega\tau = 4$ it equals 0.058 824.

while in general a stable system does not.

None of this is proved here: it would require Hardy spaces on the right half-plane, inner-outer factorisation and the Kramers–Kronig relations, none of which appears in the treatise. The whole paragraph is therefore **panorama**, and what remains **imported** is: the existence and uniqueness of the minimum-phase/all-pass factorisation, the variational characterisation of the minimum group delay, and the stability of the inverse. The source is Oppenheim and Schaffer, entry [4] of the Sources environment. In this chapter the expression “minimum phase” does not occur in any statement and is not used in any proof.

24.8. The Nyquist-Shannon sampling theorem

Remark 24.14: Prerequisites. The following lemma presupposes the Fourier series expansion of a periodic function (Section 4.2) and the elementary properties of the Dirac delta (Appendix A.1, in particular $\int f(t)\delta(t)dt = f(0)$). Those who wish to go directly to the sampling theorem may accept the result of Lemma 24.2 as stated and move on.

The convolution theorem (Theorem 19.4) turns convolution in time into a product in frequency. What is needed here is the *dual fact* — a product in time becomes a convolution in frequency, divided by 2π — which Chapter 19 does not state separately. It is not a new fact: it follows from the convolution theorem by exchanging the roles of f and $\hat{f}$ through the inversion formula, and the factor $1/2\pi$ is exactly the one that the convention in ω puts in front of the inverse transform. We prove it here once and for all, in the only case in which all the objects involved are summable functions.

Lemma 24.1: Product/convolution duality. Let $F, G \in L^1(\mathbb{R})$ and let

$$f(t) = \frac{1}{2\pi} \int_{\mathbb{R}} F(\omega) e^{i\omega t} d\omega, \quad g(t) = \frac{1}{2\pi} \int_{\mathbb{R}} G(\omega) e^{i\omega t} d\omega$$

be their inverse transforms: these are $f(t) = \frac{1}{2\pi} \hat{F}(-t)$ and $g(t) = \frac{1}{2\pi} \hat{G}(-t)$, continuous and bounded functions by Proposition 19.1 and Theorem 19.1. If the product fg belongs to

$L^1(\mathbb{R})$, then

$$\widehat{fg}(\omega) = \frac{1}{2\pi} (F * G)(\omega) \quad \text{for almost every } \omega \in \mathbb{R}.$$

If moreover $f, g \in L^1(\mathbb{R})$, then $F = \hat{f}$ and $G = \hat{g}$ almost everywhere, and the statement takes the usual form $\widehat{fg} = \frac{1}{2\pi} \hat{f} * \hat{g}$.

Proof. All formulas are written in the convention in ω of this chapter; the results of Chapter 19 are read in it with the dictionary of Remark 19.1, which for convolution and for inversion leaves the formulas unchanged in form.

Step 1 — an inversion criterion «the other way round». Let $H \in L^1(\mathbb{R})$ and let $u(t) = \frac{1}{2\pi} \int H(\omega) e^{i\omega t} d\omega$ be its inverse transform. If $u \in L^1(\mathbb{R})$, then $\hat{u} = H$ almost everywhere. Indeed

$$\hat{H}(t) = \int_{\mathbb{R}} H(\omega) e^{-i\omega t} d\omega = 2\pi u(-t),$$

so that $\hat{H} \in L^1(\mathbb{R})$: Theorem 19.9, applied to H read as a function of its own variable, gives for almost every ω

$$H(\omega) = \frac{1}{2\pi} \int_{\mathbb{R}} \hat{H}(t) e^{i\omega t} dt = \int_{\mathbb{R}} u(-t) e^{i\omega t} dt = \int_{\mathbb{R}} u(s) e^{-i\omega s} ds = \hat{u}(\omega),$$

where in the last step we set $s = -t$.

Step 2 — the inverse transform of $\frac{1}{2\pi}(F * G)$ is fg . By Theorem 19.4(ii) we have $F * G \in L^1(\mathbb{R})$, hence $H := \frac{1}{2\pi}(F * G) \in L^1(\mathbb{R})$; by item (iv) of the same theorem,

$$\hat{H}(t) = \frac{1}{2\pi} \widehat{F * G}(t) = \frac{1}{2\pi} \hat{F}(t) \hat{G}(t).$$

As in Step 1, $\hat{F}(t) = 2\pi f(-t)$ and $\hat{G}(t) = 2\pi g(-t)$, hence $\hat{H}(t) = 2\pi f(-t)g(-t)$. The inverse transform of H is then

$$u(t) = \frac{1}{2\pi} \int_{\mathbb{R}} H(\omega) e^{i\omega t} d\omega = \frac{1}{2\pi} \hat{H}(-t) = f(t)g(t).$$

Step 3 — conclusion. By hypothesis $u = fg \in L^1(\mathbb{R})$, and $H \in L^1(\mathbb{R})$ by Step 2: Step 1 gives $\widehat{fg} = \hat{u} = H = \frac{1}{2\pi}(F * G)$ almost everywhere.

Step 4 — the identification $F = \hat{f}$. If $f \in L^1(\mathbb{R})$, Step 1 applied to $H = F$ (whose inverse transform is $u = f$) gives $\hat{f} = F$ almost everywhere; likewise for g and G . $\square$

Lemma 24.2: Fourier transform of the Dirac comb (Poisson summation). Let $\Delta_T(t) = \sum_{k \in \mathbb{Z}} \delta(t - kT)$ be the Dirac comb of step $T > 0$, and let $\omega_c = 2\pi/T$. Then its Fourier transform is again a Dirac comb, in frequency, of step ω_c :

$$\widehat{\Delta_T}(\omega) = \omega_c \sum_{n \in \mathbb{Z}} \delta(\omega - n\omega_c).$$

Proof. The computation that follows is *formal*: the comb is manipulated in it as if it were a function, in two steps (the series expansion and the term-by-term transformation) declared **imported** in Remark 24.16.

Δ_T is periodic of period T : like any periodic (distribution) function of period T it expands in Fourier series in the basis $e^{in\omega_c t}$ (the analog, with $\theta = \omega_c t$, of the basis $e^{in\theta}$ of Section 4.2),

$$\Delta_T(t) = \sum_{n \in \mathbb{Z}} c_n e^{in\omega_c t}, \quad c_n = \frac{1}{T} \int_{-T/2}^{T/2} \Delta_T(t) e^{-in\omega_c t} dt.$$

On the integration interval $(-T/2, T/2)$ the sum Δ_T reduces to the single term $k = 0$, i.e. $\delta(t)$; by the sampling property of the delta (Appendix A.1),

$$c_n = \frac{1}{T} \int_{-T/2}^{T/2} \delta(t) e^{-in\omega_c t} dt = \frac{1}{T} e^0 = \frac{1}{T} \quad \text{for every } n \in \mathbb{Z},$$

hence $\Delta_T(t) = \frac{1}{T} \sum_{n \in \mathbb{Z}} e^{in\omega_c t}$: the Dirac comb is rewritten (in the sense of distributions) as a sum of complex exponentials of equal amplitude $1/T$. Transforming term by term, and using $\hat{1}(\omega) = 2\pi\delta(\omega)$ (Appendix A.1) together with the frequency translation — obtained directly from the definition,

$$\widehat{e^{i\omega_0 t}}(\omega) = \int_{\mathbb{R}} e^{i\omega_0 t} e^{-i\omega t} dt = \int_{\mathbb{R}} e^{-i(\omega - \omega_0)t} dt = 2\pi\delta(\omega - \omega_0),$$

i.e. $\hat{1}$ shifted to ω_0 — one obtains

$$\widehat{\Delta_T}(\omega) = \frac{1}{T} \sum_{n \in \mathbb{Z}} \widehat{e^{in\omega_c t}}(\omega) = \frac{1}{T} \sum_{n \in \mathbb{Z}} 2\pi\delta(\omega - n\omega_c) = \frac{2\pi}{T} \sum_{n \in \mathbb{Z}} \delta(\omega - n\omega_c) = \omega_c \sum_{n \in \mathbb{Z}} \delta(\omega - n\omega_c),$$

using $\omega_c = 2\pi/T$ in the last step. $\square$

Remark 24.15: Name and scope of the result. The identity $\Delta_T(t) = \frac{1}{T} \sum_n e^{in\omega_c t}$ (and its transform) is the special case, for $f = \delta$, of the Poisson summation formula $\sum_{k \in \mathbb{Z}} f(kT) = \frac{1}{T} \sum_{n \in \mathbb{Z}} \hat{f}(n\omega_c)$, which connects sums in the time domain to sums in the frequency domain and is a central tool in harmonic analysis, analytic number theory (Jacobi theta function, Riemann functional equation) and crystallography (diffraction on periodic lattices). See Stein-Shakarchi, Ch. 4, for the general statement and validity conditions on f .

Theorem 24.8: Sampling theorem (Nyquist-Shannon). Let $x_c(t)$ be a continuous bandlimited signal, i.e. $\hat{x}_c(\omega) = 0$ for $|\omega| > \omega_{\max}$. If the sampling period T satisfies

$$\frac{2\pi}{T} \geq 2\omega_{\max} \quad \left(\text{equivalently } f_c = \frac{1}{T} \geq 2f_{\max} \right),$$

then $x_c(t)$ is exactly reconstructible from the samples $x[n] = x_c(nT)$.

Proof. We model sampling as multiplication by a Dirac comb $\Delta_T(t) = \sum_k \delta(t - kT)$: the sampled signal is $x_s(t) = x_c(t)\Delta_T(t)$. By the product/convolution duality $\widehat{fg} = \frac{1}{2\pi} \hat{f} * \hat{g}$ — applied here to the product of a function by a *distribution*, hence outside the hypotheses of Lemma 24.1: it is the third of the three formal steps declared **imported** in Remark 24.16 — and by Lemma 24.2, according to which $\widehat{\Delta_T}(\omega) = \omega_c \sum_{k \in \mathbb{Z}} \delta(\omega - k\omega_c)$ with $\omega_c = 2\pi/T$, one obtains

$$\hat{x}_s(\omega) = \frac{1}{2\pi} (\hat{x}_c * \widehat{\Delta_T})(\omega) = \frac{1}{2\pi} \int_{\mathbb{R}} \hat{x}_c(\omega - \xi) \omega_c \sum_{k \in \mathbb{Z}} \delta(\xi - k\omega_c) d\xi = \frac{\omega_c}{2\pi} \sum_{k \in \mathbb{Z}} \hat{x}_c(\omega - k\omega_c) = \frac{1}{T} \sum_{k \in \mathbb{Z}} \hat{x}_c(\omega - k\omega_c),$$

i.e.: sampling in time periodically replicates the spectrum in frequency, with period ω_c . If $\omega_c \geq 2\omega_{\max}$, the replicas do not overlap, and the original spectrum $\hat{x}_c(\omega)$ (hence $x_c(t)$ itself) is recovered by applying an ideal low-pass filter that isolates the central replica. If instead $\omega_c < 2\omega_{\max}$, the replicas overlap (*aliasing*) and the lost information is no longer recoverable. The three steps with distributions carried out here and in Lemma 24.2 are listed one by one in Remark 24.16: they are **imported** and not justified with the rigour of the rest of the chapter. The explicit reconstruction of x_c from its samples, and its proof carried out in full *without*

distributions, are in Theorem 24.9. □

Remark 24.16: What we import in the comb Lemma and in this proof.

Lemma 24.2 and the proof of Theorem 24.8 carry out three formal steps with distributions, in which the Dirac comb is manipulated as if it were a function. They are not justified with the rigour of the rest of the chapter, and we isolate them here one by one, saying exactly what is missing.

- (P1) Fourier series expansion of the comb. One writes $\Delta_T(t) = \sum_n c_n e^{in\omega_c t}$ «like any periodic (distribution) function»: but Δ_T is not a function, and the L^2 convergence theorem for Fourier series (Theorem 17.1) does not cover it. One would need the notion of periodic tempered distribution and the convergence of the series in $\mathcal{S}'(\mathbb{R})$.
- (P2) Term-by-term transformation. The series $\frac{1}{T} \sum_n e^{in\omega_c t}$ converges at no point t , and it is transformed summand by summand. One would need the continuity of the Fourier transform on $\mathcal{S}'(\mathbb{R})$ and the identity $\hat{1} = 2\pi\delta$, itself defined only in $\mathcal{S}'(\mathbb{R})$.
- (P3) Product of a function by a distribution, and product/convolution duality. One forms $x_s = x_c \Delta_T$ and applies to it the duality $\widehat{fg} = \frac{1}{2\pi} \hat{f} * \hat{g}$: Lemma 24.1 proves it when the inverse transforms involved are summable functions, a hypothesis that Δ_T does not satisfy. One would need the product of a tempered distribution by a C^∞ function of slow growth and the convolution between distributions.

The three points are therefore **imported**. The theory that justifies them — tempered distributions, the delta never treated as a function (Proposition 19.8), the comb proved self-dual (Theorem 19.14) — is that of Section 19.12 of Chapter 19, with the sources already recorded there: NIST, Digital Library of Mathematical Functions, §1.16(v) «Tempered Distributions» and §1.16(vii) «Fourier Transforms of Tempered Distributions», and Bracewell, Chapter 10 «Sampling and Series» for the distributional apparatus of sampling. This is exactly what Remark 19.10 of that chapter states: the sampling theorem follows from the self-duality of the comb, «but its complete proof requires the product of a tempered distribution by a C^∞ function of slow growth and the convolution between distributions», which are not constructed there.

Consequently the route through the Dirac comb is to be read as a context remark — the quickest way of seeing why sampling periodizes the spectrum — and not as the formal proof of the result. The formal proof is that of Theorem 24.9, which uses distributions in no step and reconstructs the signal with an explicit formula; no later statement of the chapter depends on (P1)–(P3).

Remark 24.17: Practical relevance for control and automation. In choosing the scan time of a PLC, the theorem imposes an absolute upper limit (the sampling period cannot be slower than half the period of the fastest dynamics one wishes to observe or control), but in engineering practice one samples much faster than the theoretical minimum — typically 5–10 times the process bandwidth — both because an ideal low-pass filter does not exist (real anti-aliasing filters have a gradual transition, not a sharp cutoff) and to limit the delay introduced by sampling itself in the control loop. An analog sensor (temperature, pressure, level) should always be preceded by an analog anti-aliasing filter that attenuates components above $f_c/2$ before A/D conversion: otherwise high-frequency noise folds (aliasing) into the useful band and becomes indistinguishable from the signal.

Remark 24.18: Beyond Nyquist-Shannon: compressed sensing. Theorem 24.8 sets a sufficient limit on the sampling frequency for exact reconstruction of a generic bandlimited signal, but it is not necessary if the signal has richer structure than just a bandwidth limit: for example, that it is sparse in some basis (few non-zero components, perhaps not in the

Figure 24.3: Sampling in time periodically replicates the spectrum with step $\omega_c = 2\pi/T$: if $\omega_c \geq 2\omega_{\max}$ the replicas remain separate (i) and the signal is exactly reconstructed; otherwise they overlap (ii, shaded areas) and lost information is no longer recoverable — exactly the two cases of the proof just seen.

time basis but in that of frequencies or wavelets). Compressed sensing (or compressive sampling), developed in the mid-2000s by Candès, Romberg and Tao (2006) and independently by Donoho (2006), shows that an S -sparse signal of length N can be exactly reconstructed from only $O(S \log N)$ appropriately chosen linear measurements (typically random), well below the N samples required by Theorem 24.8 in the generic case — provided one replaces linear reconstruction (the low-pass filter of the proof of Theorem 24.8) with a nonlinear optimization problem (ℓ_1 norm minimization). This result has had direct impacts in medical imaging (accelerated MRI), astronomy, and is today an active area of research also for compressed acquisition of industrial vibration signals, where battery-powered wireless sensors benefit from transmitting as few samples as possible. It is an instructive example of how a classical limit (Nyquist-Shannon, 1949) remains fully valid within its assumptions (generically bandlimited signal) while subsequent research explores its boundaries under more realistic additional assumptions.

24.9. The reconstruction formula with the sinc function

The proof of Theorem 24.8 establishes the structural fact — sampling periodicizes the spectrum, and if the replicas do not touch the information is fully preserved — by going through the Dirac comb, that is, through an object that is a distribution and not a function. This section completes the picture by proving the *explicit* reconstruction formula, and it does so without distributions: the only tool is the Fourier series expansion of the spectrum on the bandwidth interval, together with the inversion formula. The result is that the samples not only *determine* the signal, but reconstruct it with a formula that can be written down and evaluated.

Definition 24.10: Bandlimited and Nyquist frequency. A signal $x \in L^1(\mathbb{R})$ is **bandlimited** to $\omega_{\max} > 0$ if $\hat{x}(\omega) = 0$ for every $|\omega| > \omega_{\max}$. Given a sampling step $T > 0$, the **sampling angular frequency** is $\omega_c = 2\pi/T$ and the **sampling frequency** is $\nu_c = 1/T$; the **Nyquist frequency** is $\nu_c/2 = 1/(2T)$, i.e. half the sampling frequency. The condition of Theorem 24.8, $\omega_c \geq 2\omega_{\max}$, thus reads: the band of the signal must lie below the Nyquist frequency.

Theorem 24.9: Shannon's reconstruction formula. Let $x \in L^1(\mathbb{R})$ with $\hat{x}$ zero outside $[-\omega_{\max}, \omega_{\max}]$, and let $T > 0$ be such that

$$\Omega := \frac{\pi}{T} \geq \omega_{\max} \quad \left(\text{equivalently } \omega_c = \frac{2\pi}{T} \geq 2\omega_{\max} \right).$$

Then x coincides a.e. with a continuous function, still denoted x , and for every $t \in \mathbb{R}$

$$x(t) = \sum_{n \in \mathbb{Z}} x(nT) \operatorname{sinc}\left(\frac{t - nT}{T}\right),$$

where the series converges for every t in the sense of the symmetric sums $\sum_{|n| \leq N}$, $N \rightarrow \infty$.

Proof. Step 0 — x is continuous and the inversion formula applies. The function $\hat{x}$ is continuous (Theorem 19.1) and zero outside the compact set $[-\omega_{\max}, \omega_{\max}]$, hence bounded and with compact support: therefore $\hat{x} \in L^1(\mathbb{R}) \cap L^2(\mathbb{R})$, with $\|\hat{x}\|_1 \leq 2\omega_{\max} \sup |\hat{x}| < \infty$ and similarly for the quadratic norm. Since $x \in L^1$ and $\hat{x} \in L^1$, Theorem 19.9 gives that x coincides a.e. with the continuous function

$$x(t) = \frac{1}{2\pi} \int_{\mathbb{R}} \hat{x}(\omega) e^{i\omega t} d\omega = \frac{1}{2\pi} \int_{-\Omega}^{\Omega} \hat{x}(\omega) e^{i\omega t} d\omega,$$

where in the second equality the domain was restricted because $\hat{x} = 0$ outside $[-\omega_{\max}, \omega_{\max}] \subseteq [-\Omega, \Omega]$, since $\Omega \geq \omega_{\max}$ by hypothesis. From here on x denotes this continuous representative.

Step 1 — the spectrum as a Fourier series on $[-\Omega, \Omega]$. Consider the restriction of $\hat{x}$ to $[-\Omega, \Omega]$ and transport it onto the circle with the linear change of variable

$$\omega = \frac{\Omega}{\pi} \theta, \quad \theta \in [-\pi, \pi],$$

setting $F(\theta) = \hat{x}(\Omega\theta/\pi)$. The function F is continuous on $[-\pi, \pi]$, hence $F \in L^2(\mathbb{T})$. By Theorem 17.1 of Chapter 17 its partial Fourier sums $S_N F = \sum_{|n| \leq N} \hat{F}(n) e_n$, with

$$\hat{F}(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} F(\theta) e^{-in\theta} d\theta,$$

converge to F in the $L^2(\mathbb{T})$ norm. Returning to the variable ω (the change of variable is affine and bijective between $[-\pi, \pi]$ and $[-\Omega, \Omega]$, with $d\omega = \frac{\Omega}{\pi} d\theta$), this means: setting

$$c_n := \hat{F}(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \hat{x}\left(\frac{\Omega\theta}{\pi}\right) e^{-in\theta} d\theta = \frac{1}{2\Omega} \int_{-\Omega}^{\Omega} \hat{x}(\omega) e^{-in\pi\omega/\Omega} d\omega,$$

the functions $S_N(\omega) := \sum_{|n| \leq N} c_n e^{in\pi\omega/\Omega}$ converge to $\hat{x}$ in the $L^2([-\Omega, \Omega])$ norm.

Step 2 — the coefficients are the samples. Evaluate the inversion formula of Step 0 at the points $t = nT$. Since $T = \pi/\Omega$, one has $nT = n\pi/\Omega$ and

$$x(nT) = \frac{1}{2\pi} \int_{-\Omega}^{\Omega} \hat{x}(\omega) e^{in\pi\omega/\Omega} d\omega.$$

Comparing with the expression for c_{-n} of Step 1, which is $\frac{1}{2\Omega} \int_{-\Omega}^{\Omega} \hat{x}(\omega) e^{in\pi\omega/\Omega} d\omega$, one obtains

$$c_{-n} = \frac{2\pi}{2\Omega} x(nT) = \frac{\pi}{\Omega} x(nT) = T x(nT) \quad \text{for every } n \in \mathbb{Z}.$$

Step 3 — exchanging sum and integral. Fix $t \in \mathbb{R}$. By Step 0,

$$x(t) = \frac{1}{2\pi} \int_{-\Omega}^{\Omega} \hat{x}(\omega) e^{i\omega t} d\omega.$$

Replace $\hat{x}$ by S_N and estimate the error committed: by the Cauchy–Schwarz inequality on the bounded interval $[-\Omega, \Omega]$,

$$\left| \int_{-\Omega}^{\Omega} (\hat{x}(\omega) - S_N(\omega)) e^{i\omega t} d\omega \right| \leq \|\hat{x} - S_N\|_{L^2([-\Omega, \Omega])} \cdot \left(\int_{-\Omega}^{\Omega} |e^{i\omega t}|^2 d\omega \right)^{1/2} = \sqrt{2\Omega} \|\hat{x} - S_N\|_{L^2([-\Omega, \Omega])},$$

which tends to 0 as $N \rightarrow \infty$ by Step 1 (and the bound does not depend on t). Hence

$$x(t) = \lim_{N \rightarrow \infty} \frac{1}{2\pi} \int_{-\Omega}^{\Omega} S_N(\omega) e^{i\omega t} d\omega = \lim_{N \rightarrow \infty} \sum_{|n| \leq N} \frac{c_n}{2\pi} \int_{-\Omega}^{\Omega} e^{i\omega(t+n\pi/\Omega)} d\omega,$$

where exchanging the *finite* sum and the integral is the linearity of the integral.

Step 4 — the elementary integral. For every $s \in \mathbb{R}$,

$$\int_{-\Omega}^{\Omega} e^{i\omega s} d\omega = \left[\frac{e^{i\omega s}}{is} \right]_{-\Omega}^{\Omega} = \frac{e^{i\Omega s} - e^{-i\Omega s}}{is} = \frac{2 \sin(\Omega s)}{s} \quad (s \neq 0),$$

and $\int_{-\Omega}^{\Omega} 1 d\omega = 2\Omega$ for $s = 0$, which is also the limit of the right-hand side. With $s = t + n\pi/\Omega = t + nT$ and $\Omega = \pi/T$:

$$\frac{1}{2\pi} \int_{-\Omega}^{\Omega} e^{i\omega(t+nT)} d\omega = \frac{1}{2\pi} \cdot \frac{2 \sin(\pi(t+nT)/T)}{t+nT} = \frac{1}{\pi} \cdot \frac{\sin(\pi(t+nT)/T)}{t+nT}.$$

Multiplying and dividing by T and using the definition $\text{sinc}(v) = \sin(\pi v)/(\pi v)$ with $v = (t+nT)/T$,

$$\frac{1}{\pi} \cdot \frac{\sin(\pi v)}{Tv} = \frac{1}{T} \cdot \frac{\sin(\pi v)}{\pi v} = \frac{1}{T} \text{sinc}\left(\frac{t+nT}{T}\right).$$

Step 5 — conclusion. Substituting into Step 3 and using Step 2 in the form $c_n = T x(-nT)$:

$$x(t) = \lim_{N \rightarrow \infty} \sum_{|n| \leq N} T x(-nT) \cdot \frac{1}{T} \text{sinc}\left(\frac{t+nT}{T}\right) = \lim_{N \rightarrow \infty} \sum_{|n| \leq N} x(-nT) \text{sinc}\left(\frac{t+nT}{T}\right).$$

With the change of index $m = -n$, which is a bijection of $\{-N, \dots, N\}$ onto itself,

$$x(t) = \lim_{N \rightarrow \infty} \sum_{|m| \leq N} x(mT) \text{sinc}\left(\frac{t-mT}{T}\right) = \sum_{m \in \mathbb{Z}} x(mT) \text{sinc}\left(\frac{t-mT}{T}\right),$$

which is the claim. □

Corollary 24.4: The sinc function is the impulse response of the reconstructor.

Under the hypotheses of Theorem 24.9, the reconstruction formula is the interpolation of the samples with the function

$$g(t) = \text{sinc}(t/T),$$

which has $g(0) = 1$ and $g(mT) = 0$ for every nonzero integer m . Consequently the formula returns exactly the sample at the sampling points: evaluating at $t = kT$, all the terms vanish except the one with $m = k$, which equals $x(kT) \cdot 1$.

Proof. By definition, $\text{sinc}(0) = 1$ and $\text{sinc}(v) = \sin(\pi v)/(\pi v) = 0$ exactly when $\sin(\pi v) = 0$ and $v \neq 0$, i.e. when v is a nonzero integer. Setting $v = (kT - mT)/T = k - m$, one has $v = 0$ if and only if $m = k$, and v a nonzero integer otherwise. Hence in the sum of Theorem 24.9 evaluated at $t = kT$ only the term $m = k$ survives, and $x(kT) = x(kT)$. □

Example 24.7: Reconstruction checked on a bandlimited signal. Take $x(t) = \text{sinc}(t)^2$. Its band is determined in two steps. First: by Proposition 19.2 and the inversion formula (Theorem 19.9), $\text{sinc}(t) = \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{i\omega t} d\omega$, i.e. $\widehat{\text{sinc}} = \mathbf{1}_{[-\pi, \pi]}$ — the same computation as in Corollary 24.2 with $\Omega = \pi$. Second: by Lemma 24.1, applied to $F = G = \mathbf{1}_{[-\pi, \pi]} \in L^1(\mathbb{R})$ — whose inverse transforms are $f = g = \text{sinc}$, by the previous step, and whose product sinc^2 lies in $L^1(\mathbb{R})$ because it is continuous and $O(t^{-2})$ at infinity —,

$$\widehat{\text{sinc}^2} = \frac{1}{2\pi} (\mathbf{1}_{[-\pi, \pi]} * \mathbf{1}_{[-\pi, \pi]}),$$

and the convolution of two functions with support in $[-\pi, \pi]$ has support contained in $[-2\pi, 2\pi]$, because $|\omega| > 2\pi$ implies that for every ξ at least one of $\mathbf{1}_{[-\pi, \pi]}(\xi)$ and $\mathbf{1}_{[-\pi, \pi]}(\omega - \xi)$ vanishes. Hence $\omega_{\max} = 2\pi$, i.e. the signal has a 1 Hz band. The condition of Theorem 24.9 is $\Omega = \pi/T \geq 2\pi$, i.e. $T \leq 1/2$: one chooses $T = 1/2$, the critical step.

Check (Python script executed). Truncating the series to $|n| \leq 4000$:

t	$x(t)$ (closed form)	truncated series	gap
0.3	0.736 839 729 322 3	0.736 839 729 321 9	$3.83 \cdot 10^{-13}$
1.234	0.029 930 079 376 2	0.029 930 079 374 6	$1.65 \cdot 10^{-12}$
-0.75	0.090 063 274 348 7	0.090 063 274 349 8	$1.01 \cdot 10^{-12}$
2.5	0.016 211 389 382 8	0.016 211 389 382 8	0

✓The four gaps are of the order of the truncation error of the series, which for an x with t^{-2} decay and symmetric tails is of order N^{-1} but with strong cancellations; the value $t = 2.5 = 5T$ falls on a sampling point, where by Corollary 24.4 the series has only one nonzero term and the result is exact.

Counter-check: what happens below Nyquist. With the same x and $T = 1$ (i.e. $\nu_c = 1$ Hz, half the required minimum of 2 Hz), the same truncated series gives 0.858 393 691 3 at $t = 0.3$ against the true value 0.736 839 729 3: a gap of 0.121 553 962, i.e. over 16% of the value. And at $t = 1.234$ it gives -0.173 003 119 6 against 0.029 930 079 4: the reconstruction even changes sign. ✓The hypothesis $\Omega \geq \omega_{\max}$ is not a precaution, it is the validity condition.

24.10. Aliasing

Definition 24.11: Alias frequency. Let $\nu_c = 1/T$ be the sampling frequency and let $\nu_0 \geq 0$ be the frequency of a sinusoidal component of the signal. Its **alias frequency** is

$$\nu_a = |\nu_0 - k\nu_c|, \quad k = \text{an integer closest to } \nu_0/\nu_c,$$

(if there are two closest integers, i.e. if ν_0/ν_c is a half-integer, the choice does not matter because the two values of $|\nu_0 - k\nu_c|$ coincide and equal $\nu_c/2$), that is, the unique number in $[0, \nu_c/2]$ congruent to $\pm\nu_0$ modulo ν_c . If $\nu_0 \leq \nu_c/2$ one has $k = 0$ and $\nu_a = \nu_0$; if $\nu_0 > \nu_c/2$ one has $\nu_a < \nu_0$ and one speaks of **aliasing** or **folding**.

Theorem 24.10: Two sinusoids indistinguishable in the samples. Let $\nu_0 \geq 0$, $\nu_c > 0$, $A \in \mathbb{R}$, $\varphi_0 \in \mathbb{R}$, $T = 1/\nu_c$, and let ν_a be the alias frequency of Definition 24.11, with k the integer defined there. Set

$$x(t) = A \cos(2\pi\nu_0 t + \varphi_0), \quad \tilde{x}(t) = A \cos(2\pi\nu_a t + \varepsilon\varphi_0), \quad \varepsilon = \text{sgn}(\nu_0 - k\nu_c)$$

(with $\varepsilon = 1$ if $\nu_0 = k\nu_c$). Then

$$x(nT) = \tilde{x}(nT) \quad \text{for every } n \in \mathbb{Z} :$$

the two signals, of different frequencies, produce the same sample sequence, and no processor working only with the samples can distinguish them.

Proof. Step 1 — reduction modulo ν_c . Set $\mu = \nu_0 - k\nu_c$, so that $\nu_a = |\mu|$ and $\mu = \varepsilon\nu_a$ by the definition of ε . For every $n \in \mathbb{Z}$, since $T = 1/\nu_c$,

$$2\pi\nu_0 nT + \varphi_0 = 2\pi(\mu + k\nu_c)\frac{n}{\nu_c} + \varphi_0 = 2\pi\mu nT + 2\pi kn + \varphi_0.$$

Step 2 — periodicity of the cosine. Since $kn \in \mathbb{Z}$ and the cosine is 2π -periodic, $\cos(\alpha + 2\pi kn) = \cos \alpha$ for every α ; hence

$$x(nT) = A \cos(2\pi\mu nT + \varphi_0).$$

Step 3 — evenness of the cosine. If $\varepsilon = 1$, then $\mu = \nu_a$ and Step 2 already gives $x(nT) = A \cos(2\pi\nu_a nT + \varphi_0) = \tilde{x}(nT)$. If $\varepsilon = -1$, then $\mu = -\nu_a$ and, using $\cos(-\beta) = \cos \beta$ with $\beta = 2\pi\nu_a nT - \varphi_0$,

$$x(nT) = A \cos(-2\pi\nu_a nT + \varphi_0) = A \cos(2\pi\nu_a nT - \varphi_0) = A \cos(2\pi\nu_a nT + \varepsilon\varphi_0) = \tilde{x}(nT).$$

In both cases the equality holds for every $n \in \mathbb{Z}$. $\square$

Example 24.8: The numerical example, checked sample by sample. Sample at $\nu_c = 1\,000$ Hz, i.e. with $T = 1$ ms; the Nyquist frequency is 500 Hz.

(a) A component at $\nu_0 = 1\,300$ Hz. Here $\nu_0/\nu_c = 1.3$, hence $k = 1$ and $\mu = 1\,300 - 1\,000 = 300$ Hz, with $\varepsilon = +1$: the alias frequency is $\nu_a = 300$ Hz. The first six samples of $\cos(2\pi \cdot 1\,300 t)$, computed by hand from standard angles — $2\pi \cdot 1\,300 \cdot n/1\,000 = 2.6\pi n$, which modulo 2π equals $0.6\pi n$, i.e. $108^\circ \cdot n$ — are

$$1, \quad \cos 108^\circ, \quad \cos 216^\circ, \quad \cos 324^\circ, \quad \cos 432^\circ, \quad \cos 540^\circ = 1, \quad -0.309\,017, \quad -0.809\,017, \quad 0.809\,017, \quad 0.309\,017,$$

and are *exactly* the samples of $\cos(2\pi \cdot 300 t)$, for which $2\pi \cdot 300 \cdot n/1\,000 = 0.6\pi n$, i.e. the same angle. $\checkmark$

(b) A component at $\nu_0 = 700$ Hz. Here $\nu_0/\nu_c = 0.7$, hence $k = 1$ and $\mu = 700 - 1\,000 = -300$ Hz, with $\varepsilon = -1$: again $\nu_a = 300$ Hz, but with the phase sign changed. The two components at 700 and 1 300 Hz therefore fall *on the same* alias: a spectrum computed from the samples sums them without being able to separate them.

Independent check (Python script executed). Over 101 samples, from $n = -50$ to $n = 50$, the maximum gap between $\cos(2\pi \cdot 1\,300 nT)$ and $\cos(2\pi \cdot 300 nT)$ equals $5.64 \cdot 10^{-14}$; between $\cos(2\pi \cdot 700 nT)$ and $\cos(2\pi \cdot 300 nT)$ it equals $4.52 \cdot 10^{-14}$; and, with the phase, between $\cos(2\pi \cdot 700 nT + 0.7)$ and $\cos(2\pi \cdot 300 nT - 0.7)$ it equals $5.53 \cdot 10^{-14}$, also confirming the sign of ε in Theorem 24.10. $\checkmark$ All gaps are of the order of double-precision machine error.

(c) The industrial case. A sensor read by a PLC at $\nu_c = 50$ Hz and disturbed by the mains at $\nu_0 = 60$ Hz: $\nu_0/\nu_c = 1.2$, $k = 1$, $\nu_a = |60 - 50| = 10$ Hz. The mains disturbance appears in the data as a slow 10 Hz oscillation, indistinguishable from a real variation of the process. The maximum gap between the samples of $\cos(2\pi \cdot 60 t)$ and of $\cos(2\pi \cdot 10 t)$, over 101 samples, is $6.43 \cdot 10^{-14}$. $\checkmark$ No *digital* filter, however sophisticated, can remove it: the only defence is the *analog* anti-aliasing filter of Remark 24.17, which acts before conversion.

(d) A limiting case. If $\nu_0 = 2\,000$ Hz, then $k = 2$ and $\nu_a = 0$: the sampled signal is constant, and the sinusoid disappears entirely. This is the phenomenon that makes wagon wheels appear motionless in films shot at 24 frames per second.

Figure 24.4: Aliasing, Example 24.8(a): sampling at $\nu_c = 1000$ Hz (step 1 ms) the 1300 Hz sinusoid (grey) and the 300 Hz one (blue) pass through the *same* six red points, whose values 1, -0.309017 , -0.809017 , 0.809017 , 0.309017 , -1 are the cosines of the angles 0° , 108° , 216° , 324° , 432° , 540° , computed by hand and confirmed by the script. From the samples alone the two sinusoids are indistinguishable, as Theorem 24.10 states.

Best practice. How to choose a sampling frequency. (1) Establish the band $\nu_{\max}$ of the *useful signal*, not of the signal one hopes to measure. (2) Insert an *analog* anti-aliasing filter that attenuates everything above $\nu_c/2$ by at least the resolution of the converter (for a 12-bit A/D, about 72 dB). (3) Choose ν_c equal to 5–10 times $\nu_{\max}$, not 2 times: the factor 2 is the mathematical limit of Theorem 24.8, not a design target, and the margin serves the non-ideal transition of the filter (Remark 24.17). (4) Verify the result by feeding the system a sinusoid of known frequency *above* $\nu_c/2$ and checking that its alias does not appear in the spectrum: if it appears, the filter is not attenuating enough. The computation of the expected alias is that of Definition 24.11, and must be done *before* the test, not after.

24.11. The analytic signal and the Hilbert transform

By Theorem 24.6(iii) the spectrum of a real signal is redundant: the negative half is the conjugate reflection of the positive half, and carries no new information. The **analytic signal** is the canonical way of eliminating the redundancy — the negative frequencies are suppressed and the positive ones are doubled — and the **Hilbert transform** is the operator that this suppression requires. This section defines both, proves the fact that justifies them, and states precisely the perimeter: what is proved here and what remains imported.

Definition 24.12: Hilbert transform on $L^2(\mathbb{R})$. For $x \in L^2(\mathbb{R})$, the **Hilbert transform** $\mathcal{H}x \in L^2(\mathbb{R})$ is defined as the unique function of $L^2(\mathbb{R})$ whose Fourier transform is

$$\widehat{\mathcal{H}x}(\omega) = -i \operatorname{sgn}(\omega) \hat{x}(\omega) \quad \text{for almost every } \omega \in \mathbb{R}.$$

$\mathcal{H}$ is also said to be the *filter* with frequency response $H_{\mathcal{H}}(\omega) = -i \operatorname{sgn}(\omega)$.

Proposition 24.4: The definition is well posed, and $\mathcal{H}$ is an isometry. Definition 24.12 determines a unique $\mathcal{H}x \in L^2(\mathbb{R})$ for every $x \in L^2(\mathbb{R})$, and the operator $\mathcal{H} : L^2(\mathbb{R}) \rightarrow L^2(\mathbb{R})$ so obtained is linear and satisfies

$$\|\mathcal{H}x\|_2 = \|x\|_2 \quad \text{and} \quad \mathcal{H}(\mathcal{H}x) = -x \quad \text{for every } x \in L^2(\mathbb{R}).$$

(The value of the multiplier at the single point $\omega = 0$ is irrelevant, because $\{0\}$ has measure zero and no L^2 norm is affected by it.)

Proof. Step 1 — existence and uniqueness. By Corollary 19.4 of Chapter 19 the Fourier transform is an isometric bijection (up to the factor $\sqrt{2\pi}$ of the convention) of $L^2(\mathbb{R})$ onto itself. The function $\omega \mapsto -i \operatorname{sgn}(\omega) \hat{x}(\omega)$ is measurable and satisfies $|-i \operatorname{sgn}(\omega) \hat{x}(\omega)| \leq |\hat{x}(\omega)|$ for every ω , hence it belongs to $L^2(\mathbb{R})$: it therefore has a unique inverse transform in $L^2(\mathbb{R})$, which is $\mathcal{H}x$. Uniqueness is that of the inverse transform, i.e. the injectivity of the transform on L^2 .

Step 2 — isometry. Since $|-i \operatorname{sgn}(\omega)| = 1$ for every $\omega \neq 0$, one has $|\widehat{\mathcal{H}x}(\omega)| = |\hat{x}(\omega)|$ for almost every ω (the only excluded point is $\omega = 0$, a set of measure zero). Hence $\|\widehat{\mathcal{H}x}\|_2 = \|\hat{x}\|_2$, and by Plancherel's isometry (Corollary 19.4) $\|\mathcal{H}x\|_2 = \|x\|_2$.

Step 3 — $\mathcal{H}^2 = -\operatorname{id}$. Applying the definition twice,

$$\widehat{\mathcal{H}(\mathcal{H}x)}(\omega) = -i \operatorname{sgn}(\omega) \widehat{\mathcal{H}x}(\omega) = (-i \operatorname{sgn}(\omega))^2 \hat{x}(\omega) = -\operatorname{sgn}(\omega)^2 \hat{x}(\omega) = -\hat{x}(\omega)$$

for almost every ω , because $\operatorname{sgn}(\omega)^2 = 1$ for $\omega \neq 0$ and $\{0\}$ has measure zero. By injectivity of the transform on L^2 , $\mathcal{H}(\mathcal{H}x) = -x$. $\square$

Definition 24.13: Analytic signal. Let $x \in L^2(\mathbb{R})$ be real-valued. Its **analytic signal** is

$$x_a = x + i \mathcal{H}x \in L^2(\mathbb{R}; \mathbb{C}).$$

The modulus $A(t) = |x_a(t)|$ is called the **envelope** of x , and, where x_a does not vanish, any continuous determination ψ of $\arg x_a$ is called the **instantaneous phase**; its derivative $\psi'(t)/(2\pi)$, where it exists, is the **instantaneous frequency**.

Theorem 24.11: The analytic signal suppresses the negative frequencies. Let $x \in L^2(\mathbb{R})$ and $x_a = x + i \mathcal{H}x$. Then, for almost every $\omega \in \mathbb{R}$,

$$\hat{x}_a(\omega) = (1 + \operatorname{sgn}(\omega)) \hat{x}(\omega) = \begin{cases} 2 \hat{x}(\omega), & \omega > 0, \\ \hat{x}(0), & \omega = 0, \\ 0, & \omega < 0. \end{cases}$$

In particular the spectrum of x_a is zero on the whole negative-frequency half-line, and on the positive one it is twice that of x .

Proof. Step 1 — linearity of the transform. Since $x \in L^2(\mathbb{R})$ and $\mathcal{H}x \in L^2(\mathbb{R})$ by Proposition 24.4, also $x_a = x + i \mathcal{H}x \in L^2(\mathbb{R}; \mathbb{C})$, and the Fourier transform on L^2 is linear (Corollary 19.4):

$$\hat{x}_a(\omega) = \hat{x}(\omega) + i \widehat{\mathcal{H}x}(\omega).$$

Step 2 — substituting the definition. By Definition 24.12, for almost every ω ,

$$\hat{x}_a(\omega) = \hat{x}(\omega) + i \cdot (-i \operatorname{sgn}(\omega)) \hat{x}(\omega) = \hat{x}(\omega) + (-i^2) \operatorname{sgn}(\omega) \hat{x}(\omega) = \hat{x}(\omega) + \operatorname{sgn}(\omega) \hat{x}(\omega) = (1 + \operatorname{sgn}(\omega)) \hat{x}(\omega),$$

having used $i \cdot (-i) = -i^2 = 1$.

Step 3 — the three cases. By definition of sgn : for $\omega > 0$ one has $1 + \operatorname{sgn}(\omega) = 1 + 1 = 2$; for $\omega < 0$ one has $1 + \operatorname{sgn}(\omega) = 1 - 1 = 0$; for $\omega = 0$ one has $1 + \operatorname{sgn}(0) = 1 + 0 = 1$. Substituting gives the three lines of the statement. $\square$

Corollary 24.5: Recovering the real signal and the envelope. With the notation of Definition 24.13, for x real one has

$$x = \operatorname{Re} x_a, \quad \mathcal{H}x = \operatorname{Im} x_a, \quad |x(t)| \leq A(t) = |x_a(t)| \text{ for every } t.$$

Proof. Step 1 — the spectrum of a real signal of L^2 is Hermitian. Let $x \in L^2(\mathbb{R})$ be real and let $x_N = x \mathbf{1}_{[-N, N]}$ be its truncations. By Cauchy–Schwarz $\int_{-N}^N |x| \leq \sqrt{2N} \|x\|_2 < \infty$, hence $x_N \in L^1(\mathbb{R}) \cap L^2(\mathbb{R})$, and it is real; moreover $x_N \rightarrow x$ in $L^2(\mathbb{R})$ by dominated convergence. Theorem 24.6(iii), applied to $x_N \in L^1(\mathbb{R})$ real, gives $\hat{x}_N(-\omega) = \overline{\hat{x}_N(\omega)}$ for every ω . By Plancherel’s isometry (Corollary 19.4) one has $\hat{x}_N \rightarrow \hat{x}$ in $L^2(\mathbb{R})$, hence there is a subsequence along which $\hat{x}_N \rightarrow \hat{x}$ a.e.; the reflection $\omega \mapsto -\omega$ sends sets of measure zero to sets of measure zero, so along the same subsequence also $\hat{x}_N(-\cdot) \rightarrow \hat{x}(-\cdot)$ a.e. Passing to the limit on both sides (conjugation is continuous) gives $\hat{x}(-\omega) = \overline{\hat{x}(\omega)}$ for almost every ω .

Step 2 — $\mathcal{H}x$ is also real. For almost every ω ,

$$\widehat{\mathcal{H}x}(-\omega) = -i \operatorname{sgn}(-\omega) \hat{x}(-\omega) = i \operatorname{sgn}(\omega) \overline{\hat{x}(\omega)} = \overline{-i \operatorname{sgn}(\omega) \hat{x}(\omega)} = \overline{\widehat{\mathcal{H}x}(\omega)},$$

using $\operatorname{sgn}(-\omega) = -\operatorname{sgn}(\omega)$, Step 1 and $\overline{-iz} = iz$. A function of L^2 whose spectrum has Hermitian symmetry is real a.e.: indeed the function $\widehat{\mathcal{H}x}$ has as its transform $\omega \mapsto \widehat{\mathcal{H}x}(-\omega)$, which by what was just shown coincides a.e. with $\widehat{\mathcal{H}x}$; by injectivity of the transform on L^2 , $\widehat{\mathcal{H}x} = \mathcal{H}x$ a.e.

Step 3 — conclusion. Since x and $\mathcal{H}x$ are both real, the expression $x_a = x + i\mathcal{H}x$ is exactly the decomposition of x_a into real part and imaginary part: $x = \operatorname{Re} x_a$ and $\mathcal{H}x = \operatorname{Im} x_a$. Finally, for every $z = \alpha + i\beta$ with α, β real one has $|\alpha| \leq \sqrt{\alpha^2 + \beta^2} = |z|$: applied to $z = x_a(t)$ this gives $|x(t)| \leq A(t)$. $\square$

Definition 24.14: Extension to trigonometric polynomials. A sinusoid does not belong to $L^2(\mathbb{R})$ (Remark 24.1), and Definition 24.12 does not apply to it. For a **trigonometric polynomial** $p(t) = \sum_{j=1}^m c_j e^{i\omega_j t}$ (a *finite* sum, with $c_j \in \mathbb{C}$ and $\omega_j \in \mathbb{R}$) one then defines

$$\mathcal{H}p := \sum_{j=1}^m (-i \operatorname{sgn}(\omega_j)) c_j e^{i\omega_j t},$$

i.e. by applying the multiplier $-i \operatorname{sgn}$ to each exponential, as if it were an eigenfunction in the sense of Theorem 24.2.

Proposition 24.5: Hilbert sends the cosine to the sine. Let $\omega_0 > 0$. With Definition 24.14,

$$\mathcal{H}[\cos(\omega_0 t)] = \sin(\omega_0 t), \quad \mathcal{H}[\sin(\omega_0 t)] = -\cos(\omega_0 t),$$

and the analytic signal of the cosine is the complex exponential:

$$(\cos(\omega_0 \cdot))_a(t) = \cos(\omega_0 t) + i \sin(\omega_0 t) = e^{i\omega_0 t},$$

whose envelope is the constant $A \equiv 1$ and whose instantaneous frequency is the constant $\omega_0/(2\pi)$.

Proof. Step 1 — the cosine. By Euler’s formula, $\cos(\omega_0 t) = \frac{1}{2}e^{i\omega_0 t} + \frac{1}{2}e^{-i\omega_0 t}$: this is a trigonometric polynomial with $m = 2$, $c_1 = c_2 = \frac{1}{2}$, $\omega_1 = \omega_0 > 0$, $\omega_2 = -\omega_0 < 0$. By Definition 24.14,

$$\mathcal{H}[\cos(\omega_0 t)] = \frac{1}{2}(-i)(+1)e^{i\omega_0 t} + \frac{1}{2}(-i)(-1)e^{-i\omega_0 t} = -\frac{i}{2}(e^{i\omega_0 t} - e^{-i\omega_0 t}) = -\frac{i}{2} \cdot 2i \sin(\omega_0 t) = \sin(\omega_0 t),$$

using $e^{i\theta} - e^{-i\theta} = 2i \sin \theta$ and $-i \cdot i = 1$.

Step 2 — the sine. Similarly $\sin(\omega_0 t) = \frac{1}{2i}e^{i\omega_0 t} - \frac{1}{2i}e^{-i\omega_0 t}$, hence

$$\mathcal{H}[\sin(\omega_0 t)] = \frac{-i}{2i}e^{i\omega_0 t} - \frac{(-i)(-1)}{2i}e^{-i\omega_0 t} = -\frac{1}{2}e^{i\omega_0 t} - \frac{1}{2}e^{-i\omega_0 t} = -\cos(\omega_0 t),$$

having simplified $-i/(2i) = -1/2$ and $i/(2i) = 1/2$. Note that, consistently with Proposition 24.4, applying $\mathcal{H}$ twice to the cosine gives $\mathcal{H}[\sin] = -\cos$: i.e. $\mathcal{H}^2 = -\text{id}$ also on these signals.

Step 3 — the analytic signal. By Definition 24.13 and Step 1, $(\cos(\omega_0 \cdot))_a(t) = \cos(\omega_0 t) + i \sin(\omega_0 t)$, which is $e^{i\omega_0 t}$ by Euler's formula. Its modulus is $|e^{i\omega_0 t}| = 1$ for every t ; a continuous determination of the argument is $\psi(t) = \omega_0 t$, and $\psi'(t)/(2\pi) = \omega_0/(2\pi)$.

Independent numerical check. With $\omega_0 = 2\pi \cdot 5$ rad/s, at $t = 0.017$ s one has $\cos(\omega_0 t) + i \sin(\omega_0 t) = 0.860\,742\,027\,0 + 0.509\,041\,415\,8\,i$, which coincides with $e^{i\omega_0 t}$ computed independently within machine error, with modulus 1.000 000 0; the instantaneous frequency computed by centred differences with step 10^{-7} equals 4.999 999 999 89 Hz against the expected value of 5 Hz. $\checkmark$ $\square$

Figure 24.5: Theorem 24.11 in a picture. The spectrum of a real signal (i) has two halves linked by the Hermitian symmetry of Theorem 24.6(iii): the negative half carries no new information. The analytic signal (ii) eliminates it and doubles the positive half, so that the energy is conserved: indeed, by Theorem 24.11 and by Plancherel, $\|x_a\|_2^2 = \frac{1}{2\pi} \int_0^{+\infty} 4|\hat{x}|^2 = \frac{2}{2\pi} \int_{\mathbb{R}} |\hat{x}|^2 = 2\|x\|_2^2$, consistent with $\|x_a\|_2^2 = \|x\|_2^2 + \|\mathcal{H}x\|_2^2 = 2\|x\|_2^2$ of Proposition 24.4. The two vertices are at $(\pm 1.6, 0.9)$ in panel (i) and at $(1.6, 1.5)$ in panel (ii): the ratio $1.5/0.9 = 5/3$ is only graphical, the figure is schematic and not to scale in energy.

Remark 24.19: What we import about the Hilbert transform. Of this section, everything concerning the multiplier is proved in full: the well-posedness on L^2 (Proposition 24.4), the isometry, the identity $\mathcal{H}^2 = -\text{id}$, the suppression of the negative frequencies (Theorem 24.11) and the computation on cosine and sine (Proposition 24.5). What remains **imported**, that is, stated and used but not proved here, is the following.

(H1) The integral form. For $x \in L^2(\mathbb{R})$, for almost every t ,

$$(\mathcal{H}x)(t) = \frac{1}{\pi} \text{p.v.} \int_{\mathbb{R}} \frac{x(s)}{t-s} ds := \frac{1}{\pi} \lim_{\varepsilon \rightarrow 0^+} \int_{|t-s| > \varepsilon} \frac{x(s)}{t-s} ds.$$

The equivalence between this formula and Definition 24.12 requires the theory of singular integrals (the kernel $1/(\pi t)$ is not integrable in any neighbourhood of the origin, and lies neither in L^1 nor in L^2 : the system does not fall under Definition 24.4). What is exactly missing: the proof that the limit exists a.e. and that the limit function has transform $-i \operatorname{sgn} \hat{x}$.

(H2) The M. Riesz theorem. $\mathcal{H}$ extends to a bounded operator on $L^p(\mathbb{R})$ for every $1 < p < \infty$, but not on L^1 nor on L^∞ . What is missing: the interpolation and the weak-type estimates on which the proof rests.

(H3) The Bedrosian theorem. If x is narrowband around ω_0 and a has band contained in $[-\omega_0, \omega_0]$, then $\mathcal{H}[a \cdot x] = a \cdot \mathcal{H}[x]$; this is the result that makes it legitimate to call the modulus $A(t)$ the “envelope” in a modulated signal $a(t) \cos(\omega_0 t)$. What is missing: the proof, which is a computation on frequency supports but requires (H1).

The source of (H1) and (H2) is King, *Hilbert Transforms*, entry [6] of the *Sources* environment; that of (H3), together with the engineering use of the envelope, is Oppenheim and Schaffer, entry [4]. None of these three results is used in any statement or proof of this chapter: they appear only in this remark, as **panorama** of what the theory contains beyond the perimeter covered here.

Remark 24.20: The envelope is not what it seems. Envelope and instantaneous frequency are defined for every real signal of $L^2(\mathbb{R})$, but they are useful only for narrowband signals. For an arbitrary signal the instantaneous frequency can turn out negative, or diverge where x_a vanishes, without this indicating anything physical: it is an artifact of the definition. The criterion that makes the concept reliable is the Bedrosian condition (H3) of Remark 24.19, and it must be checked before interpreting the results — for instance before reading the envelope of a vibration signal as the “instantaneous amplitude of the defect”. The case of Proposition 24.5 is the ideal case, and should be used as a benchmark: there the envelope is exactly constant and the instantaneous frequency exactly $\omega_0/(2\pi)$.

24.12. Exercises inherited from Volume II

The exercises below come from Volume II, Chapter 4, and concern the topics of this chapter. They are reproduced in full, together with their solutions, which follow in the same order as the exercises.

Exercises

Exercise 24.1. (Application to water treatment) — A turbidity sensor in a water treatment line has dynamics with significant frequency components up to 2 Hz. What is the minimum sampling frequency imposed by Nyquist? Why would an engineer in practice choose a higher PLC sampling frequency, for example 20 Hz?

Solutions

Solution. By Theorem 24.8, the minimum sampling frequency is $f_c \geq 2f_{\max} = 2 \times 2 \text{ Hz} = 4 \text{ Hz}$: this is the absolute theoretical limit below which information is irreversibly lost to aliasing.

In practice, however, an engineer would choose a higher frequency (for example 20 Hz, i.e. 5 times the bandwidth) for at least three reasons, already discussed in Remark 24.17: (a) real anti-aliasing filters do not have a sharp cutoff at $f_c/2$, so a margin is needed for the components just above 2 Hz to be sufficiently attenuated before sampling; (b) sampling exactly at the Nyquist limit introduces a phase lag and poor time resolution in the control loop (few samples per period of the fastest signal degrade the performance of the PID controller); (c) a margin also makes it possible to observe correctly any disturbances or noise at a frequency slightly above $f_{\max}$ without their aliasing into the useful band of the turbidity signal.

Inherited quiz

The items below come from the quiz of Volume II, Chapter 4, and are renumbered here.

1. The Nyquist-Shannon theorem requires a sampling frequency
 - A) equal to the bandwidth of the signal
 - B) at least twice the maximum frequency
 - C) arbitrary
 - D) lower than the bandwidth

BEST PRACTICE

Answer key.

1-B: Theorem 24.8.

24.13. Assigned exercises

These are *new* exercises, distinct both from the inherited ones of Section 24.12 and from the worked ones of Section 24.14. The answers are in the Teacher’s key (Section 24.16).

Exercise 24.2: A first-order filter, from beginning to end. *Goal:* to walk through the whole chain of the chapter on a single system — impulse response, stability, causality, frequency response, the two delays — and to know how to translate every number into a sentence about the physical behaviour. *Estimated time:* 45 minutes. *Type:* symbolic and numerical. *Level:* basic–intermediate. Consider the low-pass RC filter with $\tau = RC = 5$ ms.

- (a) Write h , verify $h \in L^1(\mathbb{R})$ by computing $\|h\|_1$ in closed form, and deduce BIBO stability and the gain from Theorem 24.4. Say why the system is causal by citing Theorem 24.5.
- (b) Compute $H(\omega)$ by direct integration, then $|H|$ and ϕ . Determine the -3 dB frequency in hertz and verify that at that frequency the gain equals $1/\sqrt{2}$ and the phase -45° .
- (c) Compute τ_p and τ_g in milliseconds at $\omega = 1/\tau$ and at $\omega = 3/\tau$, and the limiting value $\tau_g(0)$. Say which of the two delays is read as the “delay of the envelope” and why (Theorem 24.7).
- (d) Does the system satisfy the no-distortion condition of Corollary 24.3 on some band? Justify the answer *without* computing anything new, using only the form of $\tau_g(\omega)$.
- (e) Verify (b) and (c) with a script: H by numerical quadrature of the defining integral, τ_g by centred differences; report the gaps.

Exercise 24.3: Linear phase is not enough. *Goal:* to distinguish the *two* conditions of Corollary 24.3, which are often conflated into one. *Estimated time:* 40 minutes. *Type:* proof-based and numerical. *Level:* intermediate. Consider the moving average with window $T_0 = 10$ ms.

- (a) Derive $H(\omega)$ by retracing the computation of Example 24.5, and determine the frequencies in hertz of the first three zeros of the gain.
- (b) Show that, on every frequency interval where $\sin(\omega T_0/2) > 0$, the continuous phase is exactly $\phi(\omega) = -\omega T_0/2$ and hence $\tau_g \equiv T_0/2$, constant. What is its value in milliseconds?
- (c) Despite (b), the system *distorts* a signal with a band reaching 150 Hz. Explain why, indicating which of the two hypotheses of Corollary 24.3 fails, and compute $|H|$ at 25, 50, 100 and 150 Hz.

- (d) Determine the maximum band $\nu_{\max}$ within which the gain does not drop below 0.9, and verify that within that band the “no distortion” approximation is reasonable. (It suffices to solve $\text{sinc}(\nu T_0) = 0.9$ numerically by trial.)
- (e) What changes if the moving average is replaced with an RC filter of equal low-frequency group delay, i.e. with $\tau = T_0/2$? Compare the two $\tau_g(\omega)$ and comment.

Exercise 24.4: Sampling an industrial signal. *Goal:* to apply in sequence Theorem 24.8, Theorem 24.9 and Theorem 24.10 to a concrete case, and to know how to compute *before* the measurement what will appear in the spectrum. *Estimated time:* 50 minutes. *Type:* numerical and computational. *Level:* intermediate. An accelerometer on a gearbox produces a signal with significant components at 250, 1 200 and 3 000 Hz, plus a disturbance at 9 500 Hz and a resonance at 12 000 Hz. The converter operates at $\nu_c = 8\,000$ Hz.

- (a) Which components satisfy the condition of Theorem 24.8? What is the Nyquist frequency?
- (b) Compute, with Definition 24.11, the alias frequency of each of the two out-of-band components. In which zone of the measured spectrum will they appear, and with what risk of being mistaken for real phenomena?
- (c) Verify with a script that the samples of $\cos(2\pi \cdot 9\,500 t)$ at $\nu_c = 8\,000$ Hz coincide with those of the sinusoid at the alias frequency computed in (b), reporting the maximum gap over at least 200 samples; repeat with a nonzero initial phase and verify the sign of ε in Theorem 24.10.
- (d) Design the countermeasure: which sampling frequency would you choose, and which anti-aliasing filter? Apply the four points of the Good practice of Section 24.10 and justify each choice with a number.
- (e) Assuming the two out-of-band components have been eliminated, write explicitly the reconstruction formula of Theorem 24.9 for $\nu_c = 8\,000$ Hz and evaluate its first nonzero term at $t = 1/16\,000$ s.

24.14. Worked exercises

Exercise 24.5: Two tones through an RC : the waveform changes. *Type:* symbolic and numerical computation with cross-check. Consider the RC filter with $\tau = 1$ ms and the input

$$x(t) = \cos(\omega_1 t) + \cos(\omega_2 t), \quad \omega_1 = \frac{1}{\tau} = 1\,000, \quad \omega_2 = \frac{3}{\tau} = 3\,000 \text{ rad/s}.$$

Compute the output, show that it is not of the form $Ax(t - t_0)$ for any pair (A, t_0) , and quantify the distortion.

Solution. Strategy. The input is a *finite* sum of sinusoids: by Corollary 24.1 and by linearity it suffices to treat them one at a time, without ever computing a convolution integral. No distortion, by Corollary 24.3, requires the two tones to come out with the same gain *and* with the same delay: one checks that neither condition holds.

Step 1 — the two values of the frequency response. From the closed form $H(\omega) = 1/(1 + i\omega\tau)$ of Example 24.4, with $\omega_1\tau = 1$ and $\omega_2\tau = 3$:

$$H(\omega_1) = \frac{1}{1 + i} = \frac{1 - i}{2}, \quad H(\omega_2) = \frac{1}{1 + 3i} = \frac{1 - 3i}{10},$$

having rationalised with the conjugate: $\frac{1}{1+i} = \frac{1-i}{(1+i)(1-i)} = \frac{1-i}{2}$ and $\frac{1}{1+3i} = \frac{1-3i}{1+9} = \frac{1-3i}{10}$. Hence

$$|H(\omega_1)| = \frac{\sqrt{2}}{2} = \frac{1}{\sqrt{2}} = 0.707\,106\,781\,2, \quad |H(\omega_2)| = \frac{\sqrt{1+9}}{10} = \frac{1}{\sqrt{10}} = 0.316\,227\,766\,0,$$

$$\phi_1 = -\arctan 1 = -\frac{\pi}{4} = -0.785\,398\,163\,4 \text{ rad} = -45^\circ, \quad \phi_2 = -\arctan 3 = -1.249\,045\,772\,4 \text{ rad} = -71.565^\circ$$

Step 2 — the output. By Corollary 24.1 applied to each term and by linearity (Proposition 24.2),

$$y(t) = 0.707\,106\,781\,2 \cos(1\,000t - 0.785\,398\,163\,4) + 0.316\,227\,766\,0 \cos(3\,000t - 1.249\,045\,772\,4).$$

Step 3 — the two phase delays do not coincide. For y to be $Ax(t - t_0)$ one would need $\phi_j = -\omega_j t_0$ with the *same* t_0 for $j = 1, 2$, i.e. $\tau_p(\omega_1) = \tau_p(\omega_2)$. Instead

$$\tau_p(\omega_1) = \frac{0.785\,398\,163\,4}{1\,000} = 0.785\,398\,163\,4 \text{ ms}, \quad \tau_p(\omega_2) = \frac{1.249\,045\,772\,4}{3\,000} = 0.416\,348\,590\,8 \text{ ms},$$

whose ratio equals 1.886 395 632 8: the first tone comes out delayed by almost twice the second. This alone excludes the form $Ax(t - t_0)$.

Step 4 — nor do the gains coincide. The ratio of the two gains is $|H(\omega_1)|/|H(\omega_2)| = \sqrt{10}/\sqrt{2} = \sqrt{5} = 2.236\,067\,977\,5$: the high tone comes out attenuated more than twice as much as the low one. So the first of the two conditions of Corollary 24.3 also fails.

Independent check 1: the two group delays. From the closed formula $\tau_g(\omega) = \tau/(1 + \omega^2\tau^2)$: $\tau_g(\omega_1) = \tau/2 = 0.5 \text{ ms}$ and $\tau_g(\omega_2) = \tau/10 = 0.1 \text{ ms}$, in an exact ratio of 5. The computation by centred differences with step 10^{-6} gives 0.499 999 985 9 ms and 0.100 000 008 3 ms, with gaps $1.41 \cdot 10^{-11}$ and $8.27 \cdot 10^{-12}$ ms. ✓

Independent check 2: the quadrature. Computing $H(\omega_1)$ and $H(\omega_2)$ by Simpson's quadrature of the integral $\int_0^{60\tau} h(t)e^{-i\omega t} dt$ with $6 \cdot 10^5$ subintervals gives $0.5 - 0.5i$ and $0.1 - 0.3i$ with gaps $2.14 \cdot 10^{-13}$ and $1.36 \cdot 10^{-14}$ from the closed values $\frac{1-i}{2}$ and $\frac{1-3i}{10}$. ✓

Interpretation. The filter does not “delay the signal”: it delays *each component by a different time* and changes their proportions. The result is a new waveform, not a shifted copy. If the tone at 3 000 rad/s were the diagnostically interesting part (for instance a defect harmonic), it would come out attenuated by a factor of $\sqrt{5}$ relative to the low tone: its relative amplitude would be reduced by $1 - 1/\sqrt{5} = 0.552\,786\,4$, i.e. by over 55%.

Typical errors. (1) Adding the magnitudes instead of treating the components separately: the gain is not a single number, it is a function of ω . (2) Confusing τ_p and τ_g : here $\tau_p(\omega_2) = 0.416 \text{ ms}$ and $\tau_g(\omega_2) = 0.100 \text{ ms}$, a factor-of-4 difference. (3) Concluding “there is no distortion because the frequency does not change”: Corollary 24.1 guarantees that frequencies *never* change in an LTI system; it is precisely for this reason that distortion, when present, concerns relative amplitudes and phases.

Extension. Repeat with the moving average of window $T_0 = 2 \text{ ms}$ (Example 24.5) and verify that the two phase delays coincide — both $T_0/2 = 1 \text{ ms}$ — while the gains do not: the residual distortion is only in amplitude, and can be corrected with an equaliser, while phase distortion cannot.

Exercise 24.6: The input that saturates the gain. *Type:* proof-based with numerical check. Let $h = \mathbf{1}_{[0,1]} - \mathbf{1}_{[1,2]}$. Compute $\|h\|_1$ and $\sup_\omega |H(\omega)|$, construct the critical input of Step 2 of the proof of Theorem 24.4 and verify that it actually attains the gain, while no sinusoid reaches it.

Solution. Strategy. Theorem 24.4 says the gain is $\|h\|_1$; Theorem 24.6(iv) says the maximum of $|H|$ can be strictly smaller. Here both numbers are computed and compared.

Step 1 — the L^1 norm. $|h| = \mathbf{1}_{[0,2]}$, hence $\|h\|_1 = \int_0^2 1 dt = 2$. By Theorem 24.4 the system is BIBO stable with gain exactly 2.

Step 2 — the frequency response. For $\omega \neq 0$,

$$H(\omega) = \int_0^1 e^{-i\omega t} dt - \int_1^2 e^{-i\omega t} dt = \frac{1 - e^{-i\omega}}{i\omega} - \frac{e^{-i\omega} - e^{-2i\omega}}{i\omega} = \frac{1 - 2e^{-i\omega} + e^{-2i\omega}}{i\omega} = \frac{(1 - e^{-i\omega})^2}{i\omega},$$

recognising the square of a binomial. The modulus is

$$|H(\omega)| = \frac{|1 - e^{-i\omega}|^2}{|\omega|} = \frac{2 - 2\cos\omega}{|\omega|} = \frac{4\sin^2(\omega/2)}{|\omega|},$$

and $H(0) = \int_0^1 1 dt - \int_1^2 1 dt = 0$.

Step 3 — the maximum of $|H|$. Setting the derivative of $4\sin^2(\omega/2)/\omega$ to zero for $\omega > 0$ gives $2\sin(\omega/2)\cos(\omega/2)\omega = 2\sin^2(\omega/2)$, i.e. $\omega\sin\omega = 2\sin^2(\omega/2) = 1 - \cos\omega$, which with $\sin\omega = 2\sin(\omega/2)\cos(\omega/2)$ and $1 - \cos\omega = 2\sin^2(\omega/2)$ reduces to $\tan(\omega/2) = \omega$. The smallest positive root, found numerically, is $\omega^* = 2.331\,122\,3$, where $|H| = 1.449\,222\,707\,6$. ✓ (Two independent computations agree: an exhaustive search with step 10^{-6} on $(0, 40)$ and a refining ternary search; and the check $\tan(\omega^*/2) = 2.331\,122\,3$ of the stationarity condition.) Hence

$$\sup_{\omega} |H(\omega)| = 1.449\,222\,707\,6 < 2 = \|h\|_1.$$

Step 4 — the critical input. Since h is real, Step 2 of the proof of Theorem 24.4 gives, for $N \geq 2$, $x_N(t) = \operatorname{sgn}(h(-t))$ on $[-N, N]$. Now $h(-t) \neq 0$ if and only if $-t \in [0, 2]$, i.e. $t \in [-2, 0]$; and it equals $+1$ for $t \in [-1, 0]$, -1 for $t \in [-2, -1]$. Hence

$$x_N = \mathbf{1}_{[-1,0]} - \mathbf{1}_{[-2,-1]} \quad (N \geq 2),$$

a square wave of amplitude 1 and duration 2.

Step 5 — the output at time 0. One has $x_N(-\tau) = +1$ for $\tau \in [0, 1]$ and -1 for $\tau \in [1, 2]$, hence

$$y(0) = \int_{\mathbb{R}} h(\tau)x_N(-\tau) d\tau = \int_0^1 (+1)(+1) d\tau + \int_1^2 (-1)(-1) d\tau = 1 + 1 = 2 = \|h\|_1. \quad \checkmark$$

The critical input therefore attains the gain *exactly* — here without even needing to pass to the limit, because h has compact support.

Independent check. $|H(1)| = 0.919\,395\,388\,3$ and $|H(4)| = 0.826\,821\,810\,4$, both well below 1.449 and even further below 2: the sinusoidal exploration never finds the value 2. ✓

Interpretation. This is Remark 24.8 put into numbers: the gain of a system (the worst amplification factor over all bounded inputs) is $\|h\|_1 = 2$, while the peak of the frequency response (the worst factor over sinusoidal inputs alone) is 1.449. The ratio $2/1.449\,222\,708 = 1.380$ is, literally, what a test with pure tones alone would not see: a margin of 38%.

Typical errors. (1) Believing that the gain is $\max |H|$: this is true only for systems with $h \geq 0$, such as the RC filter and the moving average, where $\max |H| = H(0) = \int h = \|h\|_1$. (2) Forgetting that x_N is defined with h *time-reversed*: using $\operatorname{sgn}(h(t))$ instead of $\operatorname{sgn}(h(-t))$ gives, in this example, $y(0) = \int_0^1 (+1)(-1) + \int_1^2 (-1)(+1) = -2$, i.e. the right value in magnitude but with the wrong sign — and in non-symmetric examples the wrong value.

Extension. Redo the computation with $h = \mathbf{1}_{[0,1]} + \mathbf{1}_{[1,2]} = \mathbf{1}_{[0,2]}$, where $h \geq 0$: here $\|h\|_1 = 2$, $H(0) = 2$ and $\max |H| = 2$, the two numbers coincide, and the critical input is the constant 1.

Exercise 24.7: Two components, a single alias. *Type:* numerical with sample-by-sample check. A signal $x(t) = 2 \cos(2\pi \cdot 200 t) + \cos(2\pi \cdot 900 t + 0.5)$ is sampled at $\nu_c = 1\,000$ Hz. Determine what signal is “seen” by someone who has only the samples, and verify the identity of the samples.

Solution. Strategy. Apply Definition 24.11 to each component and then Theorem 24.10, which also gives the sign of the phase.

Step 1 — the Nyquist frequency. $\nu_c/2 = 500$ Hz. The component at 200 Hz lies below it, the one at 900 Hz does not: the latter will be the one that aliases.

Step 2 — the first component. $\nu_0 = 200$, $\nu_0/\nu_c = 0.2$, the closest integer is $k = 0$, hence $\mu = 200 - 0 = 200$ and $\nu_a = 200$ Hz, with $\varepsilon = \text{sgn}(200) = +1$: the component is transferred intact, phase included. This is the case $\nu_0 \leq \nu_c/2$ of Definition 24.11.

Step 3 — the second component. $\nu_0 = 900$, $\nu_0/\nu_c = 0.9$, the closest integer is $k = 1$, hence

$$\mu = 900 - 1 \cdot 1\,000 = -100, \quad \nu_a = |-100| = 100 \text{ Hz}, \quad \varepsilon = \text{sgn}(-100) = -1.$$

By Theorem 24.10 the samples of $\cos(2\pi \cdot 900 t + 0.5)$ coincide with those of $\cos(2\pi \cdot 100 t - 0.5)$: frequency 100 Hz and phase *sign reversed*.

Step 4 — the apparent signal. Someone with only the samples measures

$$\tilde{x}(t) = 2 \cos(2\pi \cdot 200 t) + \cos(2\pi \cdot 100 t - 0.5) :$$

two components at 200 and 100 Hz, both *below* Nyquist, both perfectly plausible. Nothing in the data signals that the second is an artifact.

Independent check (Python script executed). Over 121 samples, from $n = -60$ to $n = 60$, the maximum gap between $x(nT)$ and $\tilde{x}(nT)$ equals $4.75 \cdot 10^{-14}$: the two sequences coincide within machine error. ✓

Interpretation. The error is not “small”, it is *invisible*: the two sequences do not differ at all. This is the fundamental difference between a measurement error — which can be estimated and reduced — and aliasing, which irreversibly destroys information even before the data exist. The operational consequence is in the Good practice of Section 24.10: the defence is analog and must be placed *before* the converter.

Typical errors. (1) Computing $\nu_a = \nu_c - \nu_0$ without the absolute value and without choosing the closest integer: for $\nu_0 = 1\,300$ and $\nu_c = 1\,000$ this would give -300 instead of 300. (2) Forgetting the sign change of the phase when $\varepsilon = -1$: the reconstruction would come out shifted in time. (3) Hoping that a digital filter, applied afterward, could separate the two components: by Theorem 24.10 they have the same samples, and no function of the samples can distinguish them.

Extension. Add a third component at 1 000 Hz and verify that its alias frequency is 0: in the samples it appears as a constant, i.e. as a drift of the mean value.

24.15. Self-assessment quiz

1. (Definition) A system $\mathcal{T}$ is *time-invariant* if
 - A) $\mathcal{T}(\alpha x) = \alpha \mathcal{T}x$ for every scalar α
 - B) $\mathcal{T}(\sigma_a x) = \sigma_a(\mathcal{T}x)$ for every x and every $a \in \mathbb{R}$
 - C) $\mathcal{T}x$ does not depend on t
 - D) the output to a periodic input is periodic of the same period
2. (Hypothesis) In Theorem 24.1 hypothesis (S3), i.e. $\|\mathcal{T}x\|_\infty \leq C\|x\|_1$, serves to

-
- A) guarantee that the system is causal B) make the functional $x \mapsto (\mathcal{T}x)(0)$ bounded on L^1 , so that Riesz's theorem gives its representative $g \in L^\infty$ C) ensure that $\mathcal{T}x$ is continuous D) make h belong to L^1
3. (Symbolic computation) For an LTI system with impulse response $h \in L^1(\mathbb{R})$ and frequency response $H = \hat{h}$, the output to the input $e^{i\omega_0 t}$ is
- A) $\hat{h}(t) e^{i\omega_0 t}$ B) $H(\omega_0) e^{i\omega_0 t}$ C) $(h * e^{i\omega_0 \cdot})(\omega_0)$, a number D) $|H(\omega_0)| e^{i\omega_0 t}$
4. (Numerical computation) For the RC filter with $\tau = 1$ ms, the group delay at angular frequency $\omega = 3/\tau$ equals
- A) 0.5 ms B) 0.416 348 6 ms C) 0.1 ms D) 1 ms
5. (Proof step) In the proof of Theorem 24.4, the signal $x_N(t) = \overline{h(-t)}/|h(-t)|$ of Step 2 serves to
- A) make h integrable B) eliminate every cancellation in the convolution integral at $t = 0$, so that the output equals $\int_{-N}^N |h|$ C) verify that the system is causal D) prove that $\sup_\omega |H(\omega)| = \|h\|_1$
6. (Error diagnosis) A test measures the gain of an LTI system by injecting unit-amplitude sinusoids at many frequencies and recording the maximum of the output. Which statement is correct?
- A) the test measures exactly the BIBO gain, because every bounded signal is a sum of sinusoids B) the test measures $\sup_\omega |H(\omega)|$, which can be strictly less than the BIBO gain $\|h\|_1$ C) the test overestimates the BIBO gain D) the test is equivalent to measuring $\|h\|_2$
7. (Transfer) A signal with components at 250, 1 200, 3 000 and 9 500 Hz is sampled at 8 000 Hz. In the spectrum computed from the samples the component at 9 500 Hz appears at
- A) 9 500 Hz B) 4 000 Hz C) 1 500 Hz D) it does not appear, because it is beyond Nyquist
8. (Source and metacognition) The article in which the sampling theorem is stated and proved in the form used here, with its exact location, is

24.16. Teacher's key

BEST PRACTICE

Quiz — answers, rationales and diagnosis (items 1–4).

1) **B.** *Rationale:* this is condition (TI) of Definition 24.2: the system commutes with translations. *Distractors:* A is homogeneity, i.e. half of linearity (L), not invariance; C confuses “the system does not change over time” with “the output is constant”; D is a true *consequence* for stable LTI systems, not the definition — and it also holds for non-LTI systems, for instance the squarer of Example 24.1(e), which sends T -periodic signals to T -periodic signals despite not being linear. *Diagnosed error:* confusing an observable

property with the definition that implies it. *Source*: Oppenheim and Willsky, entry [3] of the *Sources* environment. *Prerequisite*: Definition 24.2. *Remediation*: redo the counterexample of Example 24.1(f) with $a = \pi/(2\omega_0)$ instead of $a = \pi/\omega_0$.

2) B. Rationale: Step 1 of the proof uses (S3) precisely to conclude $|\Lambda(x)| \leq C\|x\|_1$, i.e. $\Lambda \in (L^1)^*$; without it Step 2 (Riesz) does not apply. *Distractors*: A is false, causality is independent and has its own theorem (Theorem 24.5); C is guaranteed by the hypothesis that $\mathcal{T}$ takes values in C_b , not by (S3); D is the wrong conclusion — the theorem produces $h \in L^\infty$, not $h \in L^1$, and indeed the ideal integrator of Example 24.2(d) has $h = u \in L^\infty \setminus L^1$. *Diagnosed error*: not knowing at which step a given hypothesis is needed. *Source*: Theorem 24.1 and Remark 24.3. *Prerequisite*: duality $(L^1)^* = L^\infty$. *Remediation*: rewrite Step 1 without (S3) and identify where the reasoning breaks down.

3) B. Rationale: this is Theorem 24.2: the exponential is an eigenfunction and the eigenvalue is $H(\omega_0) = \hat{h}(\omega_0)$, a complex number that multiplies the exponential. *Distractors*: A swaps the variable of the transform with time; C confuses the output (a function of t) with its value at a point; D throws away the phase, which is half of the information — and it is precisely the half that generates the delays of Section 24.7. *Diagnosed error*: treating the frequency response as a real gain. *Source*: Oppenheim and Willsky, entry [3] of the *Sources* environment; here Theorem 24.2. *Prerequisite*: Definition 19.1. *Remediation*: redo Step 2 of the proof by writing out $e^{i\omega(t-\tau)} = e^{i\omega t}e^{-i\omega\tau}$ explicitly.

4) C. Rationale: $\tau_g(\omega) = \tau/(1 + \omega^2\tau^2)$ (Example 24.6); with $\omega\tau = 3$ one has $\tau_g = \tau/10 = 0.1$ ms. *Distractors*: A is τ_g at $\omega = 1/\tau$, i.e. $\tau/2$; B is the *phase delay* at $\omega = 3/\tau$, $\arctan(3)/3000 = 0.416\,348\,6$ ms, and is the most insidious distractor because it is a correct number from the table, but from the other column; D is τ , i.e. τ_g at $\omega = 0$. *Diagnosed error*: confusing τ_p and τ_g , or reading the wrong row. *Source*: Definition 24.9 and the check by centred differences. *Prerequisite*: derivative of $\arctan$. *Remediation*: recompute all four columns of the table of Example 24.6 for $\omega\tau = 0.5$ (answers: $0.894\,427\,2$; $-26.565\,051^\circ$; $0.927\,295\,2$ ms; 0.8 ms).

BEST PRACTICE

Quiz — answers, rationales and diagnosis (items 5–8).

5) B. Rationale: choosing $x_N(-\tau) = \overline{h(\tau)}/|h(\tau)|$ gives $h(\tau)x_N(-\tau) = |h(\tau)| \geq 0$ for every τ : all contributions are aligned and the integral equals $\int_{-N}^N |h|$, as in Step 3. *Distractors*: A reverses cause and effect — the integrability of h is the *conclusion*, not a hypothesis; C confuses two distinct theorems, even though the construction of Theorem 24.5 is analogous; D is false, and Theorem 24.6(iv) shows that the two numbers can differ (in Worked exercise 24.6 they equal 1.449 and 2). *Diagnosed error*: not recognising the role of an ad hoc construction inside a proof. *Source*: Theorem 24.4, Steps 2–3; the discrete analogue is Theorem 21.10. *Prerequisite*: $z\bar{z} = |z|^2$. *Remediation*: carry out Steps 4–5 of Worked exercise 24.6 on $h = \mathbf{1}_{[0,1]} - \mathbf{1}_{[1,2]}$.

6) B. Rationale: a sinusoidal test explores $\sup_\omega |H(\omega)|$, which by Theorem 24.6(iv) is $\leq \|h\|_1$, with strict inequality in general; the BIBO gain is $\|h\|_1$ (Theorem 24.4). *Distractors*: A contains a widespread error: a bounded signal is *not* in general a sum of sinusoids with summable coefficients, and in any case the critical input of Step 2 is not one, being a square wave with infinitely many harmonics; C gets the direction of the inequality wrong; D confuses the L^2 norm of the impulse response (which governs energy, not amplitude) with the L^1 norm. *Diagnosed error*: identifying the worst case with the worst case *among those tested*. *Source*: Remark 24.8 and Worked exercise 24.6. *Prerequisite*: Theorem 24.4. *Remediation*: compute $\|h\|_1$ and $\max |H|$ for $h = \mathbf{1}_{[0,1]} - \mathbf{1}_{[1,2]}$ and compare (2 against $1.449\,222\,707\,6$).

7) C. Rationale: by Definition 24.11, $\nu_0/\nu_c = 9\,500/8\,000 = 1.1875$, the closest integer is

$k = 1$, hence $\nu_a = |9\,500 - 8\,000| = 1\,500$ Hz. *Distractors*: A ignores aliasing; B is the alias of the component at 12 000 Hz ($k = 2$, $|12\,000 - 16\,000| = 4\,000$ Hz), i.e. the right answer to the other question; D is the central conceptual error of Section 24.10 — the component does not disappear, it disguises itself. *Diagnosed error*: believing that sampling “cuts off” whatever is above Nyquist. *Source*: Theorem 24.10 and the sample-by-sample check of Example 24.8. *Prerequisite*: Definition 24.11. *Remediation*: redo the four cases of Exercise 24.4(b) and check them with the script of point (c).

8) B. *Rationale*: this is Shannon’s 1949 article, verified against the Crossref record of the DOI 10.1109/JRPROC.1949.232969: *Proceedings of the IRE*, volume 37, issue 1, pages 10–21. *Distractors*: A is Nyquist’s 1928 article, which studies the maximum signalling speed over a telegraph line and from which the name “Nyquist frequency” comes, but does not contain the reconstruction formula; C is Gabor’s article, the source of the *analytic signal* of Section 24.11 and not of sampling; D is a historical-mathematical survey article from 1985, valuable for the history of the cardinal series but not a primary source. *Diagnosed error*: attributing a result from memory to the name that appears in its label. *Source*: entries [1], [2], [5] and [7] of this chapter’s *Sources* environment. *Prerequisite*: none. *Remediation*: check the four references against a bibliographic archive and note, for each, what it contains and what it does not.

BEST PRACTICE

Assigned exercises — answers.

Exercise 24.2 ($\tau = 5$ ms). (a) $h(t) = \frac{1}{\tau}e^{-t/\tau}u(t)$; $\|h\|_1 = \frac{1}{\tau} \int_0^{+\infty} e^{-t/\tau} dt = 1$, hence $h \in L^1(\mathbb{R})$ and by Theorem 24.4 the system is BIBO stable with gain 1. It is causal because $h(t) = 0$ for $t < 0$ (Theorem 24.5). (b) $H(\omega) = 1/(1 + i\omega\tau)$, $|H| = (1 + \omega^2\tau^2)^{-1/2}$, $\phi = -\arctan(\omega\tau)$. The -3 dB frequency is $\nu_{3\text{dB}} = \frac{1}{2\pi\tau} = 31.830\,988\,6$ Hz, i.e. $\omega = 1/\tau = 200$ rad/s, where $|H| = 1/\sqrt{2} = 0.707\,106\,781\,2$ and $\phi = -45^\circ$. (c) $\tau_g(0) = \tau = 5$ ms; at $\omega = 1/\tau = 200$: $\tau_p = \frac{\pi}{4}\tau = 3.926\,990\,817$ ms and $\tau_g = \tau/2 = 2.5$ ms; at $\omega = 3/\tau = 600$: $\tau_p = \arctan(3)/600 = 2.081\,742\,954$ ms and $\tau_g = \tau/10 = 0.5$ ms. The delay of the envelope is τ_g , because Theorem 24.7 ties the shift of the waveform to the slope of the phase, not to its quotient. (d) No, on no non-degenerate band: $\tau_g(\omega) = \tau/(1 + \omega^2\tau^2)$ is strictly decreasing for $\omega > 0$, hence it is not constant on any interval, and the second condition of Corollary 24.3 always fails. (e) The typical gaps are $\sim 10^{-13}$ for H (Simpson with $6 \cdot 10^5$ subintervals on $[0, 60\tau]$) and $\sim 10^{-11}$ ms for τ_g (centred differences with step 10^{-6}).

Exercise 24.3 ($T_0 = 10$ ms). (a) $H(\omega) = e^{-i\omega T_0/2} \text{sinc}(\omega T_0/(2\pi))$; the zeros are at $\nu = k/T_0$, i.e. 100, 200, 300 Hz. (b) Where $\sin(\omega T_0/2) > 0$ the second factor is real and positive, so the phase is that of the exponential alone: $\phi(\omega) = -\omega T_0/2$, and $\tau_g = -\phi' = T_0/2 = 5$ ms, constant. (c) The *first* condition fails: the gain is not constant. Indeed $|H| = 0.900\,316\,316$ at 25 Hz, 0.636 619 772 at 50 Hz, 0 at 100 Hz and 0.212 206 591 at 150 Hz — and at 100 Hz the component is cancelled completely, which is the most radical distortion possible. (Note also that above 100 Hz the second factor becomes negative and the phase jumps by π : the phase remains piecewise linear, not linear over the whole band.) (d) $\text{sinc}(\nu T_0) = 0.9$ at $\nu \approx 25$ Hz: indeed at 25 Hz the gain equals 0.900 316 3, just above 0.9. Within $\nu_{\max} \approx 25$ Hz the gain varies by less than 10% and the phase is exactly linear, so the no-distortion approximation is reasonable. (e) With $\tau = T_0/2 = 5$ ms the RC has $\tau_g(0) = 5$ ms, equal to that of the moving average; but τ_g collapses immediately (2.5 ms already at $\omega = 1/\tau$), whereas that of the moving average stays 5 ms at all frequencies. The moving average costs more in-band attenuation but does not introduce phase dispersion.

Exercise 24.4 ($\nu_c = 8\,000$ Hz). (a) The Nyquist frequency is 4 000 Hz; the components at 250, 1 200 and 3 000 Hz satisfy the condition. (b) For 9 500 Hz: $9\,500/8\,000 = 1.1875$, $k = 1$, $\nu_a = |9\,500 - 8\,000| = 1\,500$ Hz. For 12 000 Hz: $12\,000/8\,000 = 1.5$, $k = 2$ (or

$k = 1$: the result does not change), $\nu_a = |12\,000 - 16\,000| = 4\,000$ Hz. The first alias falls at 1 500 Hz, i.e. between the useful components at 1 200 and 3 000 Hz: it is indistinguishable from a real gearbox harmonic. The second falls exactly on the Nyquist frequency. (c) The maximum gap is of order 10^{-13} ; with initial phase $\varphi_0 \neq 0$ the alias has phase $+\varphi_0$ because $\varepsilon = \text{sgn}(9\,500 - 8\,000) = +1$. (d) With the highest component at 12 000 Hz the theorem alone would require $\nu_c \geq 24\,000$ Hz; applying the factor of 5–10 of the Good practice to the *useful* band of 3 000 Hz one instead chooses $\nu_c = 20\,000$ – $30\,000$ Hz *with* an analog anti-aliasing filter that attenuates by at least 72 dB at $\nu_c/2$ (12-bit A/D): at that point the components at 9 500 and 12 000 Hz are suppressed before conversion. (e) With $T = 1/8\,000$ s the formula is $x(t) = \sum_n x(nT) \text{sinc}(8\,000t - n)$; at $t = 1/16\,000 = T/2$ the term $n = 0$ equals $x(0) \text{sinc}(1/2) = x(0) \cdot \frac{\sin(\pi/2)}{\pi/2} = x(0) \cdot \frac{2}{\pi} = 0.636\,619\,772\,4 x(0)$.

24.17. Chapter formulary

LTI systems and convolution. $(\sigma_a x)(t) = x(t - a)$; (L) linearity, (TI) $\mathcal{T}\sigma_a = \sigma_a \mathcal{T}$.

$$(h * x)(t) = \int_{\mathbb{R}} h(\tau)x(t - \tau) d\tau = \int_{\mathbb{R}} h(t - u)x(u) du = (x * h)(t),$$

$$\|h * x\|_{\infty} \leq \|h\|_1 \|x\|_{\infty} \quad (h \in L^1, x \in L^{\infty}), \quad \|h * x\|_{\infty} \leq \|h\|_{\infty} \|x\|_1 \quad (h \in L^{\infty}, x \in L^1).$$

Representation: $\mathcal{T} : L^1 \rightarrow C_b$ linear, TI and with $\|\mathcal{T}x\|_{\infty} \leq C\|x\|_1 \implies \mathcal{T}x = h * x$ with $h \in L^{\infty}$, $\|h\|_{\infty} \leq C$, unique a.e.

Eigenfunctions and frequency response. $H(\omega) = \hat{h}(\omega)$, $\hat{h}(\Omega) = \sum_k h[k]e^{-i\Omega k}$ in the discrete case.

$$\mathcal{T}_h e^{i\omega t} = H(\omega) e^{i\omega t}, \quad \mathcal{T}_h e^{i\Omega n} = \hat{h}(\Omega) e^{i\Omega n}.$$

$$A \cos(\omega_0 t + \varphi_0) \mapsto A |H(\omega_0)| \cos(\omega_0 t + \varphi_0 + \arg H(\omega_0)) \quad (h \text{ real}).$$

$|H(\omega)| \leq \|h\|_1$; H uniformly continuous; $H(-\omega) = \overline{H(\omega)}$ for h real; $|H(\omega)| \rightarrow 0$ as $|\omega| \rightarrow \infty$; $|H|_{\text{dB}} = 20 \log_{10} |H|$.

Stability and causality.

BIBO $\iff h \in L^1(\mathbb{R})$, gain $= \|h\|_1$ (critical input $x_N = \overline{h(-t)}/|h(-t)|$ on $[-N, N]$);

$$\text{causal} \iff h = 0 \text{ a.e. on } (-\infty, 0) \implies y(t) = \int_0^{+\infty} h(\tau)x(t - \tau) d\tau.$$

In the discrete case: BIBO $\iff h \in \ell^1(\mathbb{Z})$; for a causal rational system, poles inside the unit circle.

Delays and no distortion. With $H = |H|e^{i\phi}$:

$$\tau_p(\omega) = -\frac{\phi(\omega)}{\omega}, \quad \tau_g(\omega) = -\frac{d\phi}{d\omega}(\omega).$$

No distortion on $[-\Omega, \Omega]$ $\iff |H| \equiv A$ and $\tau_g \equiv t_0 \iff H(\omega) = Ae^{-i\omega t_0} \implies y(t) = Ax(t - t_0)$. Pure delay: $H(\omega) = e^{-i\omega t_0}$, $\tau_p = \tau_g = t_0$.

The two reference filters. *RC* filter, $h(t) = \frac{1}{\tau}e^{-t/\tau}u(t)$:

$$H(\omega) = \frac{1}{1 + i\omega\tau}, \quad |H| = \frac{1}{\sqrt{1 + \omega^2\tau^2}}, \quad \phi = -\arctan(\omega\tau), \quad \tau_p = \frac{\arctan(\omega\tau)}{\omega}, \quad \tau_g = \frac{\tau}{1 + \omega^2\tau^2}.$$

At $\omega = 1/\tau$: $|H| = 1/\sqrt{2}$, $-3.010\,299\,957$ dB, $\phi = -45^\circ$, $\tau_p = \frac{\pi}{4}\tau$, $\tau_g = \tau/2$; $\nu_{3\text{dB}} = 1/(2\pi\tau)$.
Moving average, $h = \frac{1}{T_0}\mathbf{1}_{[0, T_0]}$:

$$H(\omega) = e^{-i\omega T_0/2} \text{sinc}\left(\frac{\omega T_0}{2\pi}\right), \quad \text{zeros at } \nu = \frac{k}{T_0}, \quad k \neq 0, \quad \tau_g \equiv \frac{T_0}{2}.$$

Both have $\|h\|_1 = 1$: BIBO stable with gain 1, causal.

Sampling, reconstruction, aliasing. T step, $\omega_c = 2\pi/T$, $\nu_c = 1/T$, $\Omega = \pi/T$; Nyquist frequency $\nu_c/2$.

$$\hat{x}_s(\omega) = \frac{1}{T} \sum_{k \in \mathbb{Z}} \hat{x}_c(\omega - k\omega_c); \quad \omega_c \geq 2\omega_{\max} \implies x(t) = \sum_{n \in \mathbb{Z}} x(nT) \text{sinc}\left(\frac{t - nT}{T}\right),$$

with $\text{sinc}(v) = \sin(\pi v)/(\pi v)$, $\text{sinc}(0) = 1$, $\text{sinc}(m) = 0$ for $m \in \mathbb{Z} \setminus \{0\}$. Aliasing: $\nu_a = |\nu_0 - k\nu_c|$ with k the integer closest to ν_0/ν_c ; $\varepsilon = \text{sgn}(\nu_0 - k\nu_c)$ and $\cos(2\pi\nu_0 t + \varphi_0)$ has the same samples as $\cos(2\pi\nu_a t + \varepsilon\varphi_0)$. Examples: $\nu_c = 1000$: $1\,300 \rightarrow 300$, $700 \rightarrow 300$, $2\,000 \rightarrow 0$; $\nu_c = 50$: $60 \rightarrow 10$; $\nu_c = 8\,000$: $9\,500 \rightarrow 1\,500$, $12\,000 \rightarrow 4\,000$.

Hilbert and analytic signal. On $L^2(\mathbb{R})$:

$$\widehat{\mathcal{H}x}(\omega) = -i \text{sgn}(\omega) \hat{x}(\omega), \quad \|\mathcal{H}x\|_2 = \|x\|_2, \quad \mathcal{H}^2 = -\text{id};$$

$$x_a = x + i\mathcal{H}x, \quad \hat{x}_a(\omega) = (1 + \text{sgn} \omega) \hat{x}(\omega) = \begin{cases} 2\hat{x}(\omega), & \omega > 0 \\ 0, & \omega < 0 \end{cases}$$

$$\mathcal{H}[\cos \omega_0 t] = \sin \omega_0 t, \quad \mathcal{H}[\sin \omega_0 t] = -\cos \omega_0 t, \quad (\cos \omega_0 \cdot)_a = e^{i\omega_0 t}.$$

Envelope $A(t) = |x_a(t)| \geq |x(t)|$; instantaneous phase $\psi = \arg x_a$; instantaneous frequency $\psi'/(2\pi)$.

A survey article on the cardinal series $\sum_n x(nT) \operatorname{sinc}((t - nT)/T)$, i.e. on the object of Theorem 24.9. It is cited as a bibliographic reference for the historical context and for variants of the statement, and not as the basis of any step of the proof, which is carried out here in full. *Verified on 7 September 2026* (Crossref record of the DOI: author, title, journal, volume, issue, year and pages).

The circle in control and transmission lines

In Chapter 3 we proved that Möbius transformations send circles and lines to circles and lines (Theorem, Volume II, Chapter 3), and in particular that $w = (z - 1)/(z + 1)$ sends the unit circle onto the imaginary axis (Corollary, Volume II, Chapter 3). In Chapter 4 we saw that the unit circle is the stability boundary of discrete-time systems (Theorem 21.12), and in Chapter 6 that the locus of a one-parameter admittance is a circle (Theorem, Volume II, Chapter 5).

This chapter gathers those three threads and shows they are one thread. The Nyquist criterion counts how many times a curve winds around a point; stability margins are read off the intersection with the unit circle; the constant-magnitude and constant-phase loci of the closed loop are circles; the root locus of a notable class of systems is a circle; and the Smith chart — the most used graphical tool in the history of microwave engineering — is literally the Möbius map of Chapter 3, drawn on paper.

INFO

The idea in one line. In feedback, the question “is the system stable?” becomes “how many times does a certain curve wind around the point -1 ?”; and “how far are we from instability?” becomes “how far is that curve from the unit circle?”. The circle is not an illustration: it is the object on which the answer is read.

Warning. Conventions of the chapter.

- **Laplace variable** $s = \sigma + i\omega$; **Z variable** z , as in Chapter 4. The half-plane $\text{Re } s > 0$ is called the *right half-plane* (RHP).
- **Unity negative feedback:** given the loop gain $L(s)$, the closed-loop transfer function is $T(s) = \frac{L(s)}{1 + L(s)}$.
- **Decibels:** $|H|_{\text{dB}} = 20 \log_{10} |H|$ for amplitude ratios.
- **Phase** in degrees on plots, in radians in computations.
- **Transmission lines:** characteristic impedance $Z_0 > 0$ real (lossless line), phase constant $\beta = 2\pi/\lambda$.

INFO

Prerequisites. Chapter 3 (complex numbers, Möbius maps, residues and the residue theorem); Chapter 4 (Laplace and Z transforms, BIBO stability); Chapter 6 (impedances, reflection coefficient of Exercise S1). Notions of linear system and feedback are recalled where needed.

25.1. Frequency response and transfer function

Definition 25.1: Transfer function and frequency response. For a causal linear time-invariant (LTI) system with impulse response h , the **transfer function** is $H(s) = \mathcal{L}\{h\}(s)$, and the **frequency response** is its restriction to the imaginary axis, $\omega \mapsto H(i\omega)$. The **Nyquist plot** is the image of the imaginary axis, i.e. the curve $\{H(i\omega) : \omega \in \mathbb{R}\} \subset \mathbb{C}$; the **Bode plots** are the two graphs $\omega \mapsto 20 \log_{10} |H(i\omega)|$ and $\omega \mapsto \arg H(i\omega)$ on a logarithmic frequency axis.

Theorem 25.1: Steady-state harmonic response. Let a causal LTI system have $h \in L^1(0, \infty)$ (hence BIBO stable, by the continuous-time version of Theorem 21.12). Then:

- (i) the input $u(t) = e^{i\omega t}$, defined for $t \in \mathbb{R}$, produces the output $y(t) = H(i\omega) e^{i\omega t}$, with $H(i\omega) = \int_0^\infty h(\tau) e^{-i\omega\tau} d\tau$;
- (ii) the real input $u(t) = A \cos(\omega t + \phi)$ produces $y(t) = A |H(i\omega)| \cos(\omega t + \phi + \arg H(i\omega))$;
- (iii) if the input is applied from $t = 0$ onwards, the output differs from that of (ii) by a transient tending to zero, provided all poles of H have negative real part.

Proof. (i) By the convolution representation of causal LTI systems,

$$y(t) = \int_0^\infty h(\tau) u(t - \tau) d\tau = e^{i\omega t} \int_0^\infty h(\tau) e^{-i\omega\tau} d\tau,$$

where pulling $e^{i\omega t}$ out is legitimate because it does not depend on τ , and the integral converges absolutely because $|h(\tau) e^{-i\omega\tau}| = |h(\tau)|$ with $h \in L^1$. The remaining integral is exactly $H(i\omega)$, the Laplace transform evaluated at $s = i\omega$ (Chapter 4).

(ii) By Exercise S3 of Chapter 6, $A \cos(\omega t + \phi) = \frac{1}{2} A e^{i\phi} e^{i\omega t} + \frac{1}{2} A e^{-i\phi} e^{-i\omega t}$. Applying (i) to each term and using linearity,

$$y(t) = \frac{1}{2} A e^{i\phi} H(i\omega) e^{i\omega t} + \frac{1}{2} A e^{-i\phi} H(-i\omega) e^{-i\omega t}.$$

Since h is real, $H(-i\omega) = \overline{H(i\omega)}$ (conjugate the definition of H), so the two terms are conjugate and their sum is $2 \operatorname{Re}$ of the first:

$$y(t) = A |H(i\omega)| \cos(\omega t + \phi + \arg H(i\omega)).$$

(iii) With the input applied from $t = 0$, the output is $y(t) = \int_0^t h(\tau) u(t - \tau) d\tau$, differing from (i) by $-\int_t^\infty h(\tau) u(t - \tau) d\tau$. Since $|u| \leq A$,

$$\left| \int_t^\infty h(\tau) u(t - \tau) d\tau \right| \leq A \int_t^\infty |h(\tau)| d\tau \xrightarrow{t \rightarrow \infty} 0,$$

being the tail of a convergent integral. If moreover all poles have negative real part, h is a combination of terms $t^k e^{-\alpha t}$ with $\alpha > 0$ and the convergence is exponential. $\square$

Remark 25.1: Why the frequency response is an image of the imaginary axis.

Theorem 25.1 says that $H(i\omega)$ is an eigenvalue: complex exponentials are eigenfunctions of every LTI system, and $H(i\omega)$ is the eigenvalue attached to $e^{i\omega t}$. This is the same property that in Chapter 4 made the characters e_n the right functions to diagonalise convolution (Observation, Volume II, Chapter 4): the Nyquist plot is nothing but the image of the imaginary axis — where the characters live — under the map H . In the discrete-time z -plane the locus of characters is the unit circle (Theorem, Volume II, Chapter 4), which is why there the frequency response is read on $\mathbb{T}$ and not on a line.

25.2. Bode plots

Theorem 25.2: Logarithmic additivity. If $H = H_1 H_2 \cdots H_m$, then for every ω with $H_k(i\omega) \neq 0$:

$$20 \log_{10} |H(i\omega)| = \sum_{k=1}^m 20 \log_{10} |H_k(i\omega)|, \quad \arg H(i\omega) = \sum_{k=1}^m \arg H_k(i\omega) \pmod{2\pi}.$$

Proof. By Theorem (Volume II, Chapter 3)(iii) the modulus is multiplicative, $|H| = \prod_k |H_k|$; applying $20 \log_{10}$ and the logarithm-of-a-product rule gives the first formula. For arguments, Theorem (Volume II, Chapter 3) gives $\arg(H_1 H_2) = \arg H_1 + \arg H_2$ as an equality of sets of values, i.e. modulo 2π ; induction on m concludes. $\square$

Remark 25.2: Why decibels and why a logarithmic frequency axis. Theorem 25.2 is the whole *raison d'être* of Bode plots: on a logarithmic scale the plot of a product is the sum of the plots, so it can be drawn by hand by superposing a few elementary bricks. The logarithmic abscissa serves the same purpose: it turns the slopes $\omega^{\pm k}$ into straight lines, as the next theorem shows.

Theorem 25.3: Asymptotic slopes of the elementary factors. Let $\omega_p > 0$. Then, with $\log_{10} \omega$ on the abscissa and decibels on the ordinate:

- (i) the factor s^n ($n \in \mathbb{Z}$) gives a straight line of slope $20n$ dB/decade and constant phase $n \cdot 90^\circ$;
- (ii) the factor $(1 + s/\omega_p)^{-1}$ (simple pole) has asymptotic magnitude 0 dB for $\omega \ll \omega_p$ and slope -20 dB/decade for $\omega \gg \omega_p$, with maximum error 3.01 dB at $\omega = \omega_p$; the phase goes from 0° to -90° , being exactly -45° at ω_p ;
- (iii) the factor $(1 + s/\omega_z)$ (simple zero) gives the same plots with the sign reversed.

Proof. (i) $|(i\omega)^n| = \omega^n$, so $20 \log_{10} \omega^n = 20n \log_{10} \omega$: with $x = \log_{10} \omega$ this is the line $y = 20nx$, of slope $20n$ dB per unit of x , i.e. per decade. The argument is $\arg(i^n) = n\pi/2$, constant.

(ii) Setting $u = \omega/\omega_p$,

$$\left| (1 + iu)^{-1} \right| = \frac{1}{\sqrt{1 + u^2}}, \quad \arg (1 + iu)^{-1} = -\arctan u.$$

For $u \ll 1$, $\sqrt{1 + u^2} \rightarrow 1$ and the magnitude in dB tends to 0; for $u \gg 1$, $\sqrt{1 + u^2} \sim u$ and $20 \log_{10}(1/u) = -20 \log_{10} u$, a line of slope -20 dB/decade. The two asymptotes meet at $u = 1$, i.e. $\omega = \omega_p$: the *break frequency*. The maximum gap between curve and asymptotes occurs exactly there, where the true value is $-20 \log_{10} \sqrt{2} = -3.0103$ dB against 0 dB for the asymptote. (That $u = 1$ is the point of maximum gap follows since the difference $-10 \log_{10}(1 + u^2) + 20 \log_{10} \max(1, u)$ is even in $\log u$ and has vanishing derivative only at $u = 1$.) Finally $\arctan 0 = 0$, $\arctan 1 = \pi/4$ and $\arctan u \rightarrow \pi/2$.

(iii) Since $(1 + s/\omega_z) = [(1 + s/\omega_z)^{-1}]^{-1}$, by Theorem 25.2 magnitude in dB and phase change sign. $\square$

Example 25.1: Bode plot of a second-order system. Sketch the asymptotic plots of

$$H(s) = \frac{100}{(s + 1)(s + 10)}.$$

Step 1 — normalised form. Factoring the constants out of the binomials:

$$H(s) = \frac{100}{1 \cdot 10} \cdot \frac{1}{(1+s)(1+s/10)} = \frac{10}{(1+s)(1+s/10)}.$$

The static gain is $H(0) = 10$, i.e. 20 dB.

Step 2 — elementary bricks. By Theorem 25.2 the plot is the sum of three contributions: the constant 10 (+20 dB, phase 0), the pole at $\omega_1 = 1$ and the pole at $\omega_2 = 10$.

Step 3 — asymptotic magnitude.

- $\omega < 1$: 20 dB, slope 0;
- $1 < \omega < 10$: slope -20 dB/dec; at $\omega = 10$ the asymptote equals $20 - 20 \log_{10} 10 = 0$ dB;
- $\omega > 10$: slope -40 dB/dec.

Step 4 — exact check values.

$$|H(i1)| = \frac{100}{\sqrt{2} \cdot \sqrt{101}} = \frac{100}{1.41421 \times 10.04988} = \frac{100}{14.21267} = 7.0359,$$

i.e. $20 \log_{10} 7.0359 = 16.947$ dB, against 20 dB for the asymptote: a gap of 3.05 dB, consistent with Theorem 25.3(ii) plus the small contribution of the second pole.

$$|H(i10)| = \frac{100}{\sqrt{101} \cdot \sqrt{200}} = \frac{100}{10.04988 \times 14.14214} = \frac{100}{142.127} = 0.70359,$$

i.e. -3.053 dB against 0 dB for the asymptote. ✓

Step 5 — phase.

$$\arg H(i\omega) = -\arctan \omega - \arctan \frac{\omega}{10}.$$

At $\omega = 1$: $-45^\circ - 5.71^\circ = -50.71^\circ$. At $\omega = \sqrt{10} = 3.162$ (geometric mean of the two poles): $-72.45^\circ - 17.55^\circ = -90.00^\circ$, exactly -90° by symmetry. At $\omega = 10$: $-84.29^\circ - 45^\circ = -129.29^\circ$. As $\omega \rightarrow \infty$: -180° .

Typical error. Reading the static gain straight off the numerator (100, i.e. 40 dB) without normalising the binomials. The form $\frac{100}{(s+1)(s+10)}$ has static gain $100/10 = 10$: the factor 10 in the denominator must be taken out.

Remark 25.3: Bode's gain-phase relation. In Example 25.1 the phase “follows” the slope of the magnitude: where the magnitude falls at 20 dB/dec the phase settles near -90° , where it falls at 40 dB/dec near -180° . This is no accident. Bode proved in 1945 that for minimum-phase systems (no poles or zeros in the right half-plane) the magnitude determines the phase, through the integral relation

$$\arg H(i\omega_0) = \frac{1}{\pi} \int_{-\infty}^{+\infty} \frac{d(\ln |H|)}{du} \ln \coth \frac{|u|}{2} du, \quad u = \ln \frac{\omega}{\omega_0}.$$

The kernel $\ln \coth(|u|/2)$ is strongly concentrated near $u = 0$, which explains the rule of thumb: the phase at ω_0 is determined mainly by the local slope of the magnitude, and a slope of $-20n$ dB/dec corresponds to roughly $-n \cdot 90^\circ$. Proving the integral relation requires the theory of analytic functions in a half-plane and the Hilbert relations, and goes beyond the level of this treatise: see Bode (1945), Chapter 14, cited in the bibliography. Below we use it only qualitatively, and never as a premise of a proof.

25.3. The argument principle and the Nyquist criterion

Figure 25.1: Bode magnitude plot of $G(s) = 1/(1 + s/\omega_c)$. Dashed in red are the two asymptotes (0 dB and -20 dB/decade) meeting at the corner frequency ω_c ; in blue the exact magnitude. The largest gap between curve and asymptotes occurs exactly at $\omega = \omega_c$ and equals $-20 \log_{10} \sqrt{2} = -3.01$ dB: this is why ω_c is also called the -3 dB frequency.

The Nyquist criterion is, in substance, a theorem of complex analysis applied to engineering: the *argument principle*, which counts the zeros and poles of a function inside a contour by looking at how many times the image of the contour winds around the origin. We prove it, because it is the logical heart of the whole chapter.

Theorem 25.4: Argument principle. Let F be meromorphic on an open set containing a simple closed contour γ and its interior, with no zeros or poles on γ . Writing Z and P for the sums of the multiplicities of the zeros and poles inside γ ,

$$\frac{1}{2\pi i} \oint_{\gamma} \frac{F'(s)}{F(s)} ds = Z - P,$$

and the left-hand side is the **winding number** of the image curve $F \circ \gamma$ around the origin, counted with sign according to the direction of travel.

Proof. Step 1 — local structure of F'/F . Let s_0 be a zero of F of multiplicity $m \geq 1$: then $F(s) = (s - s_0)^m g(s)$ with g holomorphic and $g(s_0) \neq 0$ nearby. Differentiating,

$$F'(s) = m(s - s_0)^{m-1} g(s) + (s - s_0)^m g'(s),$$

hence

$$\frac{F'(s)}{F(s)} = \frac{m}{s - s_0} + \frac{g'(s)}{g(s)},$$

where the second term is holomorphic near s_0 (because $g(s_0) \neq 0$). So F'/F has a simple pole at s_0 with residue m . If instead s_0 is a pole of F of order p , write $F(s) = (s - s_0)^{-p} g(s)$ and the same computation gives residue $-p$.

Step 2 — residue theorem. The function F'/F is holomorphic on γ and inside it except at the zeros and poles of F , which are finitely many (otherwise they would accumulate, contradicting holomorphy). By Theorem 15.5 of Chapter 3,

$$\frac{1}{2\pi i} \oint_{\gamma} \frac{F'}{F} ds = \sum_{\text{zeros}} m_k - \sum_{\text{poles}} p_j = Z - P.$$

Step 3 — interpretation as winding number. Parametrise γ by $s = \gamma(t)$, $t \in [0, 1]$, and set $w(t) = F(\gamma(t))$. Then

$$\oint_{\gamma} \frac{F'(s)}{F(s)} ds = \int_0^1 \frac{w'(t)}{w(t)} dt.$$

Since w never vanishes (no zeros on γ), the function $\Phi(t) = \int_0^t w'/w$ satisfies $\frac{d}{dt}(w(t)e^{-\Phi(t)}) = 0$, hence $w(t) = w(0)e^{\Phi(t)}$. Since $w(1) = w(0)$, we get $e^{\Phi(1)} = 1$, i.e. $\Phi(1) \in 2\pi i\mathbb{Z}$; and $\Phi(1)/(2\pi i)$ is by definition the winding number of w about the origin, since $\text{Im } \Phi$ is the continuous variation of the argument of w . $\square$

Theorem 25.5: Nyquist criterion. Let $L(s)$ be rational and proper, with no poles of L nor zeros of $1 + L$ on the imaginary axis, and let P be the number of poles of L in the right half-plane. Traverse the Nyquist contour γ_R — the imaginary axis from $-iR$ to $+iR$ followed by the right semicircle of radius R — clockwise, with R large enough, and let N be the number of times the curve $L(\gamma_R)$ winds around the point -1 , counted clockwise. Then the number Z of closed-loop poles in the right half-plane is

$$Z = N + P.$$

In particular the closed loop is stable if and only if $N = -P$, i.e. if and only if the Nyquist plot makes P counterclockwise encirclements of -1 .

Proof. Step 1 — the right function. The closed-loop poles are the zeros of $F(s) := 1 + L(s)$: indeed $T = L/(1 + L)$ has as poles the zeros of the denominator. On the other hand the poles of F coincide with those of L , since F and L differ by the constant 1.

Step 2 — applying the argument principle. Apply Theorem 25.4 to F on the contour γ_R , which for large R encloses all zeros and poles of F in the right half-plane (being F rational, they are finitely many and bounded). Since γ_R is traversed *clockwise*, i.e. opposite to the standard orientation, the winding number of $F(\gamma_R)$ about the origin, counted clockwise, equals $Z - P$.

Step 3 — translation. $F(\gamma_R) = 1 + L(\gamma_R)$: the curve $F(\gamma_R)$ is $L(\gamma_R)$ translated by $+1$. The encirclements of $F(\gamma_R)$ about 0 are therefore exactly those of $L(\gamma_R)$ about -1 , i.e. N . Equating, $N = Z - P$, hence $Z = N + P$.

Step 4 — the arc at infinity is irrelevant. Since L is proper, $L(s) \rightarrow L_{\infty}$ finite as $|s| \rightarrow \infty$ (with $L_{\infty} = 0$ if strictly proper): the image of the semicircle tends to a point and contributes no encirclements for large R . The Nyquist plot thus reduces to the image of the imaginary axis alone, closed through the point at infinity.

Step 5 — stability criterion. The closed loop is stable iff it has no RHP poles, i.e. $Z = 0$, i.e. $N = -P$: P counterclockwise encirclements. $\square$

Corollary 25.1: Open-loop stable case. If L has no RHP poles ($P = 0$), the closed loop is stable if and only if the Nyquist plot does not encircle the point -1 .

Proof. Immediate from Theorem 25.5 with $P = 0$: the condition $N = -P$ becomes $N = 0$. $\square$

Remark 25.4: Why the point -1 . The critical point is -1 and not something else because the feedback is negative and unity: the loop closes on $1 + L = 0$, i.e. $L = -1$. Physically, $L(i\omega) = -1$ means that a signal travelling round the loop returns to its starting point with the same amplitude ($|L| = 1$) and in antiphase ($\arg L = -180^\circ$): added to the input with the minus sign of the feedback, it reinforces it exactly. This is the condition for sustained oscillation, i.e. the boundary between stability and instability.

Definition 25.2: Stability margins. Let L have $P = 0$ and a Nyquist plot not encircling -1 .

- The **gain crossover frequency** ω_g is the one with $|L(i\omega_g)| = 1$, i.e. the intersection of the plot with the *unit circle*; the **phase margin** is

$$\text{PM} = 180^\circ + \arg L(i\omega_g).$$

- The **phase crossover frequency** ω_π is the one with $\arg L(i\omega_\pi) = -180^\circ$, i.e. the intersection with the negative real axis; the **gain margin** is

$$\text{GM} = \frac{1}{|L(i\omega_\pi)|}.$$

Theorem 25.6: Geometric meaning of the margins. With the previous notation:

- (i) GM is the factor by which the loop gain may be multiplied before the plot touches -1 ;
- (ii) PM is the angle by which the plot may be rotated clockwise before it touches -1 ;
equivalently, it is the angle $(-1)\widehat{OL}(i\omega_g)$ read on the unit circle;
- (iii) the maximum tolerable pure delay before instability is $\tau_{\max} = \text{PM} [\text{rad}] / \omega_g$.

Proof. (i) Multiplying L by $k > 0$ dilates the plot by k without rotating it (Theorem (Volume II, Chapter 3) of Chapter 3 with $\alpha = k$ real positive). The point $L(i\omega_\pi)$, lying on the negative real axis at distance $|L(i\omega_\pi)|$ from the origin, reaches -1 when $k|L(i\omega_\pi)| = 1$, i.e. $k = \text{GM}$.

(ii) Multiplying L by $e^{-i\theta}$ rotates the plot by $-\theta$ (Corollary, Volume II, Chapter 3) without changing moduli: in particular ω_g remains the point on the unit circle. That point has argument $\arg L(i\omega_g)$; it reaches -1 , of argument 180° , after a clockwise rotation of $\arg L(i\omega_g) - (-180^\circ) = \text{PM}$.

(iii) A pure delay τ has transfer function $e^{-s\tau}$, of modulus $|e^{-i\omega\tau}| = 1$ and argument $-\omega\tau$: it *does not change the magnitude* and subtracts $\omega\tau$ from the phase. At ω_g , where the magnitude is 1, the phase becomes $\arg L(i\omega_g) - \omega_g\tau$; the system reaches the critical point when this equals -180° , i.e. when $\omega_g\tau = \text{PM}$ in radians. $\square$

Example 25.2: Margins of a third-order loop. Let

$$L(s) = \frac{K}{s(s+1)(s+2)}, \quad K > 0.$$

Step 1 — phase crossover.

$$\arg L(i\omega) = -90^\circ - \arctan \omega - \arctan \frac{\omega}{2} = -180^\circ$$

requires $\arctan \omega + \arctan(\omega/2) = 90^\circ$, i.e. the two angles are complementary, i.e.

$$\omega = \frac{2}{\omega} \implies \omega_\pi = \sqrt{2}.$$

Step 2 — magnitude at ω_π .

$$|L(i\sqrt{2})| = \frac{K}{\sqrt{2} \cdot \sqrt{3} \cdot \sqrt{6}} = \frac{K}{6}.$$

Step 3 — critical gain and gain margin. The plot touches -1 when $K/6 = 1$, i.e. $K_{\text{crit}} = 6$: for $K > 6$ the closed loop is unstable. For $K = 3$,

$$\text{GM} = \frac{1}{3/6} = 2 = 6.02 \text{ dB}.$$

Step 4 — phase margin for $K = 3$. We seek ω_g with $|L| = 1$:

$$\omega \sqrt{1 + \omega^2} \sqrt{4 + \omega^2} = 3.$$

At $\omega = 0.95$ the left side is 2.9013; at $\omega = 0.97$ it is 3.0037. Interpolating, $\omega_g = 0.969$ rad/s. Then

$$\arg L(i\omega_g) = -90^\circ - \arctan(0.969) - \arctan(0.4845) = -90^\circ - 44.10^\circ - 25.85^\circ = -159.95^\circ,$$

so

$$\text{PM} = 180^\circ - 159.95^\circ = 20.05^\circ.$$

Step 5 — tolerable delay. By Theorem 25.6(iii),

$$\tau_{\max} = \frac{20.05^\circ \times \pi/180}{0.969} = \frac{0.34996}{0.969} = 0.361 \text{ s}.$$

A delay of just 361 ms in the feedback path — for instance the cycle time of a PLC sampling too slowly — suffices to destabilise this loop.

Step 6 — independent check of the critical gain. The characteristic polynomial is $s^3 + 3s^2 + 2s + K$. By the Routh–Hurwitz criterion for third order, stability requires $K > 0$ and $3 \cdot 2 > K$, i.e. $K < 6$. ✓The critical value matches the graphical one.

Typical error. Judging a large gain margin sufficient while ignoring the phase margin. Here GM = 6 dB looks reassuring, but PM = 20° is low: the step response will be strongly oscillatory. The two margins must be read *together*, since they measure the distance from -1 along two different directions.

Figure 25.2: Nyquist plot of $L(s) = 1/(1+s)^3$ (the $\omega < 0$ branch is the conjugate of the $\omega > 0$ one). The curve does not encircle -1 : since L has no right half-plane poles, the Nyquist criterion gives $N = P = 0$ and the closed loop is stable. The negative real axis is crossed at $\omega = \sqrt{3}$, where $|L| = 1/8$: the gain margin is $m_G = 8$ (18.06 dB).

25.4. The M and N circles

The Nyquist plot shows the loop gain L ; but what matters is the *closed-loop* behaviour, i.e. $T = L/(1+L)$. The link between the two is a Möbius transformation, and by Theorem (Volume II, Chapter 3) of Chapter 3 the curves of constant $|T|$ and constant $\arg T$ in the L -plane can only be circles. This section computes them.

Theorem 25.7: Constant-magnitude circles (M circles). Let $T = L/(1 + L)$ and $M > 0$. In the complex plane of the variable $L = x + iy$, the locus $\{|T| = M\}$ is:

(i) for $M \neq 1$, the circle of centre and radius

$$c_M = -\frac{M^2}{M^2 - 1}, \quad r_M = \frac{M}{|M^2 - 1|},$$

both real (the centre lies on the real axis);

(ii) for $M = 1$, the vertical line $x = -\frac{1}{2}$.

Moreover the circles with $M > 1$ lie to the left of the line $x = -\frac{1}{2}$ and contain -1 ; those with $M < 1$ lie to the right and contain the origin.

Proof. Step 1 — translating the condition. $|T| = M$ is equivalent to $|L| = M|1 + L|$, i.e. upon squaring,

$$x^2 + y^2 = M^2[(1 + x)^2 + y^2].$$

Step 2 — rearranging. Expanding and collecting,

$$(1 - M^2)(x^2 + y^2) - 2M^2x - M^2 = 0. \quad (*)$$

Step 3 — case $M = 1$. The coefficient of $x^2 + y^2$ vanishes and $(*)$ becomes $-2x - 1 = 0$, i.e. $x = -\frac{1}{2}$: a vertical line.

Step 4 — case $M \neq 1$. Dividing by $1 - M^2 \neq 0$ and completing the square in x :

$$\left(x - \frac{M^2}{1 - M^2}\right)^2 + y^2 = \frac{M^4 + M^2(1 - M^2)}{(1 - M^2)^2} = \frac{M^2}{(1 - M^2)^2}.$$

Hence the centre is $M^2/(1 - M^2) = -M^2/(M^2 - 1)$ and the radius is $M/|1 - M^2|$, as claimed.

Step 5 — relative position. For $M > 1$ we have $M^2 - 1 > 0$, hence $c_M < 0$; and

$$c_M + r_M = \frac{-M^2 + M}{M^2 - 1} = -\frac{M}{M + 1} < -\frac{1}{2}$$

for $M > 1$: the whole circle lies left of $-\frac{1}{2}$. Moreover

$$c_M - r_M = -\frac{M}{M - 1} < -1 < -\frac{M}{M + 1} = c_M + r_M,$$

so -1 lies between the endpoints of the horizontal diameter: it is *inside* the circle. For $M < 1$ the signs reverse and an identical computation shows the circle contains the origin.

Remark on structure. The result was predictable without computation: the map $L \mapsto T = L/(1 + L)$ is a Möbius transformation (Definition (Volume II, Chapter 3) with $a = 1$, $b = 0$, $c = 1$, $d = 1$, determinant $1 \neq 0$), and the loci $|T| = M$ are circles in the T -plane; by Theorem (Volume II, Chapter 3) their preimages are circles or lines in the L -plane, and lines exactly when they pass through the pole of the inverse map. The computation only serves to locate centre and radius. $\square$

Theorem 25.8: Constant-phase circles (N circles). Let $T = L/(1 + L)$ and $\alpha \in (-\pi, \pi]$ with $\alpha \neq 0$, and set $N = \tan \alpha$. In the $L = x + iy$ plane, the locus $\{\arg T = \alpha\}$ is contained in the circle

$$\left(x + \frac{1}{2}\right)^2 + \left(y - \frac{1}{2N}\right)^2 = \frac{1}{4} + \frac{1}{4N^2},$$

of centre $(-\frac{1}{2}, \frac{1}{2N})$ and radius $\frac{1}{2}\sqrt{1+1/N^2}$. All these circles pass through the origin and through the point -1 .

Proof. Step 1 — expressing the phase. With $L = x + iy$, $\arg T = \arg L - \arg(1 + L)$ by Theorem (Volume II, Chapter 3). Taking tangents and using the subtraction formula,

$$N = \frac{\frac{y}{x} - \frac{y}{1+x}}{1 + \frac{y}{x} \cdot \frac{y}{1+x}} = \frac{y(1+x) - yx}{x(1+x) + y^2} = \frac{y}{x^2 + x + y^2},$$

the terms yx cancelling in the numerator.

Step 2 — equation of the locus. $N(x^2 + x + y^2) = y$ rewrites as $x^2 + x + y^2 - y/N = 0$, and completing both squares,

$$\left(x + \frac{1}{2}\right)^2 + \left(y - \frac{1}{2N}\right)^2 = \frac{1}{4} + \frac{1}{4N^2}.$$

Step 3 — the two common points. Substituting $(x, y) = (0, 0)$ into $x^2 + x + y^2 - y/N = 0$ gives $0 = 0$: the origin lies on every N circle. Substituting $(x, y) = (-1, 0)$: $1 - 1 = 0$: so does -1 . ✓

Step 4 — why “contained in” and not “equal to”. The equation obtained expresses $\tan(\arg T) = N$, which does not distinguish α from $\alpha + \pi$. Each circle therefore contains the points of phase α and those of phase $\alpha - \pi$: the locus of phase exactly α is one of the two arcs into which the points 0 and -1 divide the circle. □

Remark 25.5: What they were really for. Superposing the grid of M and N circles on the Nyquist plot lets one read, point by point, the magnitude and phase of the closed-loop response without computing it: the resonant peak M_r is the value of the smallest M circle tangent to the plot, and the corresponding frequency is that of the tangency point. Before computers this construction — known as the Hall chart — was the standard way to design a control loop; its close relative, the Nichols chart, is the same family of circles redrawn in (phase, gain in dB) coordinates. Today the computation is instant, but the geometric content remains: the distance of the plot from -1 controls the resonant peak, which is why margins are good indicators of damping.

25.5. The modulus margin and the sensitivity circle

Gain and phase margins measure the distance from the critical point -1 along two particular directions: the first along the real axis, the second along the unit circle. But a Nyquist plot may have both margins excellent and still pass very close to -1 in an oblique direction. The remedy is to measure the distance from -1 *in all directions at once*, that is to consider the largest circle centred at -1 that the plot does not touch. This is the *modulus margin*, and it is the criterion on which modern controller tuning, PID included, is based.

Definition 25.3: Sensitivity function and sensitivity peak. Given the loop gain $L(s)$, the *sensitivity function* is

$$S(s) = \frac{1}{1 + L(s)}$$

and the *sensitivity peak* is the number $M_s = \|S\|_\infty = \sup_{\omega \in \mathbb{R}} |S(j\omega)|$. The *modulus margin* is $m = 1/M_s$.

Figure 25.3: The family of M -circles: loci of points L in the complex plane where the closed-loop magnitude $|L/(1+L)|$ equals M . For $M \neq 1$ these are circles with centre $(-M^2/(M^2-1), 0)$ and radius $M/|M^2-1|$; for $M = 1$ the circle degenerates into the line $\Re L = -1/2$, the perpendicular bisector of the segment from the origin to -1 . Circles with $M > 1$ encircle the critical point -1 and shrink onto it as M grows: the resonant peak of the closed loop is read off as the smallest M whose circle touches the Nyquist plot.

Theorem 25.9: The modulus margin is a distance. Let $\Gamma = \{L(j\omega) : \omega \in \mathbb{R}\}$ be the Nyquist plot. Then

$$m = \frac{1}{M_s} = \min_{\omega \in \mathbb{R}} |1 + L(j\omega)| = \text{dist}(-1, \Gamma)$$

that is, m is the radius of the largest circle centred at -1 that does not meet the Nyquist plot. The locus $\{L : |1 + L| = m\}$ is that circle, and is called the sensitivity circle.

Proof. **Step 1 — from sup to min.** By definition

$$M_s = \sup_{\omega} \frac{1}{|1 + L(j\omega)|} = \frac{1}{\inf_{\omega} |1 + L(j\omega)|},$$

since $t \mapsto 1/t$ is decreasing on the positive reals and $|1 + L| > 0$ for every ω (if it vanished, the closed loop would have a pole on the imaginary axis). Hence $m = 1/M_s = \inf_{\omega} |1 + L(j\omega)|$, and the infimum is a minimum because $L(j\omega) \rightarrow L(\infty)$ as $\omega \rightarrow \pm\infty$ and the continuous function $\omega \mapsto |1 + L(j\omega)|$ attains its minimum on the compactification.

Step 2 — geometric reading. In the complex plane $|1 + L| = |L - (-1)|$ is the Euclidean distance between the point L and the point -1 . Hence $\min_{\omega} |1 + L(j\omega)|$ is the smallest distance between -1 and the points of the plot, that is $\text{dist}(-1, \Gamma)$.

Step 3 — the circle. The set $\{L \in \mathbb{C} : |L + 1| = m\}$ is by definition the circle of centre -1 and radius m . By Step 2 no point of Γ lies strictly inside that circle, and at least one point belongs to it (the one attaining the minimum): the sensitivity circle is therefore the largest circle centred at -1 disjoint from the interior of the plot, and it touches it.

Step 4 — why S . The sensitivity function is the transfer function from output disturbance to output, and also the one from reference to error. Its peak M_s is thus the largest amplification factor of disturbances: a large M_s means both “close to instability” and “amplifies disturbances”. The theorem says that the two are *the same thing*, measured by the same number.

□

Theorem 25.10: The modulus margin dominates the other two. If the Nyquist plot does not enter the sensitivity circle of radius $m < 1$, then the gain margin m_G and the phase

margin φ_m satisfy

$$m_G \geq \frac{1}{1-m} = \frac{M_s}{M_s-1}, \quad \varphi_m \geq 2 \arcsin \frac{m}{2} = 2 \arcsin \frac{1}{2M_s}$$

Proof. Step 1 — gain margin. Let ω_π be the frequency at which the plot crosses the negative real half-axis, and let $L(j\omega_\pi) = -1/m_G$ with $m_G > 1$ (this is the definition of gain margin). The distance of this point from -1 equals

$$\left| -\frac{1}{m_G} - (-1) \right| = 1 - \frac{1}{m_G},$$

positive because $m_G > 1$. Since the point belongs to Γ , by Theorem 25.9 that distance is $\geq m$:

$$1 - \frac{1}{m_G} \geq m \iff \frac{1}{m_G} \leq 1 - m \iff m_G \geq \frac{1}{1-m},$$

having used $m < 1$ in order to invert.

Step 2 — phase margin. Let ω_c be the gain crossover frequency, that is $|L(j\omega_c)| = 1$, and let φ_m be the phase margin, so that $L(j\omega_c) = e^{j(-\pi+\varphi_m)}$. The distance from $-1 = e^{j\pi}$ is computed by the chord formula:

$$|e^{j\theta} + 1| = |e^{j\theta/2}| \cdot |e^{j\theta/2} + e^{-j\theta/2}| = 2|\cos(\theta/2)|.$$

With $\theta = -\pi + \varphi_m$ one has $\cos(\theta/2) = \cos(-\frac{\pi}{2} + \frac{\varphi_m}{2}) = \sin(\frac{\varphi_m}{2})$, so the distance equals $2 \sin(\varphi_m/2)$.

Step 3 — conclusion. This point too belongs to Γ , hence

$$2 \sin \frac{\varphi_m}{2} \geq m \implies \sin \frac{\varphi_m}{2} \geq \frac{m}{2} \implies \varphi_m \geq 2 \arcsin \frac{m}{2},$$

the sine being increasing on $[0, \pi/2]$ and $\varphi_m/2 \in [0, \pi/2]$ in the cases of interest.

Step 4 — reading. A single number, m , simultaneously guarantees both classical margins. The converse is false: one may have large m_G and φ_m and small m , because the plot can approach -1 from a direction that is neither the real nor the tangential one. This is why M_s has superseded the pair (m_G, φ_m) as the single robustness indicator. $\square$

Example 25.3: The modulus margin of $L(s) = K/(1+s)^3$. **Step 1 — exact computation of $|1+L|^2$.** From $(1+j\omega)^3 = (1-3\omega^2) + j(3\omega-\omega^3)$ and $|(1+j\omega)^3|^2 = (1+\omega^2)^3$ it follows that

$$|1+L(j\omega)|^2 = 1 + \frac{2K(1-3\omega^2) + K^2}{(1+\omega^2)^3}.$$

Indeed, writing $L = K\overline{(1+j\omega)^3}/(1+\omega^2)^3$, the cross term equals $2K(1-3\omega^2)/(1+\omega^2)^3$ and the quadratic term $K^2(1+\omega^2)^3/(1+\omega^2)^6 = K^2/(1+\omega^2)^3$.

Step 2 — minimum. Setting $u = \omega^2$ and $f(u) = 1 + (2K(1-3u) + K^2)/(1+u)^3$, one has

$$f'(u) = \frac{3K(4u-4-K)}{(1+u)^4},$$

which vanishes at $u^* = 1 + K/4$ and is negative before, positive after: a minimum. Hence

$$m^2 = f(u^*) = 1 - \frac{4K + \frac{1}{2}K^2}{(2 + \frac{K}{4})^3}.$$

Step 3 — the case $K = 2$. One gets $u^* = 1.5$, that is $\omega^* = \sqrt{1.5} = 1.2247$, and

$$m^2 = 1 - \frac{8+2}{2.5^3} = 1 - \frac{10}{15.625} = 1 - 0.64 = 0.36,$$

hence $m = 0.600$ exactly and $M_s = 1/0.6 = 1.667$.

Step 4 — comparison with the classical margins. The crossing of the negative real axis occurs where $3 \arctan \omega = 180^\circ$, that is $\omega = \sqrt{3}$, where $|L| = 2/8 = 0.25$: hence $m_G = 4$. The unit-modulus crossing occurs where $(1 + \omega^2)^{3/2} = 2$, that is $\omega_c = 0.7664$, where the phase is $-3 \arctan(0.7664) = -112.36^\circ$: hence $\varphi_m = 67.6^\circ$. The estimates of Theorem 25.10 give

$$m_G \geq \frac{1}{1-0.6} = 2.5 \checkmark, \quad \varphi_m \geq 2 \arcsin(0.3) = 34.9^\circ \checkmark,$$

both verified and, as always, conservative.

Step 5 — tuning the gain. Current practice recommends $M_s \in [1.2, 2.0]$: below 1.2 the system is very sluggish, above 2.0 it is not robust. Here $M_s = 1.667$ is acceptable but close to the upper desirable limit. If one wants $M_s = 1.60$, that is $m = 0.625$, one solves Step 2 numerically for K : with $K = 1.85$ one gets $u^* = 1.4625$, $(2 + K/4)^3 = 2.4625^3 = 14.9324$, $4K + K^2/2 = 9.1113$, hence $m^2 = 1 - 0.61017 = 0.38983$ and $m = 0.6244$, that is $M_s = 1.602$. Reducing the gain by 7.5% is therefore enough.

Remark 25.6: What the three PID actions do to the sensitivity circle. A PID controller has loop gain $L(s) = K_p(1 + \frac{1}{T_i s} + T_d s)G(s)$, and each of the three actions moves the Nyquist plot in a characteristic way relative to the sensitivity circle:

- the proportional action K_p is a homothety centred at the origin: it dilates the plot without rotating it, and therefore brings it closer to -1 as K_p grows, reducing m ;
- the integral action adds -90° of phase at low frequencies and infinite gain at DC: it removes the steady-state error (because $S(0) = 0$), but rotates the initial part of the plot towards the left half-plane, that is towards -1 ;
- the derivative action adds up to $+90^\circ$ at high frequencies: it rotates the plot away from -1 precisely in the critical region, and this is why it increases the modulus margin — at the price of amplifying measurement noise, which is why in practice it is always used in the filtered form $T_d s/(1 + T_d s/N)$.

Tuning a PID therefore means choosing the three parameters so that the plot stays outside the prescribed sensitivity circle: this is the modern formulation of the problem, and it replaces the empirical rules of Ziegler and Nichols with a verifiable geometric condition. Note that the constraint is a constraint on a circle: the whole of classical control theory can be summarised by saying which circles the Nyquist plot must avoid.

Warning. The modulus margin cannot be made arbitrarily large. If L has relative degree at least 2 and no unstable poles, Bode's integral imposes $\int_0^\infty \ln |S(j\omega)| d\omega = 0$: the area where the sensitivity is smaller than 1 (on a logarithmic scale) exactly equals the area where it is larger than 1. Reducing $|S|$ at certain frequencies necessarily makes it grow at others — the so-called *waterbed effect*. Designing a controller is therefore not the minimisation of M_s , but the choice of *where* to pay the unavoidable amplification.

25.6. The circle criterion for nonlinear systems

The Nyquist criterion applies to linear systems. When the loop contains a static nonlinearity — a saturation, a dead zone, a relay — the criterion does not apply. There is however a substitute

that preserves the geometric reading, and that replaces the *point* -1 by a *circle*.

Definition 25.4: L^2 gain and sector. For a causal operator G on signals defined on $[0, \infty)$, the **gain** is

$$\|G\| = \sup \left\{ \|Gu\|_{2,T} : \|u\|_{2,T} \leq 1, T > 0 \right\},$$

where $\|\cdot\|_{2,T}$ is the L^2 norm of the truncation to $[0, T]$. A function $\varphi : \mathbb{R} \rightarrow \mathbb{R}$ with $\varphi(0) = 0$ belongs to the **sector** $[k_1, k_2]$ if

$$k_1 e^2 \leq e \varphi(e) \leq k_2 e^2 \quad \text{for every } e \in \mathbb{R}.$$

Theorem 25.11: Small-gain theorem. Let G_1, G_2 be causal operators with finite gains γ_1, γ_2 , connected in feedback:

$$e_1 = u_1 - G_2 e_2, \quad e_2 = u_2 + G_1 e_1.$$

If $\gamma_1 \gamma_2 < 1$, then for every $T > 0$

$$\|e_1\|_{2,T} \leq \frac{\|u_1\|_{2,T} + \gamma_2 \|u_2\|_{2,T}}{1 - \gamma_1 \gamma_2},$$

and similarly for e_2 : the closed loop is input-output stable.

Proof. Step 1 — cross estimates. Applying the triangle inequality to the first equation, truncated to $[0, T]$, and the definition of gain:

$$\|e_1\|_{2,T} \leq \|u_1\|_{2,T} + \gamma_2 \|e_2\|_{2,T},$$

and similarly from the second,

$$\|e_2\|_{2,T} \leq \|u_2\|_{2,T} + \gamma_1 \|e_1\|_{2,T}.$$

(Causality is what makes truncation legitimate: the value of $G_k e_k$ on $[0, T]$ depends only on e_k on $[0, T]$.)

Step 2 — substitution. Inserting the second into the first,

$$\|e_1\|_{2,T} \leq \|u_1\|_{2,T} + \gamma_2 \|u_2\|_{2,T} + \gamma_1 \gamma_2 \|e_1\|_{2,T}.$$

Step 3 — solving. Since $\|e_1\|_{2,T}$ is finite for every T (the equations are well posed on every finite interval) and $1 - \gamma_1 \gamma_2 > 0$, we may move it to the left:

$$(1 - \gamma_1 \gamma_2) \|e_1\|_{2,T} \leq \|u_1\|_{2,T} + \gamma_2 \|u_2\|_{2,T},$$

which is the claim. The bound does not depend on T : if the inputs are in $L^2(0, \infty)$, so is e_1 . $\square$

Theorem 25.12: Circle criterion. Consider the loop formed by a stable LTI system of transfer function $G(s)$ and a static nonlinearity φ in the sector $[k_1, k_2]$ with $0 < k_1 < k_2$. If the Nyquist plot of G stays outside the closed disc $D(k_1, k_2)$ whose diameter is the segment of the real axis with endpoints $-1/k_1$ and $-1/k_2$, then the closed loop is input-output stable.

Proof. Step 1 — loop transformation. Set

$$k_m = \frac{k_1 + k_2}{2}, \quad r = \frac{k_2 - k_1}{2},$$

and define $\tilde{\varphi}(e) = \varphi(e) - k_m e$. The sector condition $k_1 e^2 \leq e\varphi(e) \leq k_2 e^2$ becomes $-r e^2 \leq e\tilde{\varphi}(e) \leq r e^2$, i.e. $|\tilde{\varphi}(e)| \leq r|e|$: the operator $\tilde{\varphi}$ has gain $\leq r$. At the same time, moving the linear term $k_m e$ into the linear block, the loop becomes the feedback between

$$\tilde{G}(s) = \frac{G(s)}{1 + k_m G(s)} \quad \text{and} \quad \tilde{\varphi},$$

as one checks by rewriting the loop equations and collecting.

Step 2 — applying small gain. By Theorem 25.11, the transformed loop is stable if $\|\tilde{G}\| \cdot r < 1$. For a stable LTI system the L^2 gain equals the infinity norm of the frequency response (Parseval's identity of Chapter 4 applied to the output), so the condition is

$$|\tilde{G}(i\omega)| < \frac{1}{r} \quad \text{for every } \omega.$$

Step 3 — geometric translation. The condition rewrites as $r|G| < |1 + k_m G|$, and squaring with $G = x + iy$:

$$(r^2 - k_m^2)(x^2 + y^2) - 2k_m x - 1 < 0.$$

Now

$$r^2 - k_m^2 = \frac{(k_2 - k_1)^2 - (k_1 + k_2)^2}{4} = -k_1 k_2,$$

and since $k_1 k_2 > 0$ we may divide by $-k_1 k_2 < 0$, reversing the inequality:

$$x^2 + y^2 + \frac{k_1 + k_2}{k_1 k_2} x + \frac{1}{k_1 k_2} > 0.$$

Step 4 — completing the square.

$$\left(x + \frac{k_1 + k_2}{2k_1 k_2}\right)^2 + y^2 > \frac{(k_1 + k_2)^2 - 4k_1 k_2}{4k_1^2 k_2^2} = \frac{(k_2 - k_1)^2}{4k_1^2 k_2^2}.$$

The centre is therefore

$$-\frac{k_1 + k_2}{2k_1 k_2} = -\frac{1}{2} \left(\frac{1}{k_1} + \frac{1}{k_2} \right),$$

the midpoint between $-1/k_1$ and $-1/k_2$, and the radius is

$$\frac{k_2 - k_1}{2k_1 k_2} = \frac{1}{2} \left(\frac{1}{k_1} - \frac{1}{k_2} \right),$$

half their distance. The strict inequality says $G(i\omega)$ lies *outside* that disc, which is exactly $D(k_1, k_2)$. $\square$

Remark 25.7: How the point becomes a circle. If the nonlinearity degenerates into a constant gain k , i.e. $k_1 = k_2 = k$, the disc $D(k, k)$ shrinks to the point $-1/k$, and “stay outside the disc” becomes “do not pass through $-1/k$ ”, i.e. the Nyquist condition for the gain kG . The circle criterion is thus the exact generalisation: uncertainty about the gain, expressed as the interval $[k_1, k_2]$, translates into inflating the critical point into a disc. The wider the interval, the larger the disc, the more stringent the condition — which is entirely reasonable: whoever knows less about their plant must stay further from the edge.

25.7. The root locus

Figure 25.4: The circle criterion. Left: the nonlinearity φ lies in the sector $[\alpha, \beta]$, i.e. its graph stays confined between the lines $y = \alpha x$ and $y = \beta x$ (grey region). Right: the forbidden disc $D(\alpha, \beta)$, whose diameter is the real segment from $-1/\alpha$ to $-1/\beta$; if the Nyquist plot of the linear part G does not enter the disc (and encircles it as many times as G has unstable poles) the feedback system is absolutely stable. For $\alpha = \beta$ the disc collapses to the point $-1/\alpha$ and the Nyquist criterion is recovered.

Theorem 25.13: Magnitude and angle conditions. Let $L(s) = K \frac{N(s)}{D(s)}$ with N, D monic and $K > 0$. A point s_0 belongs to the **root locus** — i.e. is a closed-loop pole for some $K > 0$ — if and only if

$$\arg L(s_0) = \arg \frac{N(s_0)}{D(s_0)} \equiv 180^\circ \pmod{360^\circ},$$

and in that case the corresponding gain is

$$K = \frac{|D(s_0)|}{|N(s_0)|}.$$

Proof. The closed-loop poles are the zeros of $1 + L$, i.e. the solutions of $L(s) = -1$. By Theorem (Volume II, Chapter 3) two complex numbers coincide iff they have equal modulus and arguments congruent modulo 2π . Now -1 has modulus 1 and argument 180° , so $L(s_0) = -1$ is equivalent to

$$|L(s_0)| = 1, \quad \arg L(s_0) \equiv 180^\circ \pmod{360^\circ}.$$

Since $K > 0$ is real, it does not change the argument (Theorem, Volume II, Chapter 3) and the second condition involves only N/D : it is the angle condition, independent of K . Given s_0 satisfying it, the first condition determines $K = |D(s_0)|/|N(s_0)|$ uniquely, and it is positive. $\square$

Theorem 25.14: Asymptotes of the locus. With $n = \deg D$, $m = \deg N$ and $q := n - m \geq 1$, as $K \rightarrow +\infty$ exactly m branches of the locus tend to the zeros of N and q branches tend to infinity along asymptotes of directions

$$\theta_k = \frac{(2k+1)180^\circ}{q}, \quad k = 0, 1, \dots, q-1,$$

meeting at the real point (centroid)

$$\sigma_a = \frac{\sum_j p_j - \sum_i z_i}{q},$$

where p_j are the poles and z_i the zeros of L , counted with multiplicity.

Proof. Step 1 — behaviour at infinity. The characteristic equation is $D(s) + KN(s) = 0$. For $|s| \rightarrow \infty$, $D(s) \sim s^n$ and $N(s) \sim s^m$, hence $s^n + Ks^m \approx 0$, i.e. $s^q \approx -K$. The q solutions of $s^q = -K$ are, by Theorem (Volume II, Chapter 3) of Chapter 3,

$$s = K^{1/q} e^{i(180^\circ + k \cdot 360^\circ)/q}, \quad k = 0, \dots, q-1,$$

whose arguments are exactly the θ_k of the statement. The other m roots stay bounded and, dividing the characteristic equation by K and letting $K \rightarrow \infty$, satisfy $N(s) = 0$: they tend to the zeros.

Step 2 — the centroid. Write $D(s) = s^n + d_{n-1}s^{n-1} + \dots$ and $N(s) = s^m + e_{m-1}s^{m-1} + \dots$. By Vieta's formulas, $\sum_j p_j = -d_{n-1}$ and $\sum_i z_i = -e_{m-1}$.

The characteristic polynomial $D + KN$ has degree n and coefficient of s^{n-1} equal to d_{n-1} when $q \geq 2$ (then $m \leq n-2$ and KN does not contribute at that degree). For $q \geq 2$, the sum of *all* closed-loop roots equals $-d_{n-1} = \sum_j p_j$ for every K .

Step 3 — passing to the limit. For large K , m roots tend to the zeros, with sum $\rightarrow \sum_i z_i$; the remaining q behave as $\sigma_a + K^{1/q}e^{i\theta_k} + o(1)$ for a suitable real σ_a . But

$$\sum_{k=0}^{q-1} e^{i\theta_k} = 0,$$

because the θ_k are equally spaced by $360^\circ/q$ and their sum is that of the q -th roots of -1 , zero by Corollary (Volume II, Chapter 3) of Chapter 3 (after factoring out $e^{i180^\circ/q}$). Hence the sum of the q large roots tends to $q\sigma_a$. Equating the two expressions for the total sum,

$$\sum_j p_j = \sum_i z_i + q\sigma_a \implies \sigma_a = \frac{\sum_j p_j - \sum_i z_i}{q}.$$

(For $q = 1$ the single asymptote is the direction 180° and the result persists by continuity of the argument on the coefficient of s^{n-1} .) $\square$

Theorem 25.15: The circular root locus. Let

$$L(s) = K \frac{s+z}{(s+p_1)(s+p_2)}, \quad z, p_1, p_2 \in \mathbb{R} \text{ distinct},$$

with $(p_1 - z)(p_2 - z) > 0$. Then the non-real part of the root locus is contained in the circle of centre $-z$ (the zero) and radius

$$\rho = \sqrt{(p_1 - z)(p_2 - z)}.$$

Proof. Step 1 — eliminating K . The characteristic equation is

$$(s+p_1)(s+p_2) + K(s+z) = 0 \iff K = -\frac{(s+p_1)(s+p_2)}{s+z},$$

for $s \neq -z$. Since K must be real, the locus condition is

$$\operatorname{Im} \left[\frac{(s+p_1)(s+p_2)}{s+z} \right] = 0.$$

Step 2 — change of variable. Set $u = s + z$, $a = p_1 - z$, $b = p_2 - z$, so that $s + p_1 = u + a$ and $s + p_2 = u + b$, with a, b real. Then

$$\frac{(u+a)(u+b)}{u} = u + (a+b) + \frac{ab}{u}.$$

Step 3 — imaginary part. Writing $u = \xi + i\eta$ and using $\text{Im}(1/u) = -\eta/|u|^2$,

$$\text{Im} \left[u + (a+b) + \frac{ab}{u} \right] = \eta \left(1 - \frac{ab}{|u|^2} \right).$$

Step 4 — the two components of the locus. This vanishes iff $\eta = 0$ (the real part of the locus) or

$$|u|^2 = ab \iff |s+z|^2 = (p_1-z)(p_2-z),$$

i.e. s lies on the circle of centre $-z$ and radius $\rho = \sqrt{ab}$, real and positive by the hypothesis $ab > 0$. $\square$

Example 25.4: A circular root locus, with numerical check. Let

$$L(s) = K \frac{s+3}{(s+1)(s+2)}.$$

Step 1 — applying the theorem. Here $z = 3$, $p_1 = 1$, $p_2 = 2$, and $(1-3)(2-3) = 2 > 0$, so the complex locus is the circle of centre -3 and radius $\rho = \sqrt{2} = 1.41421$.

Step 2 — intersections with the real axis.

$$s = -3 \pm \sqrt{2} \implies s_1 = -1.58579, \quad s_2 = -4.41421.$$

These are the *breakaway* and *break-in* points.

Step 3 — corresponding gains. By Theorem 25.13,

$$K(s_1) = -\frac{(s_1+1)(s_1+2)}{s_1+3} = -\frac{(-0.58579)(0.41421)}{1.41421} = \frac{0.24264}{1.41421} = 0.17157,$$

$$K(s_2) = -\frac{(-3.41421)(-2.41421)}{-1.41421} = \frac{8.24264}{1.41421} = 5.82843.$$

Both positive $\checkmark$. One recognises the exact values $K_1 = 3 - 2\sqrt{2} = 0.171573$ and $K_2 = 3 + 2\sqrt{2} = 5.828427$, whose product is $9 - 8 = 1$ and whose sum is 6.

Step 4 — checking a complex point. Take $K = 1$. The characteristic equation is

$$s^2 + 4s + 5 = 0 \implies s = -2 \pm i.$$

Membership of the circle: $|(-2+i)+3| = |1+i| = \sqrt{2} = \rho \checkmark$

Step 5 — design reading. For K between 0.1716 and 5.8284 the closed-loop poles are complex conjugate and lie on the circle: is their modulus (i.e. the natural frequency) constant? No — the modulus is measured from the *origin*, not from the centre of the circle, and it varies. What stays constant is the distance from the *zero*: this is the property guaranteed by Theorem 25.15, and it makes drawing the locus immediate with ruler and compass.

25.8. Transmission lines and the reflection coefficient

Figure 25.5: Root locus of $L(s) = K(s+3)/(s(s+1))$: poles at 0 and -1 (crosses), zero at -3 (small circle). The branches leaving the real axis trace exactly a circle centred at the zero -3 with radius $\sqrt{(3-0)(3-1)} = \sqrt{6} \simeq 2.449$. In red the real-axis portions belonging to the locus: the breakaway point is $-3 + \sqrt{6} = -0.551$, the break-in point $-3 - \sqrt{6} = -5.449$. Whenever exactly one finite zero is present, the complex locus is always a circle centred at that zero.

Definition 25.5: Lossless line and reflection coefficient. On a lossless transmission line of real characteristic impedance $Z_0 > 0$ and phase constant $\beta = 2\pi/\lambda$, voltage and current in the sinusoidal steady state are written, as functions of the distance d from the load towards the generator,

$$\underline{V}(d) = V^+ e^{i\beta d} + V^- e^{-i\beta d}, \quad \underline{I}(d) = \frac{1}{Z_0} (V^+ e^{i\beta d} - V^- e^{-i\beta d}),$$

where V^+ and V^- are the amplitudes of the forward and reflected waves. The **reflection coefficient** at d is

$$\Gamma(d) = \frac{V^- e^{-i\beta d}}{V^+ e^{i\beta d}} = \Gamma_L e^{-2i\beta d}, \quad \Gamma_L := \frac{V^-}{V^+}.$$

Theorem 25.16: The reflection coefficient as a Möbius map. Let $\underline{Z}_L$ be the load impedance and $z_L = \underline{Z}_L/Z_0$ its normalised form. Then:

- (i) $\Gamma_L = \frac{\underline{Z}_L - Z_0}{\underline{Z}_L + Z_0} = \frac{z_L - 1}{z_L + 1}$, and conversely $z_L = \frac{1 + \Gamma_L}{1 - \Gamma_L}$;
- (ii) the map $z \mapsto \Gamma$ is a Möbius transformation carrying the closed half-plane $\operatorname{Re} z \geq 0$ (passive loads) into the closed disc $|\Gamma| \leq 1$, and the imaginary axis $\operatorname{Re} z = 0$ (purely reactive loads) onto the unit circle $|\Gamma| = 1$;
- (iii) $\Gamma_L = 0$ if and only if $\underline{Z}_L = Z_0$ (matching); $\Gamma_L = +1$ for an open circuit, $\Gamma_L = -1$ for a short circuit.

Proof. (i) Evaluating Definition 25.5 at $d = 0$:

$$\underline{Z}_L = \frac{\underline{V}(0)}{\underline{I}(0)} = Z_0 \frac{1 + \Gamma_L}{1 - \Gamma_L},$$

after dividing numerator and denominator by $V^+ \neq 0$. Solving for Γ_L : $\Gamma_L(\underline{Z}_L + Z_0) = \underline{Z}_L - Z_0$, whence the formula. Dividing numerator and denominator by Z_0 gives the normalised form.

(ii) This is Exercise S1 of Chapter 6, proved there directly: with $\underline{Z} = R + iX$ and $Z_0 > 0$,

$$|\underline{Z} + Z_0|^2 - |\underline{Z} - Z_0|^2 = 4RZ_0,$$

which is ≥ 0 iff $R \geq 0$, i.e. $|\Gamma| \leq 1$ iff $\text{Re } \underline{Z} \geq 0$, with simultaneous equality. In normalised form ($Z_0 = 1$) the map is exactly $w = (z - 1)/(z + 1)$ of Corollary (Volume II, Chapter 3) of Chapter 3, read the other way round.

(iii) $\Gamma_L = 0 \iff \underline{Z}_L = Z_0$ from (i). For an open circuit, $\underline{Z}_L \rightarrow \infty$ and $\Gamma_L \rightarrow 1$; for a short circuit, $\underline{Z}_L = 0$ and $\Gamma_L = -1$. $\square$

Theorem 25.17: Propagation along the line: rotation on the circle. On a lossless line:

- (i) $|\Gamma(d)| = |\Gamma_L|$ for every d : moving along the line is a rotation on the circle of radius $|\Gamma_L|$, by the angle $-2\beta d$;
- (ii) Γ is periodic in d with period $\lambda/2$;
- (iii) the input impedance at distance d is

$$\underline{Z}_{\text{in}}(d) = Z_0 \frac{\underline{Z}_L + iZ_0 \tan \beta d}{Z_0 + i\underline{Z}_L \tan \beta d};$$

(iv) (quarter-wave transformer) for $d = \lambda/4$, $\underline{Z}_{\text{in}} = Z_0^2/\underline{Z}_L$.

Proof. (i) From Definition 25.5, $\Gamma(d) = \Gamma_L e^{-2i\beta d}$, and $|e^{-2i\beta d}| = 1$ (Corollary, Volume II, Chapter 3); hence the modulus is unchanged and the argument decreases by $2\beta d$: the rotation of Theorem (Volume II, Chapter 3).

(ii) $\Gamma(d + \Delta) = \Gamma(d)$ requires $2\beta\Delta \in 2\pi\mathbb{Z}$, i.e. $\Delta \in (\lambda/2)\mathbb{Z}$: the minimal period is $\lambda/2$, not λ . This is why the Smith chart carries a “wavelengths towards generator” scale graduated from 0 to 0.5.

(iii) By Theorem 25.16(i) applied at d ,

$$\underline{Z}_{\text{in}}(d) = Z_0 \frac{1 + \Gamma_L e^{-2i\beta d}}{1 - \Gamma_L e^{-2i\beta d}}.$$

Substituting $\Gamma_L = (\underline{Z}_L - Z_0)/(\underline{Z}_L + Z_0)$ and multiplying numerator and denominator by $(\underline{Z}_L + Z_0)e^{i\beta d}$, then collecting and using the inverse Euler formulas (Theorem, Volume II, Chapter 3),

$$\text{numerator} = 2\underline{Z}_L \cos \beta d + 2iZ_0 \sin \beta d, \quad \text{denominator} = 2Z_0 \cos \beta d + 2i\underline{Z}_L \sin \beta d.$$

Dividing both by $2 \cos \beta d$ gives the stated formula.

(iv) For $d = \lambda/4$ we have $\beta d = \pi/2$ and $\tan \beta d \rightarrow \infty$. Passing to the limit in (iii), the terms with $\tan$ dominate:

$$\underline{Z}_{\text{in}} \rightarrow \frac{Z_0^2}{\underline{Z}_L}.$$

(Equivalently, from (i): Γ rotates by $-\pi$, i.e. changes sign, and by (i) of Theorem 25.16 changing the sign of Γ amounts to replacing z by $1/z$.) $\square$

Theorem 25.18: Standing wave ratio. On a lossless line, the ratio of the maximum to the minimum of the voltage magnitude along the line is

$$\text{SWR} = \frac{1 + |\Gamma_L|}{1 - |\Gamma_L|} \in [1, +\infty],$$

and it equals 1 if and only if the line is matched. Voltage maxima and minima are $\lambda/4$ apart.

Proof. Step 1 — voltage magnitude. From Definition 25.5,

$$\underline{V}(d) = V^+ e^{i\beta d} (1 + \Gamma(d)) \implies |\underline{V}(d)| = |V^+| \cdot |1 + \Gamma(d)|.$$

Step 2 — extremes of $|1 + \Gamma|$. By Theorem 25.17(i), $\Gamma(d)$ traverses the whole circle of centre the origin and radius $|\Gamma_L|$ as d varies. By the triangle inequality (Theorem (Volume II, Chapter 3)(iv),(v)),

$$1 - |\Gamma_L| \leq |1 + \Gamma(d)| \leq 1 + |\Gamma_L|,$$

with equality on the right when $\Gamma(d)$ is real positive and on the left when it is real negative. Both positions are attained because the argument of $\Gamma(d)$ takes all values.

Step 3 — ratio and spacing. The ratio of the two extremes is as stated. The two cases correspond to arguments of Γ differing by π ; since the argument is $\arg \Gamma_L - 2\beta d$, a difference of π corresponds to $2\beta \Delta d = \pi$, i.e. $\Delta d = \lambda/4$.

Step 4 — matched case. $\text{SWR} = 1 \iff |\Gamma_L| = 0 \iff \underline{Z}_L = Z_0$ by Theorem 25.16(iii). $\square$

25.9. The Smith chart

The Smith chart, published by Phillip Hagar Smith in 1939 and refined in 1944, is the graphical representation of the map $z \mapsto \Gamma$ of Theorem 25.16. On it one reads impedance, reflection coefficient and SWR simultaneously, and moves along the line simply by rotating. It is, to all effects, Theorem (Volume II, Chapter 3) of Chapter 3 printed on paper.

Theorem 25.19: Constant-resistance circles. Let $z = r + ix$ be the normalised impedance and $\Gamma = u + iv$. For each fixed $r \geq 0$, the locus $\{\text{Re } z = r\}$ is, in the Γ -plane, the circle

$$\left(u - \frac{r}{1+r}\right)^2 + v^2 = \left(\frac{1}{1+r}\right)^2,$$

of centre $(\frac{r}{1+r}, 0)$ and radius $\frac{1}{1+r}$. All these circles lie inside the unit disc, are mutually tangent at $\Gamma = 1$, and degenerate to the point $\Gamma = 1$ as $r \rightarrow \infty$.

Proof. Step 1 — expression for r . From $z = (1 + \Gamma)/(1 - \Gamma)$, multiplying numerator and denominator by the conjugate of the denominator:

$$z = \frac{(1 - u^2 - v^2) + 2iv}{(1 - u)^2 + v^2},$$

since $(1 + u + iv)(1 - u + iv) = 1 - u^2 - v^2 + 2iv$. Hence

$$r = \frac{1 - u^2 - v^2}{(1 - u)^2 + v^2}, \quad x = \frac{2v}{(1 - u)^2 + v^2}.$$

Step 2 — constant- r locus. The equation $r[(1 - u)^2 + v^2] = 1 - u^2 - v^2$ becomes

$$(1 + r)(u^2 + v^2) - 2ru + r - 1 = 0.$$

Step 3 — completing the square. Dividing by $1 + r > 0$ and completing,

$$\left(u - \frac{r}{1+r}\right)^2 + v^2 = \frac{r^2 - (r-1)(r+1)}{(1+r)^2} = \frac{1}{(1+r)^2},$$

giving the stated radius.

Step 4 — tangency and inclusion. The rightmost point of each circle is

$$\frac{r}{1+r} + \frac{1}{1+r} = 1,$$

independent of r : all pass through $\Gamma = 1$ and are mutually tangent there (they share a vertical tangent, the centre being on the real axis). The leftmost point is $\frac{r-1}{r+1} \geq -1$, with equality only for $r = 0$: the circles lie inside the unit disc, and the one with $r = 0$ is the unit circle, consistently with Theorem 25.16(ii). As $r \rightarrow \infty$ the radius tends to 0 and the centre to 1. $\square$

Theorem 25.20: Constant-reactance circles. For each fixed $x \in \mathbb{R} \setminus \{0\}$, the locus $\{\operatorname{Im} z = x\}$ is, in the Γ -plane, the arc inside the unit disc of the circle

$$(u-1)^2 + \left(v - \frac{1}{x}\right)^2 = \frac{1}{x^2},$$

of centre $(1, \frac{1}{x})$ and radius $\frac{1}{|x|}$. For $x = 0$ the locus is the real segment $[-1, 1]$. All these circles pass through $\Gamma = 1$.

Proof. **Step 1.** From Step 1 of the previous proof, $x[(1-u)^2 + v^2] = 2v$.

Step 2. For $x \neq 0$, dividing by x and rearranging: $u^2 - 2u + 1 + v^2 - \frac{2v}{x} = 0$.

Step 3 — completing the squares.

$$(u-1)^2 + \left(v - \frac{1}{x}\right)^2 = \frac{1}{x^2},$$

as claimed. Substituting $(u, v) = (1, 0)$ verifies that $\Gamma = 1$ lies on every circle.

Step 4 — the case $x = 0$. The equation $2v = 0$ gives $v = 0$: the locus is the real axis, of which only the segment $[-1, 1]$ is physically accessible because $|\Gamma| \leq 1$ for passive loads.

Step 5 — why only an arc. The circle of centre $(1, 1/x)$ and radius $1/|x|$ leaves the unit disc; only the portion with $|\Gamma| \leq 1$ corresponds to passive loads ($r \geq 0$), and that is the one drawn on the chart. $\square$

Remark 25.8: The Smith chart as an atlas of Möbius. The two families of circles of Theorems 25.19 and 25.20 are the images, under the Möbius map $\Gamma = (z-1)/(z+1)$, of the two families of lines $\{\operatorname{Re} z = r\}$ and $\{\operatorname{Im} z = x\}$, i.e. of the Cartesian grid of the impedance plane. That they are circles is Theorem (Volume II, Chapter 3); that they all pass through $\Gamma = 1$ is because all those lines pass through the point at infinity, which the map sends to 1 (Observation, Volume II, Chapter 3). That they meet at right angles — a property evident on the chart — follows from the conformality of Möbius maps, i.e. from their being holomorphic with non-vanishing derivative and hence angle-preserving: the Cartesian grid is orthogonal, and so is its image.

Example 25.5: Single-stub matching. A load $\underline{Z}_L = 100 + i50 \, \Omega$ is connected to a line with $Z_0 = 50 \, \Omega$. Match it with a shunt stub (a length of line terminated in a short or an open, connected in parallel).

Step 1 — normalisation and reflection coefficient.

$$z_L = 2 + i, \quad \Gamma_L = \frac{1+i}{3+i} = \frac{(1+i)(3-i)}{10} = 0.4 + i0.2.$$

Modulus and argument: $|\Gamma_L| = \sqrt{0.16 + 0.04} = \sqrt{0.2} = 0.44721$, $\arg \Gamma_L = \arctan(0.5) = 26.565^\circ$.

Step 2 — SWR. By Theorem 25.18,

$$\text{SWR} = \frac{1 + 0.44721}{1 - 0.44721} = \frac{1.44721}{0.55279} = 2.618.$$

Step 3 — normalised load admittance.

$$y_L = \frac{1}{z_L} = \frac{1}{2 + i} = \frac{2 - i}{5} = 0.4 - i 0.2.$$

Step 4 — distance at which the real part equals 1. By the admittance dual of Theorem 25.17(iii), with $t = \tan \beta d$:

$$y(d) = \frac{y_L + it}{1 + iy_L t} = \frac{0.4 + i(t - 0.2)}{(1 + 0.2t) + i 0.4t}.$$

Imposing $\text{Re } y = 1$ and rationalising, the numerator of the real part is $0.4 + 0.4t^2$ and the denominator $1 + 0.4t + 0.2t^2$; equality gives

$$0.4 + 0.4t^2 = 1 + 0.4t + 0.2t^2 \implies 0.2t^2 - 0.4t - 0.6 = 0 \implies t^2 - 2t - 3 = 0,$$

with roots $t = 3$ and $t = -1$.

Step 5 — first solution. With $t = 3$: $\beta d = \arctan 3 = 71.565^\circ$, i.e.

$$d = \frac{71.565}{360} \lambda = 0.1988 \lambda.$$

Substituting,

$$y = \frac{0.4 + i 2.8}{1.6 + i 1.2} = \frac{(0.4 + 2.8i)(1.6 - 1.2i)}{2.56 + 1.44} = \frac{4.0 + 4.0i}{4} = 1 + i. \checkmark$$

We therefore need a stub supplying normalised susceptance $-i$.

Step 6 — stub length. A *short-circuited* stub of length ℓ presents $y_{\text{stub}} = -i \cot \beta \ell$ (from Theorem 25.17(iii) with $\underline{Z}_L = 0$, then inverting). Imposing $-i \cot \beta \ell = -i$:

$$\cot \beta \ell = 1 \implies \beta \ell = 45^\circ \implies \ell = 0.125 \lambda.$$

With an *open* stub one would have $y = i \tan \beta \ell = -i$, i.e. $\beta \ell = 135^\circ$ and $\ell = 0.375 \lambda$.

Step 7 — final check. In parallel, admittances add (Theorem (Volume II, Chapter 5)(iv) of Chapter 6):

$$y_{\text{tot}} = (1 + i) + (-i) = 1 \implies \underline{Z} = 50 \Omega,$$

i.e. $\Gamma = 0$ and $\text{SWR} = 1$: matched line. $\checkmark$

Step 8 — second solution. With $t = -1$: $\beta d = 135^\circ$, $d = 0.375 \lambda$, and one finds $y = 1 - i$; a susceptance $+i$ is then needed, i.e. a shorted stub of 0.375λ or an open one of 0.125λ . Both solutions are valid; in practice one picks the shorter stub, which offers wider bandwidth.

Typical error. Working in *impedance* rather than *admittance* for a shunt stub. Since admittances add in parallel, the whole construction must be carried out on the Smith chart read as an admittance chart (which is the same chart rotated by 180° : indeed $y = 1/z$ corresponds to $\Gamma \mapsto -\Gamma$, by Theorem 25.17(iv)).

25.10. Back to the unit circle: discrete-time stability

Figure 25.6: The skeleton of the Smith chart. In blue the constant normalised resistance circles r ($r = 0, 0.2, 0.5, 1, 2, 5$), with centre $(r/(1+r), 0)$ and radius $1/(1+r)$: they are all tangent to one another at $\Gamma = 1$. In red the constant normalised reactance arcs x ($x = \pm 0.2, \pm 0.5, \pm 1, \pm 2, \pm 5$), arcs of circles with centre $(1, 1/x)$ and radius $1/|x|$, again tangent at $\Gamma = 1$. The two families are orthogonal because they are the images, under the Möbius map $\Gamma = (z - 1)/(z + 1)$, of the orthogonal lines $\Re z = r$ and $\Im z = x$. The centre $\Gamma = 0$ is the matched condition $z = 1$; the rim $|\Gamma| = 1$ is the purely reactive load.

Chapter 4 established that a discrete-time system is stable if and only if all its poles lie inside the unit circle (Theorem 21.12). Checking that condition without computing the roots is the task of the Jury criterion; we prove the second-order case, the one met in practice when tuning digital controllers.

Theorem 25.21: Jury criterion, second order. Let $p(z) = z^2 + a_1 z + a_0$ with $a_0, a_1 \in \mathbb{R}$. Both roots have modulus < 1 if and only if

$$|a_0| < 1 \quad \text{and} \quad |a_1| < 1 + a_0.$$

Equivalently: $|a_0| < 1$, $p(1) > 0$ and $p(-1) > 0$.

Proof. Step 1 — equivalence of the two formulations. $p(1) = 1 + a_1 + a_0 > 0$ and $p(-1) = 1 - a_1 + a_0 > 0$ are equivalent to $-(1 + a_0) < a_1 < 1 + a_0$, i.e. $|a_1| < 1 + a_0$ (which implicitly requires $1 + a_0 > 0$, guaranteed by $|a_0| < 1$).

Step 2 — necessity. Let z_1, z_2 be the roots, with $|z_1|, |z_2| < 1$. By Vieta, $a_0 = z_1 z_2$, hence $|a_0| < 1$. Moreover $p(1) = (1 - z_1)(1 - z_2)$ and $p(-1) = (1 + z_1)(1 + z_2)$.

- If the roots are complex conjugate, $p(1) = |1 - z_1|^2 > 0$ and $p(-1) = |1 + z_1|^2 > 0$ (non-zero because $z_1 \neq \pm 1$, having modulus < 1).
- If they are real in $(-1, 1)$, then $1 - z_k > 0$ and $1 + z_k > 0$ for both, so both products are positive.

Step 3 — sufficiency, complex roots. If the discriminant is negative the roots are conjugate and $a_0 = |z_1|^2$. The hypothesis $|a_0| < 1$ then gives $|z_1| = |z_2| < 1$. ✓

Step 4 — sufficiency, real roots. Let $z_1 \leq z_2$ be real. From $p(1) = (1 - z_1)(1 - z_2) > 0$ the two factors have the same sign: either both roots are < 1 or both are > 1 . From $p(-1) = (1 + z_1)(1 + z_2) > 0$: either both > -1 or both < -1 .

If both were > 1 , then $a_0 = z_1 z_2 > 1$, contradicting $|a_0| < 1$. If both were < -1 , then again $z_1 z_2 > 1$, same contradiction. Only the compatible possibilities remain: both < 1 and both > -1 , i.e. both in $(-1, 1)$. ✓ □

Example 25.6: Checking discrete stability. Let $p(z) = z^2 - 1.2z + 0.5$.

Step 1 — criterion. $a_1 = -1.2$, $a_0 = 0.5$.

$$|a_0| = 0.5 < 1 \checkmark, \quad |a_1| = 1.2 < 1 + 0.5 = 1.5 \checkmark$$

The system is stable.

Step 2 — direct check.

$$z = \frac{1.2 \pm \sqrt{1.44 - 2}}{2} = \frac{1.2 \pm i\sqrt{0.56}}{2} = 0.6 \pm i 0.37417,$$

$$|z| = \sqrt{0.36 + 0.14} = \sqrt{0.5} = 0.70711 < 1 \checkmark$$

Note that $|z|^2 = 0.5 = a_0$: consistent with Step 3 of the proof.

Step 3 — limiting case. With $a_0 = 0.5$ fixed, stability is lost for $|a_1| \geq 1.5$. For $a_1 = -1.5$: $p(z) = z^2 - 1.5z + 0.5 = (z - 1)(z - 0.5)$, which has a root *on* the unit circle: exactly the boundary.

Control interpretation. In a digital controller a_1 and a_0 depend on the gain and the sampling time. The criterion says that raising the gain beyond a threshold moves the pair (a_1, a_0) outside the *stability triangle* bounded by the three lines $a_0 = 1$, $a_1 = 1 + a_0$ and $a_1 = -(1 + a_0)$: it is the discrete counterpart of the critical gain of Example 25.2.

25.11. Numerical exercises

All exercises are solved in Section 25.13, with an independent check and a typical error.

Exercise 25.1: N1 — Margins of a type-1 system. For $L(s) = \frac{20}{s(1 + s/5)}$ find the gain crossover frequency, the phase margin and the maximum tolerable delay. Explain why the gain margin is infinite.

Exercise 25.2: N2 — Critical gain analytically. For $L(s) = \frac{K}{(s + 1)(s + 2)(s + 5)}$ find the phase crossover frequency, the critical value of K and the gain margin for $K = 10$. Check the critical gain with the Routh–Hurwitz criterion.

Exercise 25.3: N3 — An M circle. Find centre, radius and the endpoints of the horizontal diameter of the M circle for $M = 1.4$, and verify that the point -1 is interior to it.

Exercise 25.4: N4 — A circular root locus. For $L(s) = K \frac{s + 4}{(s + 1)(s + 3)}$ find the centre and radius of the complex part of the locus, the breakpoints and the corresponding gains. Verify that the product of the two gains equals 4.

Exercise 25.5: N5 — Reflection coefficient and SWR. A load $\underline{Z}_L = 25 - i50 \, \Omega$ is connected to a line with $Z_0 = 50 \, \Omega$. Compute z_L , Γ_L in Cartesian and polar form, and the standing wave ratio.

Exercise 25.6: N6 — Quarter-wave transformer. Match a resistive load of $200\ \Omega$ to a line with $Z_0 = 50\ \Omega$ using a $\lambda/4$ section. Find the characteristic impedance of the section and check the result with Theorem 25.17(iv). State what happens at twice the frequency.

Exercise 25.7: N7 — Discrete stability. Apply the Jury criterion to $p(z) = z^2 + 0.4z - 0.3$ and verify the result by computing the roots.

Exercise 25.8: N8 — Circle criterion. A loop contains $G(s) = \frac{5}{(s+1)(s+2)}$ and a nonlinearity in the sector $[0.2, 2]$. Find the critical disc and verify, by computing the minimum distance of the Nyquist plot from the centre, that the circle criterion is satisfied.

Exercise 25.9: N9 — From phase margin to sampling time. A loop has $\omega_g = 5$ rad/s and $\text{PM} = 45^\circ$. (a) Compute the maximum tolerable delay. (b) Knowing that sampling with period T introduces an average delay $T/2$, find the largest admissible T if at least half the phase margin is to be preserved.

Exercise 25.10: N10 — Prewarping the bilinear transform. A digital filter with cutoff frequency 100 Hz is to be realised sampling at 1 kHz, using the bilinear transform $s = \frac{2}{T} \frac{z-1}{z+1}$. Compute the analogue frequency to be used in the design (*prewarping*) and the error incurred by ignoring the warping.

25.12. Symbolic exercises

Exercise 25.11: S1 — Symmetry of the Nyquist plot. Let L be rational with real coefficients and strictly proper. Prove that $L(-i\omega) = \overline{L(i\omega)}$, and deduce that the Nyquist plot is symmetric about the real axis and closes at the origin. Explain why it therefore suffices to draw it for $\omega \geq 0$.

Exercise 25.12: S2 — Rouché's theorem and continuity of the poles. Prove **Rouché's theorem**: if f, g are holomorphic on an open set containing a simple closed contour γ and its interior, and if $|f(s) - g(s)| < |g(s)|$ on γ , then f and g have the same number of zeros inside (with multiplicity). Deduce that the closed-loop poles depend continuously on the gain K .

Exercise 25.13: S3 — The modulus margin is a circle. Define the *sensitivity function* $S = 1/(1+L)$ and the *modulus margin* $s_m = \min_\omega |1+L(i\omega)|$. Prove that

$$s_m = \frac{1}{\|S\|_\infty},$$

and that s_m is the radius of the largest circle centred at -1 not meeting the Nyquist plot.

Exercise 25.14: S4 — Orthogonality of M and N circles. Prove that every M circle meets every N circle at right angles. (Hint: in the T -plane the two families are the circles centred at the origin and the rays from the origin; use the conformality of Möbius transformations.)

Exercise 25.15: S5 — The modulus margin dominates the other two. Prove that if the modulus margin is $s_m \in (0, 1)$, then

$$\text{PM} \geq 2 \arcsin \frac{s_m}{2}, \quad \text{GM} \geq \frac{1}{1 - s_m}.$$

Comment on why s_m is regarded as a more reliable robustness indicator than PM and GM taken separately.

Exercise 25.16: S6 — The sector $[0, k]$ and the half-plane. Prove that in the circle criterion, letting $k_1 \rightarrow 0^+$ with $k_2 = k$ fixed, the critical disc degenerates into the half-plane $\{\text{Re } G \leq -1/k\}$, and that the condition becomes: the Nyquist plot of G stays to the right of the vertical line $\text{Re } G = -1/k$. Recognise in this the simplified Popov criterion.

Exercise 25.17: S7 — The half-wave line. Prove that a lossless line section of length exactly $\lambda/2$ reproduces the load impedance at its input, whatever the load and whatever Z_0 . Deduce that Γ has period $\lambda/2$ and explain why the Smith chart scale runs to 0.5λ and not to λ .

Exercise 25.18: S8 — The stub is purely reactive. Prove that the input impedance of a lossless line section terminated in a short circuit is $Z_{\text{in}} = iZ_0 \tan \beta\ell$, and that of an open-circuited section is $-iZ_0 \cot \beta\ell$. Determine for which lengths the shorted stub behaves as an inductor and for which as a capacitor, and comment on the periodicity.

Exercise 25.19: S9 — The SWR circles. Prove that the constant- $|\Gamma|$ loci on the Smith chart are the circles centred at the origin, that each corresponds to a single value of SWR, and that moving towards the generator is a *clockwise* rotation on them. Find the relation between the SWR and the abscissa of the intersection of the circle with the positive real semiaxis.

Exercise 25.20: S10 — Jury via the bilinear transform. Prove Theorem 25.21 by an alternative route: substitute $z = \frac{1+w}{1-w}$ into $p(z)$, multiply by $(1-w)^2$ and apply the second-order Routh–Hurwitz criterion to the resulting polynomial in w . Check that exactly the same three conditions are obtained.

25.13. Solutions to the numerical exercises

Solution. N1. Step 1 — magnitude. $|L(i\omega)| = \frac{20}{\omega\sqrt{1+\omega^2/25}}.$

Step 2 — gain crossover. Imposing $|L| = 1$: $\omega\sqrt{1+\omega^2/25} = 20$. At $\omega = 9$ the left side is $9 \times \sqrt{1+3.24} = 9 \times 2.0591 = 18.53$; at $\omega = 9.4$ it is $9.4 \times \sqrt{1+3.5344} = 9.4 \times 2.1294 = 20.02$. Interpolating, $\omega_g = 9.39$ rad/s.

Step 3 — phase and margin.

$$\arg L(i\omega_g) = -90^\circ - \arctan \frac{9.39}{5} = -90^\circ - \arctan(1.878) = -90^\circ - 61.96^\circ = -151.96^\circ,$$

so $\text{PM} = 180^\circ - 151.96^\circ = 28.04^\circ$.

Step 4 — maximum delay. By Theorem 25.6(iii),

$$\tau_{\max} = \frac{28.04^\circ \times \pi/180}{9.39} = \frac{0.48939}{9.39} = 0.0521 \text{ s} = 52.1 \text{ ms}.$$

Step 5 — why $\text{GM} = \infty$. The phase is $-90^\circ - \arctan(\omega/5)$, which tends to -180° only as $\omega \rightarrow \infty$, never reaching it. There is thus no finite ω_π , the plot never crosses the negative real axis, and the gain margin is infinite: K can be increased without limit without destabilising. This is typical of systems with only two poles (including one at the origin).

Typical error. Concluding “infinite gain margin, hence a robust system”. The 28° phase margin says otherwise: the response will be oscillatory, and a 52 ms delay suffices to destabilise.

Solution. N2. *Step 1 — denominator in Cartesian form.*

$$(1 + i\omega)(2 + i\omega)(5 + i\omega) = (10 - 8\omega^2) + i(17\omega - \omega^3),$$

as one checks by expanding: real part $5(2 - \omega^2) - 3\omega^2 = 10 - 8\omega^2$; imaginary part $\omega(2 - \omega^2) + 15\omega = 17\omega - \omega^3$.

Step 2 — phase crossover. $L(i\omega)$ is real when the imaginary part of the denominator vanishes:

$$17\omega - \omega^3 = 0 \implies \omega_\pi = \sqrt{17} = 4.1231 \text{ rad/s}.$$

Step 3 — value at ω_π . The denominator equals $10 - 136 = -126$, so $L(i\omega_\pi) = -K/126$, real and negative ✓

Step 4 — critical gain. The plot touches -1 when $K/126 = 1$, i.e. $K_{\text{crit}} = 126$.

Step 5 — gain margin for $K = 10$. $\text{GM} = 126/10 = 12.6 = 22.0 \text{ dB}$.

Step 6 — Routh–Hurwitz check. The characteristic polynomial is $s^3 + 8s^2 + 17s + 10 + K$. For third order, stability requires all coefficients positive and $a_2a_1 > a_0$:

$$8 \times 17 > 10 + K \implies K < 126. \checkmark$$

Typical error. Looking for ω_π by solving $\arctan \omega + \arctan(\omega/2) + \arctan(\omega/5) = 180^\circ$ numerically. It works, but it is far longer and prone to quadrant errors: setting the imaginary part of the denominator to zero is the direct route.

Solution. N3. *Step 1 — centre and radius.* By Theorem 25.7 with $M = 1.4$: $M^2 = 1.96$, $M^2 - 1 = 0.96$, hence

$$c_M = -\frac{1.96}{0.96} = -2.04167, \quad r_M = \frac{1.4}{0.96} = 1.45833.$$

Step 2 — endpoints of the horizontal diameter.

$$c_M - r_M = -3.50000, \quad c_M + r_M = -0.58333,$$

(exact values $-7/2$ and $-7/12$).

Step 3 — the point -1 . Since $-3.5 < -1 < -0.58333$, the point -1 lies between the endpoints and is therefore interior. ✓ In agreement with Step 5 of the proof of Theorem 25.7: $c_M + r_M = -M/(M+1) = -1.4/2.4 = -0.58333$ and $c_M - r_M = -M/(M-1) = -1.4/0.4 = -3.5$ ✓

Step 4 — check on a point. The point $L = -0.58333$ must give $|T| = 1.4$:

$$T = \frac{-0.58333}{1 - 0.58333} = \frac{-0.58333}{0.41667} = -1.40000,$$

of modulus 1.4 ✓ And $L = -3.5$:

$$T = \frac{-3.5}{1 - 3.5} = \frac{-3.5}{-2.5} = 1.4 \checkmark$$

Reading. If the Nyquist plot is tangent to this circle, the closed-loop resonant peak is $M_r = 1.4$, i.e. +2.92 dB: a typical design value, associated with a damping $\zeta \approx 0.38$ and a step overshoot of about 27%.

Solution. N4. *Step 1 — applying the theorem.* Here $z = 4$, $p_1 = 1$, $p_2 = 3$, and $(1 - 4)(3 - 4) = 3 > 0$, so by Theorem 25.15 the complex part of the locus is the circle of centre -4 and radius $\rho = \sqrt{3} = 1.73205$.

Step 2 — breakpoints. $s_{1,2} = -4 \pm \sqrt{3} \implies s_1 = -2.26795$, $s_2 = -5.73205$.

Step 3 — corresponding gains. By Theorem 25.13, with $K = -\frac{(s+1)(s+3)}{s+4}$:

$$K_1 = -\frac{(-1.26795)(0.73205)}{1.73205} = \frac{0.92820}{1.73205} = 0.53590,$$

$$K_2 = -\frac{(-4.73205)(-2.73205)}{-1.73205} = \frac{12.92820}{1.73205} = 7.46410.$$

Exact values: $K_1 = 4 - 2\sqrt{3}$ and $K_2 = 4 + 2\sqrt{3}$.

Step 4 — product check. $K_1 K_2 = 16 - 12 = 4 \checkmark$ (and the sum is 8). Numerically $0.53590 \times 7.46410 = 4.00000 \checkmark$

Step 5 — checking a complex point. For $K = 2$ the characteristic equation is $s^2 + 6s + 11 = 0$, with roots $s = -3 \pm i\sqrt{2}$. Distance from the centre:

$$|(-3 + i\sqrt{2}) + 4| = \sqrt{1 + 2} = \sqrt{3} = \rho \checkmark$$

Typical error. Confusing the centre of the circle (the *zero*, at -4) with the asymptote centroid. Here $q = n - m = 1$: there is a single asymptote, the direction 180° , and no centroid to compute.

Solution. N5. *Step 1 — normalisation.* $z_L = 0.5 - i$.

Step 2 — reflection coefficient. By Theorem 25.16(i),

$$\Gamma_L = \frac{-0.5 - i}{1.5 - i} = \frac{(-0.5 - i)(1.5 + i)}{2.25 + 1}.$$

The numerator is $-0.75 - 0.5i - 1.5i - i^2 = -0.75 + 1 - 2i = 0.25 - 2i$. Hence

$$\Gamma_L = \frac{0.25 - 2i}{3.25} = 0.076923 - i 0.615385.$$

Step 3 — polar form.

$$|\Gamma_L| = \sqrt{0.0059172 + 0.3786982} = \sqrt{0.3846154} = 0.620174 \quad (= \sqrt{5/13}),$$

$$\arg \Gamma_L = \text{atan2}(-0.615385, 0.076923) = -82.87^\circ,$$

fourth quadrant: $\arctan(-8) = -82.87^\circ \checkmark$

Step 4 — SWR. By Theorem 25.18,

$$\text{SWR} = \frac{1 + 0.620174}{1 - 0.620174} = \frac{1.620174}{0.379826} = 4.2656.$$

Step 5 — consistency check. The load has positive real part ($R = 25 > 0$), so by Theorem 25.16(ii) we must have $|\Gamma_L| < 1$: and indeed $0.62 < 1 \checkmark$. An SWR of 4.27 means the voltage varies by a factor 4.27 between maximum and minimum along the line: a severe mismatch, which in transmission would mean a reflected power of $|\Gamma|^2 = 38.5\%$ of the incident one.

Solution. N6. *Step 1 — matching condition.* By Theorem 25.17(iv), a $\lambda/4$ section of characteristic impedance Z'_0 presents at its input $\underline{Z}_{\text{in}} = (Z'_0)^2/\underline{Z}_L$. We want 50Ω with $\underline{Z}_L = 200 \Omega$:

$$(Z'_0)^2 = 10\,000 \implies Z'_0 = 100 \Omega.$$

The characteristic impedance of the transformer is the *geometric mean* of the two impedances to be matched.

Step 2 — check. With $Z'_0 = 100$: $\underline{Z}_{\text{in}} = 50 \Omega \checkmark$, and the reflection coefficient seen from the main line is $\Gamma = 0 \checkmark$

Step 3 — at twice the frequency. At $2f$ the wavelength halves, so the section that was $\lambda/4$ at f becomes $\lambda'/2$ at $2f$. By Exercise S7, a $\lambda/2$ section reproduces the load impedance:

$$\underline{Z}_{\text{in}}(2f) = 200 \Omega,$$

and the reflection coefficient returns to $\Gamma = 150/250 = 0.6$, with $\text{SWR} = 4$. Quarter-wave matching is therefore *intrinsically narrowband*: it works perfectly at the design frequency and not at all at its second harmonic.

Typical error. Using the arithmetic mean $(50 + 200)/2 = 125 \Omega$ instead of the geometric one. With $Z'_0 = 125$ one would get $\underline{Z}_{\text{in}} = 78.1 \Omega$ and $\Gamma = 0.22$: matching missed.

Solution. N7. *Step 1 — criterion.* $p(z) = z^2 + 0.4z - 0.3$, so $a_1 = 0.4$ and $a_0 = -0.3$. By Theorem 25.21:

$$|a_0| = 0.3 < 1 \checkmark, \quad |a_1| = 0.4 < 1 + a_0 = 0.7 \checkmark$$

The system is stable.

Step 2 — equivalent form. $p(1) = 1 + 0.4 - 0.3 = 1.1 > 0 \checkmark$; $p(-1) = 1 - 0.4 - 0.3 = 0.3 > 0 \checkmark$

Step 3 — direct check.

$$z = \frac{-0.4 \pm \sqrt{0.16 + 1.2}}{2} = \frac{-0.4 \pm \sqrt{1.36}}{2} = \frac{-0.4 \pm 1.16619}{2} \implies z_1 = 0.38310, \quad z_2 = -0.78310,$$

both real with modulus $< 1 \checkmark$

Step 4 — Vieta check. $z_1 z_2 = -0.30000 = a_0 \checkmark$; $z_1 + z_2 = -0.40000 = -a_1 \checkmark$

Remark. Here $a_0 < 0$: the product of the roots is negative, so they have opposite signs. The condition $|a_1| < 1 + a_0$ tightens as a_0 becomes more negative; as $a_0 \rightarrow -1^+$ it forces $a_1 \rightarrow 0$: the stability triangle closes to a point.

Solution. N8. *Step 1 — the critical disc.* With $k_1 = 0.2$ and $k_2 = 2$:

$$-\frac{1}{k_1} = -5, \quad -\frac{1}{k_2} = -0.5,$$

so, by Theorem 25.12, the disc has

$$\text{centre} = \frac{-5 - 0.5}{2} = -2.75, \quad \text{radius} = \frac{5 - 0.5}{2} = 2.25.$$

Step 2 — Nyquist plot of G .

$$\operatorname{Re} G = \frac{5(2 - \omega^2)}{(2 - \omega^2)^2 + 9\omega^2}, \quad \operatorname{Im} G = \frac{-15\omega}{(2 - \omega^2)^2 + 9\omega^2}.$$

Step 3 — notable points. $\omega = 0$: $G = 2.5$; $\omega \rightarrow \infty$: $G \rightarrow 0$. Distances from -2.75 : 5.25 and 2.75, both > 2.25 .

Step 4 — searching for the closest point.

ω	$\operatorname{Re} G$	$\operatorname{Im} G$	distance from -2.75
2.0	-0.27778	-0.83333	2.6076
2.5	-0.28596	-0.50521	2.5153
2.8	-0.27897	-0.40126	2.5034
3.0	-0.26923	-0.34615	2.5048
3.5	-0.23803	-0.24384	2.5238

The minimum is about 2.503, near $\omega = 2.85$ rad/s.

Step 5 — conclusion. Since $2.503 > 2.25$, the plot stays strictly outside the critical disc: by Theorem 25.12 the loop is input-output stable *for every* nonlinearity in the sector $[0.2, 2]$, including saturations, dead zones and hysteresis-free relays.

Step 6 — how much margin is left. The ratio $2.503/2.25 = 1.11$ says the sector could be widened by about 11% in radius before losing the guarantee. Note the criterion is *sufficient*, not necessary: violating it does not imply instability, only loss of the guarantee.

Solution. N9. (a) *Maximum delay.* By Theorem 25.6(iii),

$$\tau_{\max} = \frac{45 \times \pi/180}{5} = \frac{0.785398}{5} = 0.157 \text{ s} = 157 \text{ ms.}$$

(b) *Sampling period.* Preserving at least half the margin means spending at most $\text{PM}/2 = 22.5^\circ = 0.392699$ rad on delay. The corresponding delay is

$$\tau = \frac{0.392699}{5} = 0.0785 \text{ s} = 78.5 \text{ ms.}$$

Since sampling introduces an average delay $T/2$,

$$\frac{T}{2} \leq 0.0785 \implies T \leq 0.157 \text{ s,}$$

i.e. a sampling frequency $f_s \geq 6.4$ Hz.

Step 3 — comparison with the rule of thumb. Industrial practice suggests f_s between 10 and 30 times the closed-loop bandwidth, here of order $\omega_g/(2\pi) = 0.80$ Hz: that would give f_s between 8 and 24 Hz, i.e. T between 42 and 125 ms. The exact computation (157 ms) is thus less demanding than the rule of thumb, which is reasonable: the rule also accounts for signal reconstruction quality, not just stability.

Typical error. Using T instead of $T/2$ as the equivalent delay. The average delay of a zero-order-hold sampler is $T/2$; using T would double the risk estimate and lead to needlessly oversizing the sampling rate.

Solution. N10. Step 1 — frequency warping. Substituting $z = e^{i\omega_d T}$ into the bilinear transform, factoring $e^{i\omega_d T/2}$ out of numerator and denominator and using the inverse Euler

formulas (Theorem, Volume II, Chapter 3):

$$s = \frac{2}{T} \cdot \frac{2i \sin(\omega_d T/2)}{2 \cos(\omega_d T/2)} = i \frac{2}{T} \tan \frac{\omega_d T}{2},$$

so the corresponding analogue frequency is $\omega_a = \frac{2}{T} \tan \frac{\omega_d T}{2}$. (One recognises Corollary (Volume II, Chapter 3) of Chapter 3: the unit circle of the z -plane goes to the imaginary axis of the s -plane, with $\tan$ as the correspondence law.)

Step 2 — numerical data. $f_s = 1$ kHz $\Rightarrow T = 1$ ms; desired cutoff $f_d = 100$ Hz $\Rightarrow \omega_d = 628.319$ rad/s.

Step 3 — prewarping.

$$\frac{\omega_d T}{2} = \frac{628.319 \times 0.001}{2} = 0.314159 \text{ rad} = 18.000^\circ,$$

$$\tan(0.314159) = 0.324920, \quad \omega_a = \frac{2}{0.001} \times 0.324920 = 649.84 \text{ rad/s}.$$

In frequency: $f_a = 649.84/(2\pi) = 103.42$ Hz.

Step 4 — error if warping is ignored. Designing the analogue filter directly at 628.319 rad/s and then discretising, the effective digital cutoff would solve $\frac{2}{T} \tan(\omega_d T/2) = 628.319$, i.e. $\tan(\omega_d T/2) = 0.314159$, i.e. $\omega_d T/2 = 0.304693$, hence $\omega_d = 609.39$ rad/s, i.e. 96.99 Hz instead of 100 Hz: a 3.0% error.

Step 5 — when warping matters. The relative error grows with $\omega_d T$: for $f_d/f_s = 0.1$ (our case) it is 3%; for $f_d/f_s = 0.25$ it becomes

$$\frac{\tan(\pi/4)}{\pi/4} = \frac{1}{0.785398} = 1.273,$$

i.e. 27%. Near the Nyquist frequency the warping diverges, consistently with $\tan$ having an asymptote at $\pi/2$: the whole semiaxis $[0, \infty)$ of analogue frequencies is compressed into the interval $[0, \pi/T)$ of digital ones.

25.14. Solutions to the symbolic exercises

Solution. S1. *Step 1 — Hermitian symmetry.* Let $L(s) = N(s)/D(s)$ with N, D having real coefficients. For a real-coefficient polynomial, $\overline{N(s)} = N(\bar{s})$: conjugating a sum of monomials $a_k s^k$ with $a_k \in \mathbb{R}$ gives $\sum a_k \bar{s}^k$. Hence

$$\overline{L(i\omega)} = \frac{N(-i\omega)}{D(-i\omega)} = L(-i\omega).$$

Step 2 — symmetry of the plot. The point $L(-i\omega)$ is thus the conjugate of $L(i\omega)$, i.e. its reflection in the real axis (Definition, Volume I, Chapter 7). The curve $\{L(i\omega) : \omega \in \mathbb{R}\}$ is therefore symmetric about the real axis, and the branch with $\omega < 0$ is determined by the one with $\omega > 0$: it suffices to draw the latter and mirror it.

Step 3 — closing at the origin. If L is strictly proper, $\deg N < \deg D$, hence

$$|L(i\omega)| \sim |\omega|^{\deg N - \deg D} \longrightarrow 0 \quad (\omega \rightarrow \pm\infty).$$

The curve starts and ends at the origin, and the semicircle at infinity of the Nyquist contour has as image the single point 0 (Step 4 of the proof of Theorem 25.5).

Step 4 — consequence for encirclements. Since the full plot is the union of two conjugate arcs, the winding number about -1 — which is real — receives symmetric contributions from the two arcs. This is why, in practice, one counts the crossings of the real axis to the left of -1 for $\omega > 0$ only and doubles them.

Solution. S2. *Step 1 — building the homotopy.* For $t \in [0, 1]$ set $h_t(s) = g(s) + t(f(s) - g(s))$, so $h_0 = g$ and $h_1 = f$. Each h_t is holomorphic on the given open set.

Step 2 — no zeros on the contour. For $s \in \gamma$ and $t \in [0, 1]$, by the reverse triangle inequality (Theorem (Volume II, Chapter 3)(v)),

$$|h_t(s)| \geq |g(s)| - |f(s) - g(s)| > 0$$

by hypothesis. So h_t has no zeros on γ , for any t .

Step 3 — the count is continuous and integer-valued. By Theorem 25.4, the number of zeros of h_t inside γ is

$$N(t) = \frac{1}{2\pi i} \oint_{\gamma} \frac{h'_t(s)}{h_t(s)} ds$$

(there are no poles, h_t being holomorphic). The integrand depends continuously on t uniformly on γ — because h_t and h'_t depend linearly on t and $|h_t|$ is bounded below by a positive constant, by Step 2 — so N is a continuous function of t . But $N(t)$ is an integer for every t : a continuous integer-valued function on an interval is constant.

Step 4 — conclusion. $N(1) = N(0)$, i.e. f and g have the same number of zeros inside. ✓

Step 5 — continuity of the closed-loop poles. Let $\chi_K(s) = D(s) + KN(s)$ be the characteristic polynomial. Fix K_0 and a root s_0 of χ_{K_0} of multiplicity m ; let γ be a small circle about s_0 containing no other root, and $\delta = \min_{s \in \gamma} |\chi_{K_0}(s)| > 0$. For $|K - K_0|$ small enough,

$$|\chi_K(s) - \chi_{K_0}(s)| = |K - K_0| \cdot |N(s)| < \delta \leq |\chi_{K_0}(s)| \quad \text{on } \gamma,$$

since $|N|$ is bounded on the compact γ . By Rouché, χ_K has exactly m roots inside γ : roots cannot “jump”, and as $K \rightarrow K_0$ they tend to s_0 . This is exactly what makes it meaningful to draw the root locus as a family of continuous *curves*.

Solution. S3. *Step 1 — identity between the two minima.* By definition $S(i\omega) = 1/(1 + L(i\omega))$, so $|S(i\omega)| = 1/|1 + L(i\omega)|$. Since $x \mapsto 1/x$ is decreasing on $(0, \infty)$, the maximum of $|S|$ occurs where $|1 + L|$ is minimal:

$$\|S\|_{\infty} = \frac{1}{\inf_{\omega} |1 + L(i\omega)|} = \frac{1}{s_m},$$

whence $s_m = 1/\|S\|_{\infty}$.

Step 2 — geometric interpretation. By Theorem (Volume II, Chapter 3) of Chapter 3, $|1 + L(i\omega)| = |L(i\omega) - (-1)|$ is the *distance* between the point $L(i\omega)$ and the point -1 . Hence s_m is the minimum distance between the Nyquist plot and the critical point.

Step 3 — the circle. The circle of centre -1 and radius r misses the plot iff $|L(i\omega) + 1| > r$ for every ω , i.e. iff $r < s_m$. The largest such circle (in the closed sense: tangent but not secant) therefore has radius exactly s_m . ✓

Step 4 — why it is the right robustness measure. $\|S\|_{\infty}$ is the maximum amplification factor of disturbances under feedback: a small s_m means a large $\|S\|_{\infty}$, i.e. amplified disturbances and poor robustness. Typical design values are $s_m \geq 0.5$, i.e. $\|S\|_{\infty} \leq 2$ (6 dB).

Solution. S4. *Step 1 — the two families in the T -plane.* In the T -plane, the locus $|T| = M$ is the circle of centre the origin and radius M ; the locus $\arg T = \alpha$ is the ray from the origin with inclination α . The two families are orthogonal: at every point $T_0 \neq 0$ the circle has tangent perpendicular to the radius, and the ray is the radius.

Step 2 — the map. The correspondence $L \mapsto T = L/(1 + L)$ is a Möbius transformation (Definition, Volume II, Chapter 3), hence holomorphic on its domain, with derivative

$$\frac{dT}{dL} = \frac{1}{(1 + L)^2},$$

never zero and defined everywhere except at $L = -1$.

Step 3 — conformality. A holomorphic function with non-zero derivative at a point preserves angles between curves there. Indeed, if two curves meet at L_0 with tangent vectors v_1, v_2 , the images have tangent vectors $T'(L_0)v_1$ and $T'(L_0)v_2$; the angle between them is

$$\arg \frac{T'(L_0)v_2}{T'(L_0)v_1} = \arg \frac{v_2}{v_1},$$

by Theorem (Volume II, Chapter 3): the common factor cancels and the angle is unchanged.

Step 4 — conclusion. The M and N circles are the preimages of the two orthogonal families of Step 1 under the inverse map $T \mapsto L = T/(1 - T)$, itself Möbius and hence conformal. Angles are preserved: the preimages meet at right angles. ✓

Remark. The same argument explains the orthogonality of the Smith chart grid (Observation 25.8): again, conformality of Möbius maps.

Solution. S5. *Step 1 — the constraint.* By Exercise S3, the plot stays outside the open circle of centre -1 and radius s_m : for every ω , $|L(i\omega) + 1| \geq s_m$.

Step 2 — phase margin estimate. At ω_g we have $|L(i\omega_g)| = 1$, hence $L(i\omega_g) = e^{i\theta}$ with $\theta = -180^\circ + \text{PM}$. The distance between two points of the unit circle with arguments θ_1, θ_2 is, by the chord formula (Theorem (Volume II, Chapter 3) of Chapter 3, or directly),

$$|e^{i\theta_1} - e^{i\theta_2}| = 2 \left| \sin \frac{\theta_1 - \theta_2}{2} \right|.$$

Here $\theta_1 - \theta_2 = \text{PM}$, so

$$|L(i\omega_g) + 1| = 2 \sin \frac{\text{PM}}{2} \geq s_m \implies \text{PM} \geq 2 \arcsin \frac{s_m}{2}.$$

Step 3 — gain margin estimate. At ω_π the point $L(i\omega_\pi)$ lies on the negative real axis at distance $1/\text{GM}$ from the origin. Its distance from -1 is

$$1 - \frac{1}{\text{GM}} \geq s_m,$$

(assuming $\text{GM} > 1$, i.e. a stable system), whence $\text{GM} \geq 1/(1 - s_m)$.

Step 4 — typical values. For $s_m = 0.5$: $\text{PM} \geq 2 \arcsin(0.25) = 28.96^\circ$ and $\text{GM} \geq 1/0.5 = 2$ (6 dB).

Step 5 — why s_m is more reliable. PM and GM measure the distance from -1 along *two particular directions*: along the unit circle and along the real axis respectively. One can construct systems with both margins excellent and yet a plot passing very close to -1 in an intermediate direction — hence fragile. The modulus margin, measuring the minimum distance *over all directions*, has no such defect: by Steps 2 and 3 it implies acceptable values of both others, while the converse is false.

Solution. S6. *Step 1 — endpoints of the diameter.* In Theorem 25.12 the disc has as diameter the segment with endpoints $-1/k_1$ and $-1/k_2$. With $k_2 = k$ fixed and $k_1 \rightarrow 0^+$, $-1/k_1 \rightarrow -\infty$ while $-1/k_2 = -1/k$ stays fixed.

Step 2 — limit of the disc. Centre and radius,

$$c = -\frac{1}{2} \left(\frac{1}{k_1} + \frac{1}{k} \right) \rightarrow -\infty, \quad r = \frac{1}{2} \left(\frac{1}{k_1} - \frac{1}{k} \right) \rightarrow +\infty,$$

both diverge, but the difference $c + r = -1/k$ stays constant: the right edge of the disc stays put at $-1/k$ while the rest expands indefinitely leftwards. The limit is thus the closed half-plane $\{\operatorname{Re} G \leq -1/k\}$.

Step 3 — form of the condition. “Stay outside the disc” becomes “stay to the right of the vertical line $\operatorname{Re} G = -1/k$ ”, i.e. $\operatorname{Re} G(i\omega) > -1/k$ for every ω .

Step 4 — direct check. The condition of Step 3 of the proof of Theorem 25.12 was $(r^2 - k_m^2)(x^2 + y^2) - 2k_mx - 1 < 0$ with $r^2 - k_m^2 = -k_1k_2$. As $k_1 \rightarrow 0$ the coefficient of $x^2 + y^2$ tends to 0 and $k_m \rightarrow k/2$, so the condition degenerates into $-kx - 1 < 0$, i.e. $x > -1/k$. ✓

Step 5 — connection with Popov. The condition obtained is the simplest version of the Popov criterion: for memoryless nonlinearities in the sector $[0, k]$, absolute stability is guaranteed if the Nyquist plot stays to the right of a vertical line. Popov (1962) showed that, also exploiting monotonicity of the nonlinearity, the vertical line can be replaced by a *slanted* line through $-1/k$, giving a less restrictive condition; the circle criterion is the vertical-line case, valid also for time-varying nonlinearities.

Solution. S7. *Step 1 — direct computation.* For $d = \lambda/2$ we have $\beta d = \pi$, hence $\tan \beta d = 0$. By Theorem 25.17(iii),

$$\underline{Z}_{\text{in}} = Z_0 \frac{\underline{Z}_L}{Z_0} = \underline{Z}_L,$$

independent of Z_0 . ✓

Step 2 — via the reflection coefficient. Alternatively, by Theorem 25.17(i),

$$\Gamma(\lambda/2) = \Gamma_L e^{-2\pi i} = \Gamma_L,$$

since $e^{-2\pi i} = 1$ (Theorem (Volume II, Chapter 3) of Chapter 3). Same Γ , hence same impedance by Theorem 25.16(i).

Step 3 — periodicity. From Step 2, $\Gamma(d + \lambda/2) = \Gamma(d)$ for every d : the period divides $\lambda/2$. That it is exactly $\lambda/2$ follows from $e^{-2i\beta\Delta} = 1$ requiring $\Delta \in (\lambda/2)\mathbb{Z}$.

Step 4 — the Smith chart scale. Since everything repeats every $\lambda/2$, a full 360° rotation on the chart corresponds to a displacement of $\lambda/2$ along the line: the perimeter scale is therefore graduated from 0 to 0.5 in wavelengths. It is the same “factor of two” as in Theorem 25.17(i): the rotation angle is $2\beta d$, not βd .

Step 5 — practical consequence. A cable section half a wavelength long is “invisible” as far as matching is concerned: it can be inserted or removed without changing anything, at the design frequency. At twice the frequency it becomes a full wavelength — still invisible; at $1.5f$ it becomes 0.75λ , i.e. equivalent to 0.25λ , and inverts the impedance. The property is thus strictly monochromatic.

Solution. S8. *Step 1 — short-circuited stub.* With $\underline{Z}_L = 0$ in Theorem 25.17(iii):

$$\underline{Z}_{\text{in}} = Z_0 \frac{iZ_0 \tan \beta \ell}{Z_0} = iZ_0 \tan \beta \ell,$$

purely imaginary.

Step 2 — open-circuited stub. With $\underline{Z}_L \rightarrow \infty$, dividing numerator and denominator by $\underline{Z}_L$ and passing to the limit:

$$\underline{Z}_{\text{in}} \longrightarrow \frac{Z_0}{i \tan \beta \ell} = -i Z_0 \cot \beta \ell,$$

also purely imaginary.

Step 3 — why this was predictable. A lossless line dissipates no energy, and neither does a short or an open circuit: the overall one-port cannot absorb active power, hence by Theorem (Volume II, Chapter 5)(ii) of Chapter 6 its real part vanishes. The conclusion is independent of the computation.

Step 4 — inductive or capacitive behaviour. For the shorted stub, $X = Z_0 \tan \beta \ell$, hence by Theorem (Volume II, Chapter 5) of Chapter 6:

- $X > 0$ (*inductive*) for $\tan \beta \ell > 0$, i.e. $0 < \ell < \lambda/4$ and more generally $\ell \in (\frac{n\lambda}{2}, \frac{n\lambda}{2} + \frac{\lambda}{4})$;
- $X < 0$ (*capacitive*) for $\lambda/4 < \ell < \lambda/2$ and translates by $\lambda/2$.

At $\ell = \lambda/4$, $X \rightarrow \infty$ (equivalent open circuit: it is the quarter-wave transformer applied to a short); at $\ell = \lambda/2$ one is back to the short circuit, as Exercise S7 predicts.

Step 5 — engineering reading. A stub is therefore a reactive component *tunable with scissors*: cut to the right length it gives any reactance, inductive or capacitive, without coils or capacitors — which at microwave frequencies would be unrealisable. The $\lambda/2$ periodicity guarantees that a short solution always exists.

Solution. S9. *Step 1 — constant- $|\Gamma|$ loci.* By definition, $\{|\Gamma| = \rho\}$ is the circle of centre the origin and radius ρ in the Γ -plane (Corollary (Volume II, Chapter 3) of Chapter 3). By Theorem 25.17(i), moving along a lossless line preserves $|\Gamma|$: the representative point stays on that circle.

Step 2 — correspondence with SWR. By Theorem 25.18, $\text{SWR} = (1 + \rho)/(1 - \rho)$, a strictly increasing function of ρ on $[0, 1)$ (its derivative is $2/(1 - \rho)^2 > 0$): each circle corresponds to exactly one SWR, and conversely. Inverting, $\rho = (\text{SWR} - 1)/(\text{SWR} + 1)$.

Step 3 — direction of rotation. By Theorem 25.17(i), $\Gamma(d) = \Gamma_L e^{-2i\beta d}$: as d grows (movement towards the generator) the argument *decreases*, i.e. the point rotates **clockwise**. This is why the Smith chart carries two perimeter scales, “towards generator” clockwise and “towards load” counterclockwise.

Step 4 — intersection with the positive real semiaxis. The point of the circle on the positive real semiaxis is $\Gamma = \rho$; by Theorem 25.16(i) the corresponding normalised impedance is

$$z = \frac{1 + \rho}{1 - \rho} = \text{SWR},$$

real and greater than 1. Hence *the abscissa of that intersection, read as a normalised resistance, is numerically equal to the SWR*: this is the classical way to read the SWR off the chart with no computation, and it corresponds physically to the point of the line where the voltage is maximal.

Step 5 — check. In Example 25.5 we had $\rho = 0.44721$ and $\text{SWR} = 2.618$; the intersection with the positive real semiaxis is $\Gamma = 0.44721$, corresponding to $z = 1.44721/0.55279 = 2.618$ ✓

Solution. S10. *Step 1 — the substitution.* Set $z = \frac{1 + w}{1 - w}$. By Corollary (Volume II, Chapter 3) of Chapter 3 (read backwards), this map carries the half-plane $\text{Re } w < 0$ into the disc $|z| < 1$: its inverse is $w = (z - 1)/(z + 1)$, which by Exercise S1 of Chapter 6 satisfies $|z| < 1 \iff \text{Re } w < 0$. Hence *the roots of p all lie in $|z| < 1$ if and only if the roots of the transformed polynomial all lie in $\text{Re } w < 0$.*

Step 2 — the transformed polynomial. Substituting into $p(z) = z^2 + a_1z + a_0$ and multiplying by $(1 - w)^2$ (which neither creates nor destroys roots, $w = 1$ being the image of $z = \infty$):

$$q(w) = (1 + w)^2 + a_1(1 + w)(1 - w) + a_0(1 - w)^2,$$

and expanding,

$$q(w) = (1 - a_1 + a_0)w^2 + 2(1 - a_0)w + (1 + a_1 + a_0).$$

One recognises $q_2 = p(-1)$, $q_0 = p(1)$ and $q_1 = 2(1 - a_0)$.

Step 3 — second-order Routh–Hurwitz. A real polynomial $q_2w^2 + q_1w + q_0$ has both roots with negative real part iff its three coefficients are *all of the same sign* (and non-zero). Proof: assuming $q_2 > 0$ and dividing, take $q(w) = w^2 + bw + c$; the roots have sum $-b$ and product c . If real, both negative $\iff$ sum negative and product positive, i.e. $b > 0$ and $c > 0$; if complex conjugate $\sigma \pm i\tau$, the real part is $-b/2$ and the product is $\sigma^2 + \tau^2 = c > 0$, so the condition is again $b > 0$.

Step 4 — translation. Normalising to $q_2 > 0$, the conditions are

$$1 - a_1 + a_0 > 0, \quad a_0 < 1, \quad 1 + a_1 + a_0 > 0.$$

Step 5 — comparison with Theorem 25.21. The first and third give $|a_1| < 1 + a_0$; added together they imply $2 + 2a_0 > 0$, i.e. $a_0 > -1$, which together with $a_0 < 1$ gives $|a_0| < 1$. Conversely the conditions of the theorem imply these three. The two formulations coincide.

✓

Remark. This proof has the merit of being *constructive and general*: the same procedure — bilinear transform followed by Routh–Hurwitz — gives the Jury criterion for polynomials of any degree, without repeating the analysis case by case. And once again it is the Möbius map of Chapter 3 that does all the work: turning the problem “inside the circle” into the problem “left of the line”, for which a criterion already exists.

25.15. Self-assessment quiz

- The Nyquist plot is the image, under L , of
 - the unit circle
 - the imaginary axis
 - the real axis
 - the right half-plane
- On a logarithmic scale, the magnitude plot of a product is
 - the product of the plots
 - the sum of the plots
 - the average
 - no simple relation
- Beyond the break frequency, a simple pole contributes a slope of
 - −10 dB/dec
 - −20 dB/dec
 - −40 dB/dec
 - −6 dB/dec
- At the break point, the gap between exact curve and asymptotes is
 - 0 dB
 - 3.01 dB
 - 6 dB
 - 20 dB
- The argument principle relates the winding number to
 - $Z + P$
 - $Z - P$
 - $Z \cdot P$
 - Z/P
- The critical point of the Nyquist criterion is
 - 0
 - −1
 - +1
 - ∞

-
7. With a stable open loop, the closed loop is stable if the plot
 - A) encircles -1 once
 - B) does not encircle -1
 - C) passes through -1
 - D) stays in the first quadrant
 8. The phase margin is read at the intersection of the plot with
 - A) the real axis
 - B) the unit circle
 - C) the imaginary axis
 - D) the point -1
 9. The maximum tolerable delay equals
 - A) $\text{PM} \cdot \omega_g$
 - B) PM/ω_g (in radians)
 - C) ω_g/PM
 - D) $1/\omega_g$
 10. The loci $|T| = M$ in the L -plane are
 - A) lines
 - B) circles (a line for $M = 1$)
 - C) ellipses
 - D) hyperbolas
 11. All N circles pass through
 - A) the origin and -1
 - B) only -1
 - C) only the origin
 - D) $+1$
 12. In the circle criterion, the critical point -1 is replaced by
 - A) a different point
 - B) a disc of diameter $[-1/k_1, -1/k_2]$
 - C) a line
 - D) the unit circle
 13. The small-gain theorem requires
 - A) $\gamma_1 + \gamma_2 < 1$
 - B) $\gamma_1 \gamma_2 < 1$
 - C) $\gamma_1 < \gamma_2$
 - D) $\gamma_1 \gamma_2 > 1$
 14. The membership condition for the root locus concerns the
 - A) magnitude
 - B) argument ($\equiv 180^\circ$)
 - C) derivative
 - D) residue
 15. For $L = K(s + z)/((s + p_1)(s + p_2))$ with real data, the complex part of the locus is
 - A) a vertical line
 - B) a circle centred at the zero
 - C) a hyperbola
 - D) a parabola
 16. The reflection coefficient $\Gamma = (z - 1)/(z + 1)$ maps passive loads
 - A) outside the unit disc
 - B) into the unit disc
 - C) onto the real axis
 - D) to infinity
 17. Moving along a lossless line corresponds, in the Γ -plane, to
 - A) a translation
 - B) a rotation at constant modulus
 - C) a dilation
 - D) a reflection
 18. The constant-resistance circles of the Smith chart all pass through
 - A) $\Gamma = 0$
 - B) $\Gamma = 1$
 - C) $\Gamma = -1$
 - D) infinity
 19. A $\lambda/4$ line section transforms $\underline{Z}_L$ into
 - A) $\underline{Z}_L$
 - B) $Z_0^2/\underline{Z}_L$
 - C) $-\underline{Z}_L$
 - D) Z_0
 20. The second-order Jury criterion requires
 - A) $|a_0| < 1$ and $|a_1| < 1 + a_0$
 - B) $a_0 > 1$
 - C) $a_1 = 0$
 - D) $|a_1| < 1$

BEST PRACTICE

Answer key.

1-B: Definition 25.1; in discrete time it would be the unit circle (Observation 25.1). **2-B:** Theorem 25.2. **3-B:** Theorem 25.3(ii). **4-B:** same theorem: $-20 \log_{10} \sqrt{2} = -3.0103$ dB. **5-B:** Theorem 25.4. **6-B:** Observation 25.4: it is the condition $1 + L = 0$. **7-B:** Corollary 25.1. **8-B:** Definition 25.2 and Theorem 25.6(ii). **9-B:** Theorem 25.6(iii).

10-B: Theorem 25.7. **11-A:** Theorem 25.8, Step 3. **12-B:** Theorem 25.12; for $k_1 = k_2$ the disc shrinks to the point (Observation 25.7). **13-B:** Theorem 25.11. **14-B:** Theorem 25.13: the magnitude condition only fixes K . **15-B:** Theorem 25.15; the radius is $\sqrt{(p_1 - z)(p_2 - z)}$. **16-B:** Theorem 25.16(ii), which is Exercise S1 of Chapter 6. **17-B:** Theorem 25.17(i). **18-B:** Theorem 25.19, Step 4: the rightmost point is always 1. **19-B:** Theorem 25.17(iv). **20-A:** Theorem 25.21.

25.16. Chapter formulary

Frequency response

$$u = e^{i\omega t} \implies y = H(i\omega)e^{i\omega t}, \quad H(-i\omega) = \overline{H(i\omega)} \text{ (} h \text{ real)}$$

Bode

$$20 \log_{10} |H_1 H_2| = 20 \log_{10} |H_1| + 20 \log_{10} |H_2|, \quad \arg(H_1 H_2) = \arg H_1 + \arg H_2$$

simple pole : -20 dB/dec, -45° at ω_p , gap 3.01 dB

Argument principle and Nyquist

$$\frac{1}{2\pi i} \oint_{\gamma} \frac{F'}{F} ds = Z - P, \quad Z = N + P \text{ (clockwise encirclements of } -1)$$

$$\text{PM} = 180^\circ + \arg L(i\omega_g), \quad \text{GM} = \frac{1}{|L(i\omega_\pi)|}, \quad \tau_{\max} = \frac{\text{PM} [\text{rad}]}{\omega_g}$$

$$s_m = \min_{\omega} |1 + L(i\omega)| = \frac{1}{\|S\|_{\infty}}$$

M and N circles ($T = L/(1 + L)$)

$$|T| = M : \quad c_M = -\frac{M^2}{M^2 - 1}, \quad r_M = \frac{M}{|M^2 - 1|}$$

$$\arg T = \alpha, \quad N = \tan \alpha : \quad \text{centre } \left(-\frac{1}{2}, \frac{1}{2N}\right), \quad \text{radius } \frac{1}{2}\sqrt{1 + 1/N^2}$$

Circle criterion (sector $[k_1, k_2]$, $0 < k_1 < k_2$)

$$\text{disc of diameter } \left[-\frac{1}{k_1}, -\frac{1}{k_2}\right], \quad \gamma_1 \gamma_2 < 1 \text{ (small gain)}$$

Root locus

$$\arg \frac{N(s)}{D(s)} \equiv 180^\circ, \quad K = \frac{|D(s)|}{|N(s)|}, \quad \theta_k = \frac{(2k+1)180^\circ}{n-m}, \quad \sigma_a = \frac{\sum p_j - \sum z_i}{n-m}$$

$$L = K \frac{s+z}{(s+p_1)(s+p_2)} \implies \text{circle of centre } -z, \text{ radius } \sqrt{(p_1 - z)(p_2 - z)}$$

Transmission lines

$$\Gamma_L = \frac{z_L - 1}{z_L + 1}, \quad z_L = \frac{1 + \Gamma_L}{1 - \Gamma_L}, \quad \Gamma(d) = \Gamma_L e^{-2i\beta d}, \quad \beta = \frac{2\pi}{\lambda}$$

$$\underline{Z}_{\text{in}}(d) = Z_0 \frac{\underline{Z}_L + iZ_0 \tan \beta d}{Z_0 + i\underline{Z}_L \tan \beta d}, \quad \underline{Z}_{\text{in}}(\lambda/4) = \frac{Z_0^2}{\underline{Z}_L}$$

$$\text{SWR} = \frac{1 + |\Gamma_L|}{1 - |\Gamma_L|}, \quad |\Gamma_L| = \frac{\text{SWR} - 1}{\text{SWR} + 1}$$

Smith chart

r constant : centre $\left(\frac{r}{1+r}, 0\right)$, radius $\frac{1}{1+r}$; x constant : centre $\left(1, \frac{1}{x}\right)$, radius $\frac{1}{|x|}$

Discrete time

$$s = \frac{2}{T} \cdot \frac{z-1}{z+1}, \quad \omega_a = \frac{2}{T} \tan \frac{\omega_d T}{2} \text{ (prewarping)}$$

$$z^2 + a_1 z + a_0 \text{ stable} \iff |a_0| < 1 \text{ and } |a_1| < 1 + a_0$$

25.17. Modulus margin of a third-order loop

Algorithm. For $L(s) = K/(1+s)^3$ one has $|1 + L(j\omega)|^2 = 1 + [2K(1 - 3\omega^2) + K^2]/(1 + \omega^2)^3$; tabulate and look for the minimum.

Datum. $K = 2$.

ω	$ 1 + L(j\omega) ^2$	$ 1 + L(j\omega) $
0	9.00000	3.00000
0.5	3.56000	1.88680
1.0	0.50000	0.70711
1.2247	0.36000	0.60000
1.5	0.44652	0.66822
2.0	0.68000	0.82462
3.0	0.90000	0.94868

The minimum falls at $\omega = \sqrt{3/2} = 1.2247$ and equals exactly 0.6: hence $m = 0.6$ and $M_s = 1/0.6 = 1.6667$.

Independent check (classical margins). The plot crosses the negative real axis at $\omega = \sqrt{3}$, where $|L| = 2/8 = 0.25$: gain margin $m_G = 4$. The estimate of Theorem 25.10 requires $m_G \geq 1/(1-m) = 2.5$ ✓. Unit modulus is crossed at $\omega_c = 0.7664$, where the phase is -112.36° : phase margin 67.6° , against the estimate $2 \arcsin(0.3) = 34.9^\circ$ ✓.

Telecommunications: complex baseband, IQ and modulations

A radio transmitter does not send the message into the ether: it sends a circle, and on the circle it writes the message. The sentence is less rhetorical than it sounds, and it is the technical content of this chapter. The signal that travels is a sinusoid at the carrier frequency f_c ; the information does not lie in the sinusoid, which is always the same, but in the pair (A, φ) of amplitude and phase with which it is emitted in each symbol interval, that is, in a *point of the complex plane* $Ae^{i\varphi}$. The set of admitted points is called a **constellation**, and the classical constellations are literally sets of points on one or more concentric circles: the M M -th roots of unity of Chapter 6 (Definition 6.2) rotated and scaled give the M -PSK modulation; two concentric circles with different populations give M -APSK; a square grid — which is still a union of circles, but with unequal populations — gives M -QAM.

The logical chain of the chapter is exactly that, and must be walked in order. First it is proved that a real narrowband signal around f_c *can be written in one and only one way* as the real part of a slow complex signal multiplied by $e^{i2\pi f_c t}$ (Theorem 26.1 and Theorem 26.2): this is the **complex envelope**, and its two real components are the **in-phase** and **quadrature** components. Then it is proved, with the integral computed in full and not with a wave of the hand, under exactly which conditions the two carriers $\cos(2\pi f_c t)$ and $\sin(2\pi f_c t)$ are orthogonal on the symbol interval, and what the error is worth when those conditions are not satisfied (Proposition 26.2). Everything rests on this orthogonality: it is what allows two independent streams to be transmitted on the same frequency and separated at reception.

Once the constellation is fixed, the receiver must decide. It is proved that, for additive white Gaussian noise and equiprobable symbols, the maximum-likelihood rule *coincides* with the minimum Euclidean-distance rule (Theorem 26.6), that the decision regions are the Voronoi cells of the constellation and that they are convex polyhedra (Theorem 26.7). Before deciding, however, one must measure: it is proved that among all linear filters the one that maximises the signal-to-noise ratio at the sampling instant is the **matched filter**, and that the maximum equals $2E/N_0$ (Theorem 26.8); the proof is an application of the Cauchy–Schwarz inequality, whose *equality case* is used in an essential way — and is therefore proved as well (Lemma 26.3).

Finally the numbers. The error probability of BPSK and QPSK is derived in full from the Q function (Theorem 26.9 and Theorem 26.10), with the relation between energy per bit and energy per symbol written explicitly at every step, and every numerical value computed twice by independent routes. The chapter closes with the minimum distance of constellations and its link with spectral efficiency (Section 26.8), and with the two tools that in the laboratory tell whether a link works: the **eye diagram** and the **error vector** (Section 26.9), defined precisely and not by analogy.

INFO

Level and prerequisites. Level **C** (undergraduate), with two passages at level **D**: the Nyquist criterion for the absence of intersymbol interference (Theorem 26.11), which uses the Poisson summation formula, and the optimal construction of the APSK constellation

(Theorem 26.5).

Internal prerequisites. Complex exponential, Euler's formula, M -th roots of unity and their arrangement at the vertices of a regular polygon (Chapter 6: Definition 6.2, Theorem 6.2, Theorem 6.3, Proposition 6.1); the Fourier transform on L^1 and on L^2 , the convolution theorem, the Plancherel–Parseval identity, the Poisson summation formula (Chapter 19: Definition 19.1, Theorem 19.3, Theorem 19.4, Theorem 19.10, Theorem 19.12, Proposition 19.2); the sampling theorem (Chapter 24, Theorem 24.8); frequency response and transfer function (Chapter 25, Definition 25.1).

External prerequisites, assumed and not reproved:

- elementary probability: random variable, density, independence, expected value, Bayes' formula;
- the real Gaussian density and the value of the Gauss integral, already proved in the treatise (Lemma 19.4);
- the existence of the *isonormal process* that models white noise: the probabilistic construction is stated in Definition 26.10 and *imported*, with a precise statement of what is missing, in Remark 26.8;
- the strong law of large numbers, used only once and declared *imported* in Remark 26.13;
- the central limit theorem and Shannon's channel capacity theorem, cited only in a panorama remark (Remark 26.11).

Everything else is proved here.

What is learned. Passing from the real signal travelling in the antenna to the complex number that represents it, and back; recognising that the orthogonality of the two carriers is a statement with precise hypotheses and not a dogma; reading a constellation as a set of points on circles and computing its average energy, minimum distance and peak-to-average power ratio; proving that "minimum distance" and "maximum likelihood" are the same rule under Gaussian hypotheses, and knowing what those hypotheses are; deriving the matched filter from Cauchy–Schwarz and understanding why the equality case is the essential part; deriving an error probability without copying it from a table; linking minimum distance, energy per bit and spectral efficiency; defining precisely the eye diagram and the error vector.

Warning. Conventions and notation of the chapter.

- The Fourier transform is taken in the *frequency* convention of Chapter 19:

$$\hat{x}(f) = \int_{-\infty}^{+\infty} x(t) e^{-i2\pi ft} dt,$$

with no 2π factors in the exponents. Time t is in seconds, frequency f in hertz.

- $\bar{z}$ is the conjugate of $z \in \mathbb{C}$, $\Re z$ and $\Im z$ the real part and the imaginary part, $|z|$ the modulus. The scalar product between finite-energy signals is

$$\langle u, v \rangle = \int_{-\infty}^{+\infty} u(t) \overline{v(t)} dt, \quad \|u\|^2 = \langle u, u \rangle = \int_{-\infty}^{+\infty} |u(t)|^2 dt.$$

For *real* signals conjugation is inert and $\langle u, v \rangle = \int uv$.

- $f_c > 0$ is the carrier frequency, $T > 0$ the symbol duration, $R_s = 1/T$ the symbol rate (in baud), M the cardinality of the constellation, $m = \log_2 M$ the number of bits per symbol. E_s is the average energy per symbol and E_b the average energy per bit; the relation between the two, proved in Proposition 26.3, is $E_s = mE_b$.
- N_0 is the *one-sided* power spectral density of the noise, in W/Hz. The two-sided density is therefore $N_0/2$. This is the dominant convention in the digital communications literature, and it is the one for which the error probability of BPSK is written

$Q(\sqrt{2E_b/N_0})$: Remark 26.6 warns about the formulas obtained with the other convention.

- The letter Q always denotes the tail function of the standard Gaussian (Definition 26.12); it must not be confused with the symbol $\mathbb{Q}$ of the rational numbers, which does not appear in this chapter, nor with the quadrature component, which is written s_Q with the subscript.
- Numerical values are rounded to the seventh decimal digit and computed *twice by independent routes*: a closed form (or an exact identity) and an actually executed Python script, which does not use the closed form but a different method — Simpson integration for the Q function, exhaustive enumeration of point pairs for minimum distances. The symbol $\checkmark$ signals that the comparison has been made, and the discrepancy is reported.
- All constellation figures are **redrawn from the formulas**: the coordinates printed in the TikZ sources are the values of $R\cos\theta$ and $R\sin\theta$ computed from the definitions of this chapter and re-checked with the same script. No figure is taken from a standardisation document.

26.1. The bandpass signal and its complex envelope

The signal leaving an antenna is *real*: it is a voltage, and voltages have no imaginary part. It is, however, a very particular real signal, because all its energy is concentrated in a narrow strip around a large frequency f_c . This section proves that such a signal can be written in *one and only one way* as the real part of the product of a complex carrier $e^{i2\pi f_c t}$ and a slow complex signal, and that therefore all the information lies in that slow signal: two real functions of bandwidth B instead of one real function of bandwidth $2B$ centred at f_c . This is the observation on which every digital radio is built.

Definition 26.1: Bandpass signal. Let $f_c > 0$ and $0 < B < f_c$. A signal $s: \mathbb{R} \rightarrow \mathbb{R}$ of class $L^1(\mathbb{R}) \cap L^2(\mathbb{R})$ is said to be **bandpass with carrier f_c and half-bandwidth B** if its Fourier transform satisfies

$$\hat{s}(f) = 0 \quad \text{for every } f \text{ such that } ||f| - f_c| > B.$$

In other words $\hat{s}$ vanishes outside the union of the two intervals $[-f_c - B, -f_c + B]$ and $[f_c - B, f_c + B]$. The **bandwidth** of the signal is $W = 2B$: it is the width of the interval occupied around $+f_c$.

Remark 26.1: Why $B < f_c$ is required. The condition $B < f_c$ is not a technical detail: it is what makes the two intervals $[-f_c - B, -f_c + B]$ and $[f_c - B, f_c + B]$ disjoint, because their distance equals $(f_c - B) - (-f_c + B) = 2(f_c - B) > 0$. All the proofs of this section consist in separating two contributions living on those two intervals, and without disjointness the separation is not possible: the real signal would no longer be reconstructible from the positive half of its spectrum alone, and the baseband representation would lose uniqueness (Theorem 26.2). A signal that also occupies the origin — for instance a baseband signal — is not bandpass in the sense of Definition 26.1, and for it the theory of this section does not apply: this is why, in practice, f_c is always chosen much larger than the bandwidth.

Definition 26.2: Analytic signal and complex envelope. Let s be bandpass with carrier f_c and half-bandwidth B . The **analytic signal** associated with s is the complex

signal s_+ defined by its Fourier transform

$$\widehat{s_+}(f) = 2\widehat{s}(f)\mathbf{1}_{\{f>0\}}(f) = \begin{cases} 2\widehat{s}(f), & f > 0, \\ 0, & f \leq 0, \end{cases}$$

and the **complex envelope** (or **complex baseband representation**) of s is

$$s_L(t) = s_+(t)e^{-i2\pi f_c t}.$$

The two real functions

$$s_I = \Re s_L, \quad s_Q = \Im s_L$$

are called the **in-phase component** and the **quadrature component** of s .

Theorem 26.1: Complex baseband representation. Let s be bandpass with carrier f_c and half-bandwidth $B < f_c$, and let s_+ , s_L , s_I , s_Q be as in Definition 26.2. Then:

- (i) $\widehat{s_L}(f) = 2\widehat{s}(f + f_c)$ for every f , and in particular $\widehat{s_L}(f) = 0$ for $|f| > B$: the complex envelope is a baseband signal of half-bandwidth B ;
- (ii) $s(t) = \Re s_+(t)$ for every t ;
- (iii) $s(t) = \Re\{s_L(t)e^{i2\pi f_c t}\}$ for every t ;
- (iv) $s(t) = s_I(t)\cos(2\pi f_c t) - s_Q(t)\sin(2\pi f_c t)$ for every t ;
- (v) s_I and s_Q are real and their transforms also vanish outside $[-B, B]$.

Proof. First observe that $\widehat{s}$ is well defined and continuous, because $s \in L^1(\mathbb{R})$ (Definition 19.1 and Proposition 19.1), and that $\widehat{s_+} \in L^1 \cap L^2$ because it is, up to the factor 2, the restriction of $\widehat{s}$ to a half-line: hence s_+ is well defined as an inverse transform.

Step 1 — Hermitian symmetry of the spectrum of a real signal. Since s is real-valued, $\overline{s(t)} = s(t)$, and therefore for every f

$$\overline{\widehat{s}(f)} = \overline{\int_{\mathbb{R}} s(t)e^{-i2\pi ft} dt} = \int_{\mathbb{R}} \overline{s(t)} e^{+i2\pi ft} dt = \int_{\mathbb{R}} s(t) e^{-i2\pi(-f)t} dt = \widehat{s}(-f).$$

Hence $\widehat{s}(-f) = \overline{\widehat{s}(f)}$ (Theorem 19.3). Moreover $\widehat{s}(0) = 0$, because 0 is at distance $f_c > B$ from $\pm f_c$, so $||0| - f_c| = f_c > B$.

Step 2 — the spectrum of $\overline{s_+}$. Let $v(t) = \overline{s_+(t)}$. Then

$$\widehat{v}(f) = \int_{\mathbb{R}} \overline{s_+(t)} e^{-i2\pi ft} dt = \overline{\int_{\mathbb{R}} s_+(t) e^{+i2\pi ft} dt} = \overline{\widehat{s_+}(-f)}.$$

By the definition of $\widehat{s_+}$, the number $\widehat{s_+}(-f)$ is zero if $-f \leq 0$, i.e. if $f \geq 0$, and equals $2\widehat{s}(-f)$ if $f < 0$. Using Step 1, $\overline{2\widehat{s}(-f)} = 2\widehat{s}(f)$. Hence

$$\widehat{v}(f) = \begin{cases} 2\widehat{s}(f), & f < 0, \\ 0, & f \geq 0. \end{cases}$$

Step 3 — proof of (ii). By linearity of the transform (Theorem 19.3), the signal $\frac{1}{2}(s_+ + v) = \Re s_+$ has transform

$$\frac{1}{2}(\widehat{s_+}(f) + \widehat{v}(f)) = \begin{cases} \frac{1}{2} \cdot 2\widehat{s}(f) = \widehat{s}(f), & f > 0, \\ \frac{1}{2} \cdot 0 = 0 = \widehat{s}(0), & f = 0, \\ \frac{1}{2} \cdot 2\widehat{s}(f) = \widehat{s}(f), & f < 0, \end{cases}$$

where in the case $f = 0$ we used $\widehat{s}(0) = 0$ from Step 1. The two functions $\Re s_+$ and s therefore have the same Fourier transform; both are continuous (the first because it is the inverse transform of an L^1 function, the second because s is, for the same reason), and by the L^1 inversion theorem (Theorem 19.9) they coincide everywhere. This is (ii).

Step 4 — proof of (i). Multiplication by $e^{-i2\pi f_c t}$ in time is a frequency shift (Theorem 19.3):

$$\widehat{s_L}(f) = \widehat{s_+}(f + f_c) = 2\widehat{s}(f + f_c) \mathbf{1}_{\{f+f_c>0\}}.$$

If $|f| > B$ then $f + f_c$ satisfies $||f + f_c| - f_c| > B$ or $f + f_c \leq 0$: indeed for $f > B$ we have $f + f_c > f_c + B > 0$ and $|f + f_c| - f_c = f > B$; for $f < -B$ either $f + f_c \leq 0$, and then the indicator kills everything, or $0 < f + f_c < f_c - B$, and then $f_c - |f + f_c| = -f > B$. In both cases $\widehat{s_L}(f) = 0$. For $|f| \leq B$ we have $f + f_c \geq f_c - B > 0$, the indicator equals 1 and we are left with $\widehat{s_L}(f) = 2\widehat{s}(f + f_c)$. This proves (i).

Step 5 — proof of (iii) and (iv). From $s_L(t) = s_+(t)e^{-i2\pi f_c t}$ it follows that $s_+(t) = s_L(t)e^{i2\pi f_c t}$, and by (ii)

$$s(t) = \Re s_+(t) = \Re\{s_L(t)e^{i2\pi f_c t}\},$$

which is (iii). Writing $s_L = s_I + is_Q$ with s_I, s_Q real and using Euler's formula $e^{i\theta} = \cos \theta + i \sin \theta$,

$$s_L(t)e^{i2\pi f_c t} = (s_I(t) + is_Q(t))(\cos(2\pi f_c t) + i \sin(2\pi f_c t)),$$

whose product has real part $s_I(t) \cos(2\pi f_c t) - s_Q(t) \sin(2\pi f_c t)$: this is (iv).

Step 6 — proof of (v). s_I and s_Q are real by construction. We have $s_I = \frac{1}{2}(s_L + \overline{s_L})$, and repeating the computation of Step 2 with s_L in place of s_+ gives that $\overline{s_L}$ has transform $f \mapsto \widehat{s_L}(-f)$, which vanishes for $|f| > B$ because $\widehat{s_L}$ vanishes for $|-f| = |f| > B$ by point (i). Hence $\widehat{s_I}(f) = \frac{1}{2}(\widehat{s_L}(f) + \widehat{s_L}(-f)) = 0$ for $|f| > B$. The same argument with $s_Q = \frac{1}{2i}(s_L - \overline{s_L})$ gives the conclusion for s_Q . $\square$

Theorem 26.2: Uniqueness of the representation. Let s be bandpass with carrier f_c and half-bandwidth $B < f_c$. If $u \in L^1(\mathbb{R}) \cap L^2(\mathbb{R})$ is a complex-valued signal with $\widehat{u}(f) = 0$ for $|f| > B$ and

$$s(t) = \Re\{u(t)e^{i2\pi f_c t}\} \quad \text{for every } t,$$

then $u = s_L$. The complex envelope is therefore the unique signal of half-bandwidth B representing s in the form (iii) of Theorem 26.1.

Proof. Write $\Re z = \frac{1}{2}(z + \bar{z})$ with $z = u(t)e^{i2\pi f_c t}$:

$$s(t) = \frac{1}{2}u(t)e^{i2\pi f_c t} + \frac{1}{2}\overline{u(t)}e^{-i2\pi f_c t}.$$

We transform the two terms. The first, by the frequency-shift property (Theorem 19.3), has transform $\frac{1}{2}\widehat{u}(f - f_c)$, which vanishes outside $[f_c - B, f_c + B]$. The second: setting $v = \bar{u}$, the computation of Step 2 of the previous proof gives $\widehat{v}(f) = \widehat{\bar{u}}(-f)$, so $\bar{u}e^{-i2\pi f_c t}$ has transform $\widehat{v}(f + f_c) = \widehat{\bar{u}}(-f - f_c)$, which vanishes if $|-f - f_c| > B$, i.e. outside $[-f_c - B, -f_c + B]$. Hence

$$\widehat{s}(f) = \frac{1}{2}\widehat{u}(f - f_c) + \frac{1}{2}\overline{\widehat{u}(-f - f_c)},$$

a sum of two terms with *disjoint* supports: the first lives in $[f_c - B, f_c + B] \subset (0, +\infty)$ and the second in $[-f_c - B, -f_c + B] \subset (-\infty, 0)$, because $B < f_c$ (Remark 26.1). It follows that for every $f > 0$ the second term vanishes and

$$\widehat{s}(f) = \frac{1}{2}\widehat{u}(f - f_c), \quad \text{i.e.} \quad \widehat{u}(g) = 2\widehat{s}(g + f_c) \quad \text{for every } g > -f_c.$$

For $g \leq -f_c$ we have $|g| \geq f_c > B$, so $\widehat{u}(g) = 0$ by hypothesis; on the other hand $2\widehat{s}(g + f_c)$ also vanishes there by point (i) of Theorem 26.1. The equality $\widehat{u}(g) = 2\widehat{s}(g + f_c) = \widehat{s_L}(g)$ therefore holds for every $g \in \mathbb{R}$, and by the inversion theorem (Theorem 19.9) $u = s_L$. $\square$

Corollary 26.1: The IQ demodulator. Let s be bandpass with carrier f_c and half-bandwidth $B < f_c$, and let $\mathcal{L}_B$ be the ideal low-pass filtering operator of cutoff B , defined by $\widehat{\mathcal{L}_B x}(f) = \widehat{x}(f)\mathbf{1}_{[-B, B]}(f)$. Then

$$s_I = \mathcal{L}_B\{2s(t)\cos(2\pi f_c t)\}, \quad s_Q = \mathcal{L}_B\{-2s(t)\sin(2\pi f_c t)\},$$

with exact, not approximate, equality.

Proof. Set $\theta = \theta(t) = 2\pi f_c t$. By point (iv) of Theorem 26.1, $s = s_I \cos \theta - s_Q \sin \theta$, so

$$2s \cos \theta = 2s_I \cos^2 \theta - 2s_Q \sin \theta \cos \theta = s_I(1 + \cos 2\theta) - s_Q \sin 2\theta = s_I + \underbrace{(s_I \cos 2\theta - s_Q \sin 2\theta)}_{=:r},$$

where the identities $2\cos^2 \theta = 1 + \cos 2\theta$ and $2\sin \theta \cos \theta = \sin 2\theta$ were used. The term r is, by the same computation of Theorem 26.1(iv) read backwards with carrier $2f_c$, the real part of $s_L(t)e^{i4\pi f_c t}$; by Step 4 of that proof and by Step 2, its transform vanishes outside $[2f_c - B, 2f_c + B] \cup [-2f_c - B, -2f_c + B]$. Since $2f_c - B > B$ — indeed $2f_c - B > B$ is equivalent to $f_c > B$, which is the hypothesis — this set is disjoint from $[-B, B]$, and hence $\mathcal{L}_B r = 0$. On the other hand $\widehat{s}_I$ vanishes outside $[-B, B]$ by point (v), so $\mathcal{L}_B s_I = s_I$. By linearity $\mathcal{L}_B\{2s \cos \theta\} = s_I + 0 = s_I$.

Similarly, with $2\sin^2 \theta = 1 - \cos 2\theta$,

$$-2s \sin \theta = -2s_I \sin \theta \cos \theta + 2s_Q \sin^2 \theta = -s_I \sin 2\theta + s_Q(1 - \cos 2\theta) = s_Q - (s_I \sin 2\theta + s_Q \cos 2\theta),$$

and the term in parentheses is the *imaginary* part, with sign reversed, of $s_L e^{i4\pi f_c t}$, with the same spectral support around $\pm 2f_c$: the filter kills it and s_Q remains. $\square$

Proposition 26.1: Energy is halved when passing to baseband. Under the hypotheses of Theorem 26.1,

$$\int_{-\infty}^{+\infty} s(t)^2 dt = \frac{1}{2} \int_{-\infty}^{+\infty} |s_L(t)|^2 dt = \frac{1}{2} \int_{-\infty}^{+\infty} (s_I(t)^2 + s_Q(t)^2) dt.$$

Proof. As in the proof of Theorem 26.2 (with $u = s_L$),

$$\widehat{s}(f) = \frac{1}{2} \widehat{s}_L(f - f_c) + \frac{1}{2} \overline{\widehat{s}_L(-f - f_c)},$$

and the two terms have disjoint supports. For two functions a, b with disjoint supports, $|a + b|^2 = |a|^2 + |b|^2$ pointwise, because at every point at least one of the two vanishes. Hence, by the Plancherel–Parseval identity (Theorem 19.10),

$$\int_{\mathbb{R}} s^2 dt = \int_{\mathbb{R}} |\widehat{s}(f)|^2 df = \frac{1}{4} \int_{\mathbb{R}} |\widehat{s}_L(f - f_c)|^2 df + \frac{1}{4} \int_{\mathbb{R}} |\overline{\widehat{s}_L(-f - f_c)}|^2 df.$$

In the first integral the substitution $g = f - f_c$ gives $\frac{1}{4} \|\widehat{s}_L\|^2$; in the second the substitution $g = -f - f_c$, which is an affinity of modulus of determinant -1 , also gives $\frac{1}{4} \|\widehat{s}_L\|^2$ (the modulus of the conjugate is the modulus). In total $\|\widehat{s}\|^2 = \frac{1}{2} \|\widehat{s}_L\|^2$, and again by Plancherel–Parseval $\|s\|^2 = \frac{1}{2} \|s_L\|^2$. The last equality of the statement is $|s_L|^2 = s_I^2 + s_Q^2$, i.e. $|a + ib|^2 = a^2 + b^2$ for real a, b . $\square$

Remark 26.2: What the Hilbert transform is, and why it is not needed here. The literature usually defines the analytic signal as $s_+ = s + i\mathcal{H}s$, where $\mathcal{H}$ is the **Hilbert transform**, the operator that in frequency multiplies by $-i \operatorname{sgn}(f)$. The two definitions

coincide: if $\widehat{\mathcal{H}s}(f) = -i \operatorname{sgn}(f) \widehat{s}(f)$ then

$$\widehat{s + i\mathcal{H}s}(f) = (1 + \operatorname{sgn}(f))\widehat{s}(f) = \begin{cases} 2\widehat{s}(f), & f > 0, \\ \widehat{s}(0), & f = 0, \\ 0, & f < 0, \end{cases}$$

and $\widehat{s}(0) = 0$ by Step 1 of the proof of Theorem 26.1. We have preferred the spectral definition of Definition 26.2 because it requires neither constructing $\mathcal{H}$ nor discussing the principal-value integral by which it acts in time: the proof stays entirely within the tools of Chapter 19. Readers consulting the sources will find the other route; the two paths arrive at the same s_+ .

Figure 26.1: The shift of Definition 26.2, drawn with $f_c = 3.2$ and $B = 0.8$ in the units of the figure. In (i) the spectrum of a real bandpass signal: two humps symmetric about the origin, each of width $W = 2B$, linked by the Hermitian symmetry $\widehat{s}(-f) = \widehat{s}(f)$ (Step 1 of the proof of Theorem 26.1). In (ii) the spectrum of the complex envelope: only the positive hump is kept, it is doubled and shifted to the origin. The hump in (ii) is drawn twice as tall as the one in (i) precisely because $\widehat{s}_L(f) = 2\widehat{s}(f + f_c)$; it is not symmetric, and need not be, because s_L is not real. The heights and abscissas of the four vertices of each polyline are those written in the source and do not come from any measurement.

Example 26.1: A tone shifted in frequency. Let $s(t) = A \cos(2\pi(f_c + \nu)t + \varphi)$ with $A > 0$, $|\nu| < B < f_c$ and $\varphi \in \mathbb{R}$. Then

$$s(t) = \Re\left\{A e^{i\varphi} e^{i2\pi\nu t} e^{i2\pi f_c t}\right\},$$

and the factor $u(t) = A e^{i\varphi} e^{i2\pi\nu t}$ is a signal whose transform (in the sense of tempered distributions, Definition 19.7) is concentrated at the single point ν , with $|\nu| < B$. By Theorem 26.2 it follows that $s_L(t) = A e^{i\varphi} e^{i2\pi\nu t}$, and

$$s_I(t) = A \cos(2\pi\nu t + \varphi), \quad s_Q(t) = A \sin(2\pi\nu t + \varphi).$$

The tone, which in the real domain was a sinusoid at frequency $f_c + \nu$, in baseband is a point rotating on the circle of radius A with angular velocity $2\pi\nu$: a frequency offset is a *slow rotation* of the constellation, and this is exactly how a frequency error manifests itself in a real receiver.

Independent check. Applying Corollary 26.1 directly: $2s(t) \cos(2\pi f_c t) = A \cos(2\pi \nu t + \varphi) + A \cos(2\pi(2f_c + \nu)t + \varphi)$ by the product-to-sum formula $2 \cos \alpha \cos \beta = \cos(\alpha - \beta) + \cos(\alpha + \beta)$; the second term has frequency $2f_c + \nu > 2f_c - B > B$ and is removed by the filter, the first is s_I . ✓

26.2. Orthogonality of the two carriers

Corollary 26.1 recovers s_I and s_Q with an ideal low-pass filter, which is a mathematical object and not a circuit. The real receiver does something rougher and more useful: it multiplies by the two carriers and *integrates over the symbol interval*. For this to work, the two carriers must be orthogonal with respect to that scalar product. This section proves that they are — but not always: they are exactly orthogonal when $2f_c T$ is an integer, and otherwise they are orthogonal up to an error that can be computed and bounded. The difference between "orthogonal" and "orthogonal up to $1/(4\pi f_c)$ " is what separates a statement from a slogan.

Proposition 26.2: The three integrals of the carriers over a symbol interval. Let $f_c > 0$ and $T > 0$. Then

$$\int_0^T \cos(2\pi f_c t) \sin(2\pi f_c t) dt = \frac{\sin^2(2\pi f_c T)}{4\pi f_c},$$

$$\int_0^T \cos^2(2\pi f_c t) dt = \frac{T}{2} + \frac{\sin(4\pi f_c T)}{8\pi f_c}, \quad \int_0^T \sin^2(2\pi f_c t) dt = \frac{T}{2} - \frac{\sin(4\pi f_c T)}{8\pi f_c}.$$

In particular:

- (i) the three integrals equal exactly 0, $T/2$ and $T/2$ **if and only if** $2f_c T \in \mathbb{Z}$, i.e. if and only if the symbol duration is an integer multiple of the half-period of the carrier;
- (ii) in every case

$$0 \leq \int_0^T \cos(2\pi f_c t) \sin(2\pi f_c t) dt \leq \frac{1}{4\pi f_c}, \quad \left| \int_0^T \cos^2(2\pi f_c t) dt - \frac{T}{2} \right| \leq \frac{1}{8\pi f_c},$$

and hence the relative discrepancy from the value $T/2$ is bounded by $\frac{1}{2\pi f_c T}$, which tends to zero as the number $f_c T$ of carrier periods contained in a symbol grows.

Proof. Step 1 — the mixed product. From the duplication identity $2 \sin \alpha \cos \alpha = \sin 2\alpha$, with $\alpha = 2\pi f_c t$,

$$\int_0^T \cos(2\pi f_c t) \sin(2\pi f_c t) dt = \frac{1}{2} \int_0^T \sin(4\pi f_c t) dt = \frac{1}{2} \left[\frac{-\cos(4\pi f_c t)}{4\pi f_c} \right]_0^T = \frac{1 - \cos(4\pi f_c T)}{8\pi f_c}.$$

By the half-angle formula $1 - \cos x = 2 \sin^2(x/2)$, applied with $x = 4\pi f_c T$,

$$\frac{1 - \cos(4\pi f_c T)}{8\pi f_c} = \frac{2 \sin^2(2\pi f_c T)}{8\pi f_c} = \frac{\sin^2(2\pi f_c T)}{4\pi f_c},$$

which is the first formula.

Step 2 — the two squares. From $\cos^2 \alpha = \frac{1}{2}(1 + \cos 2\alpha)$,

$$\int_0^T \cos^2(2\pi f_c t) dt = \frac{1}{2} \int_0^T dt + \frac{1}{2} \int_0^T \cos(4\pi f_c t) dt = \frac{T}{2} + \frac{1}{2} \left[\frac{\sin(4\pi f_c t)}{4\pi f_c} \right]_0^T = \frac{T}{2} + \frac{\sin(4\pi f_c T)}{8\pi f_c}.$$

From $\sin^2 \alpha = \frac{1}{2}(1 - \cos 2\alpha)$ one obtains the third formula with the opposite sign. Note, as a check, that the sum of the two integrals equals T , as it must by the identity $\cos^2 + \sin^2 = 1$. ✓

Step 3 — point (i). The first integral vanishes if and only if $\sin(2\pi f_c T) = 0$, i.e. if and only if $2\pi f_c T = k\pi$ for some $k \in \mathbb{Z}$, i.e. $2f_c T = k \in \mathbb{Z}$. If $2f_c T = k$ then $4\pi f_c T = 2k\pi$ and $\sin(4\pi f_c T) = 0$: the two squares also equal exactly $T/2$. Conversely, if the second integral equals $T/2$ then $\sin(4\pi f_c T) = 0$, i.e. $4f_c T \in \mathbb{Z}$: this is weaker than $2f_c T \in \mathbb{Z}$, and indeed for $2f_c T = k + \frac{1}{2}$ the two squares equal $T/2$ while the mixed product equals $\sin^2((k + \frac{1}{2})\pi)/(4\pi f_c) = 1/(4\pi f_c) \neq 0$: this is the worst case. The necessary and sufficient condition for *all three* equalities to hold is therefore that of the mixed product, $2f_c T \in \mathbb{Z}$.

Step 4 — point (ii). Since $0 \leq \sin^2 x \leq 1$ and $|\sin x| \leq 1$ for every real x , the three formulas immediately give $0 \leq \sin^2(2\pi f_c T)/(4\pi f_c) \leq 1/(4\pi f_c)$ and $|\sin(4\pi f_c T)/(8\pi f_c)| \leq 1/(8\pi f_c)$. Dividing the first bound by $T/2$:

$$\frac{1/(4\pi f_c)}{T/2} = \frac{1}{2\pi f_c T},$$

which is the announced relative estimate; for the second integral the relative discrepancy is half of this. $\square$

Example 26.2: Two numbers, one exact and one not. Take $f_c = 2,400$ Hz and $T = 1/600$ s. Then $2f_c T = 2 \cdot 2400/600 = 8 \in \mathbb{Z}$: we are in the exact case of Proposition 26.2(i), and

$$\int_0^T \cos(2\pi f_c t) \sin(2\pi f_c t) dt = 0, \quad \int_0^T \cos^2(2\pi f_c t) dt = \frac{T}{2} = 8.3333333 \cdot 10^{-4} \text{ s.}$$

Now take $f_c = 2,500$ Hz with the same $T = 1/600$ s. Now $2f_c T = 25/3 \notin \mathbb{Z}$, and $2\pi f_c T = 25\pi/3$; since $25\pi/3 - 8\pi = \pi/3$, we have $\sin(2\pi f_c T) = \sin(\pi/3) = \sqrt{3}/2$ and $\sin^2(2\pi f_c T) = 3/4$, hence

$$\int_0^T \cos(2\pi f_c t) \sin(2\pi f_c t) dt = \frac{3/4}{4\pi \cdot 2500} = \frac{3}{40000\pi} = 2.3873241 \cdot 10^{-5} \text{ s,}$$

i.e. 2.8647890% of $T/2$. Similarly, $4\pi f_c T = 50\pi/3$ and $50\pi/3 - 16\pi = 2\pi/3$, so $\sin(4\pi f_c T) = \sin(2\pi/3) = \sqrt{3}/2$ and

$$\int_0^T \cos^2(2\pi f_c t) dt = \frac{T}{2} + \frac{\sqrt{3}/2}{8\pi \cdot 2500} = 8.3333333 \cdot 10^{-4} + 1.3783222 \cdot 10^{-5} = 8.4711656 \cdot 10^{-4} \text{ s.}$$

The bound (ii) gives a relative discrepancy not exceeding $1/(2\pi f_c T) = 6/(50\pi) = 3.8197186\%$, consistent with the 2.8647890% found. $\checkmark$

Independent check. A Python script that numerically integrates the three integrands with Simpson's rule over 200,000 subintervals returns $9.6 \cdot 10^{-20}$ in the first case (i.e. zero up to machine error) and $2.3873241 \cdot 10^{-5}$ in the second, with a discrepancy from the closed form of $1.7 \cdot 10^{-20}$; the integral of the square gives $8.4711656 \cdot 10^{-4}$. $\checkmark$

Corollary 26.2: The two carriers as an orthonormal basis. If $2f_c T \in \mathbb{Z}$, the two functions

$$\phi_1(t) = \sqrt{\frac{2}{T}} \cos(2\pi f_c t), \quad \phi_2(t) = -\sqrt{\frac{2}{T}} \sin(2\pi f_c t), \quad t \in [0, T],$$

form an orthonormal system in $L^2([0, T])$: $\langle \phi_1, \phi_1 \rangle = \langle \phi_2, \phi_2 \rangle = 1$ and $\langle \phi_1, \phi_2 \rangle = 0$. Consequently, if s_I and s_Q are constant on $[0, T]$ and equal $\Re a$ and $\Im a$ respectively for some

$a \in \mathbb{C}$, the signal $s(t) = \Re\{a e^{i2\pi f_c t}\}$ restricted to $[0, T]$ is written

$$s = \sqrt{\frac{T}{2}} \left((\Re a) \phi_1 + (\Im a) \phi_2 \right), \quad \int_0^T s(t)^2 dt = \frac{T}{2} |a|^2.$$

Proof. By Proposition 26.2 with $2f_c T \in \mathbb{Z}$: $\int_0^T \cos^2 = \int_0^T \sin^2 = T/2$ and $\int_0^T \cos \sin = 0$. Multiplying by the factor $2/T$ gives $\|\phi_1\|^2 = \|\phi_2\|^2 = (2/T)(T/2) = 1$ and $\langle \phi_1, \phi_2 \rangle = -(2/T) \cdot 0 = 0$.

For the second part, Theorem 26.1(iv) with $s_I \equiv \Re a$ and $s_Q \equiv \Im a$ gives $s(t) = (\Re a) \cos(2\pi f_c t) - (\Im a) \sin(2\pi f_c t)$, and substituting $\cos(2\pi f_c t) = \sqrt{T/2} \phi_1(t)$ and $-\sin(2\pi f_c t) = \sqrt{T/2} \phi_2(t)$ gives the formula. The energy is computed with the Pythagorean theorem in $L^2([0, T])$, valid because $\phi_1 \perp \phi_2$:

$$\|s\|^2 = \frac{T}{2} \left((\Re a)^2 \|\phi_1\|^2 + (\Im a)^2 \|\phi_2\|^2 \right) = \frac{T}{2} ((\Re a)^2 + (\Im a)^2) = \frac{T}{2} |a|^2.$$

□

Remark 26.3: Where the hypothesis $2f_c T \in \mathbb{Z}$ hides in real systems. No real system guarantees $2f_c T \in \mathbb{Z}$: the carrier comes from one oscillator and the symbol frequency from another, and the two are not in a controlled rational ratio. What is guaranteed is the inequality $f_c T \gg 1$ — typically f_c is of the order of gigahertz and $R_s = 1/T$ of the order of megabaud, so that $f_c T$ is of the order of 10^3 — and then Proposition 26.2(ii) says that the relative discrepancy from orthogonality is at most $1/(2\pi f_c T) \approx 1.6 \cdot 10^{-4}$, entirely negligible compared with every other imperfection. This is the honest way of saying "the two carriers are orthogonal": it is not an identity, it is an inequality with an explicit constant. It should be added that in practice one does not multiply by the carrier and integrate over $[0, T]$, but filters with the transmit pulse (Section 26.6), which does not change the substance of the argument because the pulse, too, is slow compared with f_c .

Figure 26.2: The quadrature modulator and demodulator. On the left, Theorem 26.1(iv), read as a block diagram: the two components multiply $\cos(2\pi f_c t)$ and $-\sin(2\pi f_c t)$ respectively and are summed. On the right, Corollary 26.1: one multiplies by $2\cos(2\pi f_c t)$ and by $-2\sin(2\pi f_c t)$ and removes with the low-pass filter $\mathcal{L}_B$ the term around $2f_c$ that this multiplication generates. The two branches do not disturb each other because the carriers are orthogonal (Proposition 26.2 and Corollary 26.2): this is the only reason two independent streams can occupy the same frequency.

26.3. Constellations: points on the circle

Once the way of transmitting a pair (s_I, s_Q) is fixed, it remains to decide *which* pairs to use. The set of admitted values is the constellation, and the choice of which finite set of points of the complex plane to use is the design core of digital modulation: one wants many points (to carry many bits per symbol) well separated from each other (to withstand noise) and of not too

different modulus (so as not to mistreat the power amplifier). The three wishes conflict, and this section and the next quantify them.

Definition 26.3: Constellation, energy, minimum distance. Let $M \geq 2$ be an integer. A **constellation** of order M is a finite set $\mathcal{A} = \{a_0, \dots, a_{M-1}\} \subset \mathbb{C}$ of M distinct points, called **symbols**. Assuming the symbols are **equiprobable**, one defines:

- the **average energy per symbol** in baseband $E_s = \frac{1}{M} \sum_{j=0}^{M-1} |a_j|^2$;
- the number of **bits per symbol** $m = \log_2 M$ (the constellations used here have M a power of two, so that $m \in \mathbb{N}$) and the **average energy per bit** $E_b = E_s/m$;
- the **minimum distance** $d_{\min}(\mathcal{A}) = \min_{j \neq l} |a_j - a_l|$;
- the **peak-to-average power ratio** $\text{PAPR}(\mathcal{A}) = \frac{\max_j |a_j|^2}{E_s}$.

A **mapping** is a bijection $\mu: \{0, 1\}^m \rightarrow \mathcal{A}$ that assigns each word of m bits to a symbol.

Proposition 26.3: Energy per bit and energy per symbol. Transmit a sequence of K symbols chosen independently and uniformly in $\mathcal{A}$. The overall average baseband energy is KE_s , the transmitted bits are Km , and hence the average energy spent per bit equals $E_s/m = E_b$, independently of K . If the symbol is transmitted in bandpass form over an interval of duration T as in Corollary 26.2, the energy of the real signal per symbol equals $\frac{T}{2}E_s$ and that per bit $\frac{T}{2}E_b$: the factor $T/2$ is common and does not affect any energy ratio.

Proof. Let $A_1, \dots, A_K$ be the transmitted symbols, independent and uniform on $\mathcal{A}$. The baseband energy of the sequence is $\sum_{k=1}^K |A_k|^2$, and by linearity of expectation

$$\mathbb{E} \left[\sum_{k=1}^K |A_k|^2 \right] = \sum_{k=1}^K \mathbb{E}[|A_k|^2] = \sum_{k=1}^K \frac{1}{M} \sum_{j=0}^{M-1} |a_j|^2 = K E_s,$$

where the definition of expected value for a variable uniform on a finite set was used. Each symbol carries m bits and there are K symbols: the bits are Km . The ratio between average energy and number of bits is $KE_s/(Km) = E_s/m$, which does not depend on K . The last statement is Corollary 26.2, according to which $\int_0^T s^2 = \frac{T}{2}|a|^2$: averaging over a uniform in $\mathcal{A}$ gives $\frac{T}{2}E_s$, and dividing by m gives $\frac{T}{2}E_b$. $\square$

Definition 26.4: M-PSK phase modulation. Let $M \geq 2$, $E_s > 0$ and $\varphi_0 \in \mathbb{R}$. The **M-PSK** constellation of energy E_s and initial phase φ_0 is

$$\mathcal{A}_{M\text{-PSK}} = \left\{ a_k = \sqrt{E_s} e^{i\left(\frac{2\pi k}{M} + \varphi_0\right)} : k = 0, 1, \dots, M-1 \right\}.$$

The particular cases have their own names: $M = 2$ gives **BPSK** (*binary phase shift keying*), which with $\varphi_0 = 0$ is $\{+\sqrt{E_s}, -\sqrt{E_s}\}$; $M = 4$ gives **QPSK** (*quaternary*), which with $\varphi_0 = \pi/4$ is $\{\sqrt{E_s}/2(\pm 1 \pm i)\}$; $M = 8$ gives **8-PSK**.

Remark 26.4: The roots of unity, rotated and dilated. Setting $\zeta_M = e^{i2\pi/M}$, Definition 26.4 is rewritten $a_k = \sqrt{E_s} e^{i\varphi_0} \zeta_M^k$: the M -PSK constellation is exactly the set of M -th roots of unity (Definition 6.2), which are M in number by Theorem 6.2, multiplied by the complex number $\sqrt{E_s} e^{i\varphi_0}$, i.e. rotated by φ_0 and dilated by $\sqrt{E_s}$. By Theorem 6.3 its points are the vertices of a regular M -gon inscribed in the circle of radius $\sqrt{E_s}$. Every geometric property of the regular polygon is therefore immediately a property of the modula-

tion: the rotational symmetry of order M says that all symbols are equivalent (and indeed the error probability does not depend on which symbol was transmitted, Corollary 26.4), and the formula for the side of the regular polygon is the minimum distance (Theorem 26.3). Even the elementary fact that $\sum_k \zeta_M^k = 0$ for $M \geq 2$ (Theorem 6.4) has a meaning: the centroid of the constellation is the origin, i.e. the modulation does not waste energy in a DC component.

Lemma 26.1: The chord of the unit circle. For every $\alpha, \beta \in \mathbb{R}$, $|e^{i\alpha} - e^{i\beta}| = 2 \left| \sin \frac{\alpha - \beta}{2} \right|$.

Proof. Factor out the average phase term:

$$e^{i\alpha} - e^{i\beta} = e^{i\frac{\alpha+\beta}{2}} \left(e^{i\frac{\alpha-\beta}{2}} - e^{-i\frac{\alpha-\beta}{2}} \right).$$

The equality is checked by multiplying out: the first product gives $e^{i(\alpha+\beta)/2+i(\alpha-\beta)/2} = e^{i\alpha}$ and the second $e^{i(\alpha+\beta)/2-i(\alpha-\beta)/2} = e^{i\beta}$. By Euler's formula, $e^{i\theta} - e^{-i\theta} = 2i \sin \theta$ with $\theta = (\alpha - \beta)/2$. Taking moduli and using $|e^{i\gamma}| = 1$ and $|2i \sin \theta| = 2|\sin \theta|$ concludes the proof. $\square$

Theorem 26.3: Minimum distance of M -PSK. For the M -PSK constellation of energy E_s (Definition 26.4),

$$d_{\min} = 2\sqrt{E_s} \sin \frac{\pi}{M},$$

for every $M \geq 2$ and every φ_0 , and the minimum is attained exactly by pairs of adjacent symbols, i.e. with indices k, l such that $k - l \equiv \pm 1 \pmod{M}$.

Proof. By Lemma 26.1, with $\alpha = \frac{2\pi k}{M} + \varphi_0$ and $\beta = \frac{2\pi l}{M} + \varphi_0$ (the phases φ_0 cancel in the difference),

$$|a_k - a_l| = \sqrt{E_s} |e^{i\alpha} - e^{i\beta}| = 2\sqrt{E_s} \left| \sin \frac{\pi(k-l)}{M} \right|.$$

Setting $j = \langle k - l \rangle_M \in \{1, \dots, M-1\}$ (the remainder of $k - l$ modulo M , nonzero because $k \neq l$), and observing that $\sin \frac{\pi(k-l)}{M}$ and $\sin \frac{\pi j}{M}$ differ at most by sign — indeed $k - l = j + qM$ and $\sin(\frac{\pi j}{M} + q\pi) = (-1)^q \sin \frac{\pi j}{M}$ — we get

$$d_{\min} = 2\sqrt{E_s} \cdot \min_{1 \leq j \leq M-1} \sin \frac{\pi j}{M},$$

where the absolute value has been dropped because for $1 \leq j \leq M-1$ the argument $\pi j/M$ lies in $(0, \pi)$ and there the sine is positive.

It remains to minimise $j \mapsto \sin(\pi j/M)$ over $\{1, \dots, M-1\}$. The identity $\sin \frac{\pi(M-j)}{M} = \sin(\pi - \frac{\pi j}{M}) = \sin \frac{\pi j}{M}$ holds: the function is symmetric under $j \mapsto M - j$, and it therefore suffices to minimise it for $1 \leq j \leq M/2$. On that interval $\pi j/M \in (0, \pi/2]$, where the sine is *strictly increasing* (the derivative $\cos$ is positive on $[0, \pi/2)$): the minimum is at $j = 1$ and equals $\sin(\pi/M)$. By symmetry the same value is attained at $j = M-1$, and at no other j if $M \geq 3$ (for $M = 2$ the two indices coincide). Hence $d_{\min} = 2\sqrt{E_s} \sin(\pi/M)$, attained only by pairs with $k - l \equiv \pm 1 \pmod{M}$. $\square$

Corollary 26.3: *BPSK and QPSK have the same minimum distance at equal energy per bit. With the notation of Definition 26.3:*

$$\text{BPSK } (m = 1, E_s = E_b) : \quad d_{\min} = 2\sqrt{E_s} = 2\sqrt{E_b};$$

$$\text{QPSK } (m = 2, E_s = 2E_b) : \quad d_{\min} = 2\sqrt{E_s} \sin \frac{\pi}{4} = \sqrt{2} \sqrt{E_s} = \sqrt{2} \sqrt{2E_b} = 2\sqrt{E_b}.$$

The two constellations therefore have the same minimum distance when the same energy per bit is spent, even though QPSK carries twice as many bits per symbol.

Proof. For $M = 2$, Theorem 26.3 gives $d_{\min} = 2\sqrt{E_s} \sin(\pi/2) = 2\sqrt{E_s}$, and $m = \log_2 2 = 1$ gives $E_b = E_s$ by Definition 26.3. For $M = 4$ we have $\sin(\pi/4) = \sqrt{2}/2$, hence $d_{\min} = 2\sqrt{E_s} \cdot \frac{\sqrt{2}}{2} = \sqrt{2}\sqrt{E_s}$; and $m = \log_2 4 = 2$ gives $E_s = 2E_b$, from which $\sqrt{2}\sqrt{E_s} = \sqrt{2} \cdot \sqrt{2E_b} = 2\sqrt{E_b}$. $\square$

Proposition 26.4: *QPSK is the superposition of two orthogonal BPSKs. Let $\mathcal{A}$ be the QPSK constellation of energy E_s with $\varphi_0 = \pi/4$, i.e.*

$$\mathcal{A} = \left\{ \sqrt{\frac{E_s}{2}} (\varepsilon_1 + i\varepsilon_2) : \varepsilon_1, \varepsilon_2 \in \{+1, -1\} \right\}.$$

Then the in-phase and quadrature components of a symbol each take only the two values $\pm\sqrt{E_s/2} = \pm\sqrt{E_b}$, i.e. they are two BPSKs of energy E_b , and the mapping $(\varepsilon_1, \varepsilon_2) \mapsto a$ makes them independent if the two bits are independent and uniform.

Proof. With $\varphi_0 = \pi/4$ the four phases are $\pi/4, 3\pi/4, 5\pi/4, 7\pi/4$, and $\cos$ and $\sin$ of each equal $\pm\frac{\sqrt{2}}{2}$: explicitly $\sqrt{E_s}e^{i\pi/4} = \sqrt{E_s}(\frac{\sqrt{2}}{2} + i\frac{\sqrt{2}}{2}) = \sqrt{E_s/2}(1+i)$, and similarly for the other three, which correspond to the four sign choices. Hence $\Re a = \varepsilon_1\sqrt{E_s/2}$ and $\Im a = \varepsilon_2\sqrt{E_s/2}$. By Definition 26.3 with $M = 4$ we have $m = 2$ and $E_b = E_s/2$, so $\sqrt{E_s/2} = \sqrt{E_b}$: each component is a BPSK of energy E_b , in agreement with Corollary 26.3. Independence is immediate: the pair $(\varepsilon_1, \varepsilon_2)$ determines a and conversely, so if the two bits are independent so are the two components. $\square$

Definition 26.5: Gray mapping. A mapping $\mu: \{0, 1\}^m \rightarrow \mathcal{A}$ is said to be **Gray** if every pair of symbols at distance $d_{\min}$ corresponds to a pair of binary words that differ in *exactly one bit*.

Proposition 26.5: *A Gray mapping exists for M-PSK. For every $M = 2^m$ the M-PSK constellation admits a Gray mapping.*

Proof. By Theorem 26.3 the pairs at distance $d_{\min}$ are exactly those with consecutive indices modulo M . It therefore suffices to exhibit a bijection $g: \{0, \dots, M-1\} \rightarrow \{0, 1\}^m$ such that $g(k)$ and $g(k+1)$ differ in exactly one bit for every k , and also $g(M-1)$ and $g(0)$. Take the **reflected Gray code**, defined for $k = \sum_{t=0}^{m-1} b_t 2^t$ by

$$g(k) = (c_{m-1}, \dots, c_0), \quad c_t = b_t \oplus b_{t+1} \quad (t < m-1), \quad c_{m-1} = b_{m-1},$$

where $\oplus$ is addition modulo 2. The map is bijective because it can be inverted explicitly: $b_{m-1} = c_{m-1}$ and $b_t = c_t \oplus b_{t+1}$ for decreasing t , which uniquely reconstructs k from $g(k)$. That $g(k)$ and $g(k+1)$ differ in exactly one bit is seen as follows. Let t_0 be the position of the least significant bit of k equal to 0; adding 1 to k flips that bit to 1 and all bits of position $< t_0$ to 0, leaving those of position $> t_0$ unchanged. So, writing b and b' for the bits of k and $k+1$: $b'_t = b_t$ for $t > t_0$, $b'_{t_0} = 1 \neq 0 = b_{t_0}$, and $b'_t = 0$, $b_t = 1$ for $t < t_0$. It follows, for $t > t_0$, that $c'_t = b'_t \oplus b'_{t+1} = b_t \oplus b_{t+1} = c_t$; for $t = t_0$, $c'_{t_0} = b'_{t_0} \oplus b'_{t_0+1} = 1 \oplus b_{t_0+1} \neq 0 \oplus b_{t_0+1} = c_{t_0}$;

for $t < t_0 - 1$, $c'_t = 0 \oplus 0 = 0$ and $c_t = 1 \oplus 1 = 0$, equal; for $t = t_0 - 1$ (if $t_0 \geq 1$), $c'_{t_0-1} = b'_{t_0-1} \oplus b'_{t_0} = 0 \oplus 1 = 1$ and $c_{t_0-1} = b_{t_0-1} \oplus b_{t_0} = 1 \oplus 0 = 1$, equal. In total only the bit of position t_0 changes.

There remains the cyclic pair $(M - 1, 0)$. For $k = M - 1 = 2^m - 1$ all the b_t equal 1, hence $c_{m-1} = 1$ and $c_t = 1 \oplus 1 = 0$ for $t < m - 1$: $g(M - 1) = (1, 0, \dots, 0)$. For $k = 0$ all the b_t equal 0 and $g(0) = (0, 0, \dots, 0)$. The two words differ in only the most significant bit. $\square$

Figure 26.3: The three PSK constellations, drawn from Definition 26.4 with $\varphi_0 = 0$ for BPSK, $\varphi_0 = \pi/8$ for 8-PSK, and $\varphi_0 = \pi/4$ for QPSK. The radius of the dashed circle is $\sqrt{E_s}$, here 1.35 cm. The coordinates of the points are $R \cos \theta$ and $R \sin \theta$ with $R = 1.35$: for QPSK $1.35 \cdot \frac{\sqrt{2}}{2} = 0.9546$; for 8-PSK $1.35 \cos 22.5^\circ = 1.2473$ and $1.35 \sin 22.5^\circ = 0.5166$, and the boundaries between decision regions lie at $0^\circ, 45^\circ, \dots$ with $1.7 \cdot \frac{\sqrt{2}}{2} = 1.2021$. The thick lines are the boundaries of the minimum-distance decision regions (Theorem 26.7): for PSK these are the circular sectors bounded by the bisectors of the arcs between adjacent symbols. The binary labels follow a Gray mapping (Proposition 26.5).

Example 26.3: The numerical values of the minimum distance. With $E_s = 1$, Theorem 26.3 gives the following values.

M	$m = \log_2 M$	π/M	$d_{\min} = 2 \sin(\pi/M)$	$d_{\min}^2/(4E_b)$
2	1	$\pi/2$	2.0000000	1.0000000
4	2	$\pi/4$	1.4142136	1.0000000
8	3	$\pi/8$	0.7653669	0.4393398
16	4	$\pi/16$	0.3901806	0.1522409
32	5	$\pi/32$	0.1960343	0.0480368

The last column, computed with $E_b = E_s/m = 1/m$ and hence equal to $m d_{\min}^2/4$, is the ratio that will appear in the argument of the Q function (Theorem 26.9 and Remark 26.10). The first two rows are equal, which is the content of Corollary 26.3: QPSK doubles the bits per symbol *without* paying anything in minimum distance at equal energy per bit. From the third row on one pays, and dearly: going from 4 to 8 points the ratio drops by a factor $1/0.4393398 = 2.2761424$, and from 4 to 32 by a factor $1/0.0480368 = 20.8173$.

Independent check. A Python script that builds the M roots of unity in floating-point arithmetic and *enumerates all* $M(M - 1)$ ordered pairs, computing the modulus of the difference, returns, for $M = 2, 4, 8, 16, 32$, the same values with maximum discrepancy $6.9 \cdot 10^{-16}$ from the closed form. $\checkmark$

26.4. QAM and APSK: points on several circles

M -PSK spends all its energy on the same circle, and for large M the points crowd together: Theorem 26.3 says the minimum distance decreases like $2\pi\sqrt{E_s}/M$, because $\sin x \sim x$. To escape

this bottleneck one must also use the *modulus*, i.e. arrange the points on several concentric circles. The two classical families are QAM, which arranges the points on a square grid — and hence, read in polar coordinates, on circles with unequal populations — and APSK, which arranges them on a few circles with chosen populations.

Definition 26.6: Square M -QAM quadrature amplitude modulation. Let $M = L^2$ with $L \geq 2$ an even integer, and let $\Delta > 0$. The **square M -QAM** constellation of step Δ is

$$\mathcal{A}_{M\text{-QAM}} = \left\{ \Delta[(2u-1-L) + i(2v-1-L)] : u, v \in \{1, \dots, L\} \right\}.$$

The two coordinates independently range over the L levels $\Delta\{-(L-1), -(L-3), \dots, L-3, L-1\}$, symmetric about the origin and 2Δ apart from one another. For $L = 4$ the levels are $\Delta\{-3, -1, 1, 3\}$ and one obtains 16-QAM.

Lemma 26.2: Sum of squares of the levels. For every integer $L \geq 1$, $\sum_{u=1}^L (2u-1-L)^2 = \frac{L(L^2-1)}{3}$.

Proof. As u ranges from 1 to L the number $2u-1-L$ runs, in steps of two, through the values from $1-L$ to $L-1$: these are L integers, all of parity opposite to that of L , symmetric about 0.

Case L even. The values are $\pm 1, \pm 3, \dots, \pm(L-1)$, i.e. the first $L/2$ odd numbers taken with both signs. Setting $m = L/2$,

$$\sum_{u=1}^L (2u-1-L)^2 = 2 \sum_{j=1}^m (2j-1)^2.$$

Now

$$\sum_{j=1}^m (2j-1)^2 = \sum_{j=1}^m (4j^2 - 4j + 1) = 4 \cdot \frac{m(m+1)(2m+1)}{6} - 4 \cdot \frac{m(m+1)}{2} + m,$$

using the two known sums $\sum_{j \leq m} j^2 = \frac{m(m+1)(2m+1)}{6}$ and $\sum_{j \leq m} j = \frac{m(m+1)}{2}$. Reducing to the common denominator 3:

$$\frac{2m(m+1)(2m+1) - 6m(m+1) + 3m}{3} = \frac{m[2(m+1)(2m+1) - 6(m+1) + 3]}{3} = \frac{m[4m^2 - 1]}{3},$$

because $2(m+1)(2m+1) - 6(m+1) + 3 = (m+1)(4m+2-6) + 3 = (m+1)(4m-4) + 3 = 4m^2 - 1$. Hence

$$2 \sum_{j=1}^m (2j-1)^2 = \frac{2m(4m^2 - 1)}{3} = \frac{L(L^2 - 1)}{3},$$

substituting $m = L/2$, i.e. $2m = L$ and $4m^2 - 1 = L^2 - 1$.

Case L odd. The values are $0, \pm 2, \pm 4, \dots, \pm(L-1)$. Setting $m = (L-1)/2$,

$$\sum_{u=1}^L (2u-1-L)^2 = 2 \sum_{j=1}^m (2j)^2 = 8 \sum_{j=1}^m j^2 = 8 \cdot \frac{m(m+1)(2m+1)}{6} = \frac{4m(m+1)(2m+1)}{3}.$$

With $m = \frac{L-1}{2}$ we have $m+1 = \frac{L+1}{2}$ and $2m+1 = L$, hence

$$\frac{4}{3} \cdot \frac{L-1}{2} \cdot \frac{L+1}{2} \cdot L = \frac{L(L^2 - 1)}{3}.$$

The two cases exhaust all $L \geq 1$, and in both the same formula is obtained. $\square$

Theorem 26.4: Energy, minimum distance and PAPR of square QAM. For the square M -QAM constellation of step Δ , with $M = L^2$,

$$E_s = \frac{2(M-1)}{3} \Delta^2, \quad d_{\min} = 2\Delta = \sqrt{\frac{6E_s}{M-1}}, \quad \text{PAPR} = \frac{3(L-1)}{L+1} = \frac{3(\sqrt{M}-1)}{\sqrt{M}+1}.$$

Proof. Energy. By Definition 26.3 and Definition 26.6,

$$E_s = \frac{1}{L^2} \sum_{u=1}^L \sum_{v=1}^L \Delta^2 [(2u-1-L)^2 + (2v-1-L)^2].$$

The double sum splits: in the first part the index v is mute and contributes a factor L , in the second u is mute. Hence, by Lemma 26.2,

$$E_s = \frac{\Delta^2}{L^2} \left[L \sum_{u=1}^L (2u-1-L)^2 + L \sum_{v=1}^L (2v-1-L)^2 \right] = \frac{\Delta^2}{L^2} \cdot 2L \cdot \frac{L(L^2-1)}{3} = \frac{2(L^2-1)}{3} \Delta^2,$$

which is the first formula with $M = L^2$.

Minimum distance. Let $a = \Delta[(2u-1-L) + i(2v-1-L)]$ and $a' = \Delta[(2u'-1-L) + i(2v'-1-L)]$ be two distinct symbols. Then

$$|a - a'|^2 = 4\Delta^2 [(u-u')^2 + (v-v')^2],$$

because $(2u-1-L) - (2u'-1-L) = 2(u-u')$. Since $(u, v) \neq (u', v')$ and the differences are integers, the quantity $(u-u')^2 + (v-v')^2$ is an integer ≥ 1 , and equals exactly 1 for instance with $u' = u+1$, $v' = v$ (possible because $L \geq 2$). The minimum of $|a - a'|$ is therefore $\sqrt{4\Delta^2} = 2\Delta$. Substituting $\Delta^2 = \frac{3E_s}{2(M-1)}$ obtained from the first formula,

$$d_{\min} = 2\Delta = 2\sqrt{\frac{3E_s}{2(M-1)}} = \sqrt{\frac{4 \cdot 3E_s}{2(M-1)}} = \sqrt{\frac{6E_s}{M-1}}.$$

PAPR. The maximum modulus occurs at the four corner symbols, where both coordinates equal $\pm\Delta(L-1)$: there $|a|^2 = 2\Delta^2(L-1)^2$. That this is the maximum follows from the fact that $|a|^2$ is a sum of two squares and each coordinate has modulus at most $\Delta(L-1)$. Hence

$$\text{PAPR} = \frac{2\Delta^2(L-1)^2}{\frac{2}{3}(L^2-1)\Delta^2} = \frac{3(L-1)^2}{L^2-1} = \frac{3(L-1)^2}{(L-1)(L+1)} = \frac{3(L-1)}{L+1},$$

where $L-1 \neq 0$ was cancelled because $L \geq 2$. □

Example 26.4: The parameters of 16-QAM and its siblings. With $E_s = 1$, Theorem 26.4 gives:

M	$L = \sqrt{M}$	m	$d_{\min} = \sqrt{6/(M-1)}$	PAPR
4	2	2	1.4142136	1.0000000
16	4	4	0.6324555	1.8000000
64	8	6	0.3086067	2.3333333
256	16	8	0.1533930	2.6470588

The row $M = 4$ recovers QPSK: indeed $\sqrt{6/3} = \sqrt{2}$ and 4-QAM is the QPSK of Definition 26.4 with $\varphi_0 = \pi/4$ (its four points $\Delta(\pm 1 \pm i)$ all lie on the circle of radius $\Delta\sqrt{2}$), in agreement with Corollary 26.3. For $M = 16$ the comparison with 16-PSK is merciless:

0.6324555 against 0.3901806 (Example 26.3), i.e. a factor 1.6209302 in distance, which is $20 \log_{10} 1.6209302 = 4.1952855$ dB of gain.

Independent check. A Python script that builds the M -QAM constellations point by point from Definition 26.6, computes their average energy as the arithmetic mean of the $|a|^2$, normalises them to $E_s = 1$, and enumerates all $M(M-1)$ ordered pairs returns, for $M = 4, 16, 64, 256$, the same minimum distances with maximum discrepancy $2.3 \cdot 10^{-16}$, and energies in units of Δ^2 equal to 2, 10, 42, 170, which coincide with $\frac{2}{3}(M-1)$. ✓

Definition 26.7: APSK constellation with concentric circles. Let $r \geq 1$ be the number of circles, $M_1, \dots, M_r$ positive integers with $M = M_1 + \dots + M_r$, radii $0 < R_1 < \dots < R_r$ and phases $\varphi_1, \dots, \varphi_r \in \mathbb{R}$. The corresponding **APSK** (*amplitude and phase shift keying*) constellation is

$$\mathcal{A}_{\text{APSK}} = \bigcup_{\ell=1}^r \left\{ R_\ell e^{i\left(\frac{2\pi j}{M_\ell} + \varphi_\ell\right)} : j = 0, \dots, M_\ell - 1 \right\},$$

i.e. the union of r PSK constellations of different orders and radii. It is called $(M_1 + \dots + M_r)$ -**APSK**; for instance $4 + 12$ means $r = 2$, $M_1 = 4$, $M_2 = 12$, $M = 16$.

Theorem 26.5: The 4+12-APSK of maximum minimum distance. Consider the family of 4 + 12-APSK constellations with

$$\varphi_1 = \frac{\pi}{4}, \quad \varphi_2 = 0, \quad R_2 = \gamma R_1 \quad (\gamma \geq 1),$$

normalised to $E_s = 1$. Then:

- (i) normalisation forces $R_1 = \frac{2}{\sqrt{1+3\gamma^2}}$;
- (ii) the minimum distance equals

$$d_{\min}(\gamma) = \frac{2}{\sqrt{1+3\gamma^2}} \min \left\{ \sqrt{2}, \quad 2\gamma \sin \frac{\pi}{12}, \quad \sqrt{1+\gamma^2-2\gamma \cos \frac{\pi}{12}} \right\};$$

- (iii) $d_{\min}(\gamma)$ is maximal for $\gamma^* = 1 + \sqrt{3} = 2.7320508$, and the maximum value is

$$d_{\min}(\gamma^*) = \frac{2\sqrt{2}}{\sqrt{13+6\sqrt{3}}} = \sqrt{\frac{104-48\sqrt{3}}{61}} = 0.5848015;$$

- (iv) at γ^* the peak-to-average power ratio equals $\text{PAPR} = R_2^2 = \frac{64+8\sqrt{3}}{61} = 1.2763345$.

Proof. (i) Normalisation. By Definition 26.3 the 16 symbols have moduli R_1 (four times) and R_2 (twelve times), hence

$$E_s = \frac{4R_1^2 + 12R_2^2}{16} = \frac{R_1^2 + 3R_2^2}{4} = \frac{R_1^2(1+3\gamma^2)}{4}.$$

Imposing $E_s = 1$ gives $R_1^2 = 4/(1+3\gamma^2)$, i.e. the formula, having chosen the positive root because $R_1 > 0$.

(ii) The three families of pairs. Every pair of distinct symbols is of one of three types. *Both on the inner circle.* The four points $R_1 e^{i(\pi/4+k\pi/2)}$ form a 4-PSK of energy R_1^2 , so by Theorem 26.3 their minimum distance is $2R_1 \sin(\pi/4) = R_1 \sqrt{2}$.

Both on the outer circle. The twelve points $R_2 e^{i2\pi j/12}$ form a 12-PSK of energy R_2^2 , with minimum distance $2R_2 \sin(\pi/12) = 2\gamma R_1 \sin(\pi/12)$.

One per circle. For $a = R_1 e^{i\alpha}$ and $b = R_2 e^{i\beta}$,

$$\begin{aligned} |a - b|^2 &= (R_1 e^{i\alpha} - R_2 e^{i\beta}) \overline{(R_1 e^{i\alpha} - R_2 e^{i\beta})} = R_1^2 + R_2^2 - R_1 R_2 (e^{i(\alpha-\beta)} + e^{-i(\alpha-\beta)}) \\ &= R_1^2 + R_2^2 - 2R_1 R_2 \cos(\alpha - \beta), \end{aligned}$$

using $e^{i\theta} + e^{-i\theta} = 2 \cos \theta$ (Euler's formula). This quantity is smaller the larger $\cos(\alpha - \beta)$ is, i.e. the closer $\alpha - \beta$ is to a multiple of 2π . Now

$$\alpha - \beta = \frac{\pi}{4} + \frac{k\pi}{2} - \frac{j\pi}{6} = \frac{\pi}{12}(3 + 6k - 2j), \quad k \in \{0, 1, 2, 3\}, \quad j \in \{0, \dots, 11\},$$

and $3 + 6k - 2j$ is *odd*, because $6k - 2j$ is even. The minimum of $|3 + 6k - 2j|$ over a set of odd integers is therefore at least 1, and equals exactly 1 because $k = 0, j = 1$ gives $3 - 2 = 1$. Staying within $|\alpha - \beta| \leq \pi$ — which is legitimate because cosine is 2π -periodic and even — the minimum value of $|\alpha - \beta|$ is $\pi/12$, and the minimum distance between the two circles is $\sqrt{R_1^2 + R_2^2 - 2R_1 R_2 \cos(\pi/12)} = R_1 \sqrt{1 + \gamma^2 - 2\gamma \cos(\pi/12)}$.

Factoring out R_1 in the three values and taking the minimum gives formula (ii), with R_1 given by (i).

(iii) The optimum. Set $s = \sin \frac{\pi}{12}$, $c = \cos \frac{\pi}{12}$ and

$$h_1(\gamma) = \frac{2\sqrt{2}}{\sqrt{1+3\gamma^2}}, \quad h_2(\gamma) = \frac{4\gamma s}{\sqrt{1+3\gamma^2}}, \quad h_3(\gamma) = \frac{2\sqrt{1+\gamma^2-2\gamma c}}{\sqrt{1+3\gamma^2}},$$

so that $d_{\min} = \min\{h_1, h_2, h_3\}$.

The function h_1 is *strictly decreasing* on $[1, +\infty)$, because the numerator is constant and the denominator $\sqrt{1+3\gamma^2}$ is strictly increasing.

The function h_2 is *strictly increasing*: indeed $h_2(\gamma) = 4s/\sqrt{\gamma^{-2}+3}$ for $\gamma > 0$, and $\gamma^{-2}+3$ is strictly decreasing.

The two meet where $2\sqrt{2} = 4\gamma s$, i.e. $\gamma = \frac{\sqrt{2}}{2s} = \frac{1}{\sqrt{2}s}$. Since $s = \sin \frac{\pi}{12} = \frac{\sqrt{6}-\sqrt{2}}{4}$ — a value that follows from $\sin 15^\circ = \sin(45^\circ - 30^\circ) = \sin 45^\circ \cos 30^\circ - \cos 45^\circ \sin 30^\circ = \frac{\sqrt{2}}{2} \cdot \frac{\sqrt{3}}{2} - \frac{\sqrt{2}}{2} \cdot \frac{1}{2} = \frac{\sqrt{6}-\sqrt{2}}{4}$ — we have $\sqrt{2}s = \frac{\sqrt{12}-2}{4} = \frac{2\sqrt{3}-2}{4} = \frac{\sqrt{3}-1}{2}$, and

$$\gamma^* = \frac{2}{\sqrt{3}-1} = \frac{2(\sqrt{3}+1)}{(\sqrt{3}-1)(\sqrt{3}+1)} = \frac{2(\sqrt{3}+1)}{2} = \sqrt{3}+1.$$

At γ^* we have $\gamma^{*2} = (\sqrt{3}+1)^2 = 4+2\sqrt{3}$ and hence $1+3\gamma^{*2} = 13+6\sqrt{3}$. Let us check that at γ^* the third term is not the minimum: with $c = \cos \frac{\pi}{12} = \frac{\sqrt{6}+\sqrt{2}}{4}$ (same computation as before with $\cos(45^\circ - 30^\circ)$),

$$1 + \gamma^{*2} - 2\gamma^* c = 1 + 4 + 2\sqrt{3} - 2(\sqrt{3}+1) \cdot \frac{\sqrt{6}+\sqrt{2}}{4} = 3.1861847 > 2,$$

so $h_3(\gamma^*) > h_1(\gamma^*) = h_2(\gamma^*)$ and $d_{\min}(\gamma^*) = h_1(\gamma^*) = \frac{2\sqrt{2}}{\sqrt{13+6\sqrt{3}}}$.

Now maximality. Let $\gamma < \gamma^*$: then $d_{\min}(\gamma) \leq h_2(\gamma) < h_2(\gamma^*) = d_{\min}(\gamma^*)$, because h_2 is strictly increasing. Let $\gamma > \gamma^*$: then $d_{\min}(\gamma) \leq h_1(\gamma) < h_1(\gamma^*) = d_{\min}(\gamma^*)$, because h_1 is strictly decreasing. In both cases the inequality is strict: the maximum is at γ^* and is unique. For the value, rationalising with $(13 - 6\sqrt{3})$ and using $13^2 - (6\sqrt{3})^2 = 169 - 108 = 61$:

$$d_{\min}(\gamma^*)^2 = \frac{8}{13+6\sqrt{3}} = \frac{8(13-6\sqrt{3})}{61} = \frac{104-48\sqrt{3}}{61} = 0.3419928,$$

whose square root is 0.5848015.

(iv) **PAPR.** The maximum modulus is R_2 , because $R_2 > R_1$ for $\gamma > 1$, and $E_s = 1$: hence $\text{PAPR} = R_2^2 = \gamma^{*2} R_1^2 = \frac{4\gamma^{*2}}{1+3\gamma^{*2}} = \frac{4(4+2\sqrt{3})}{13+6\sqrt{3}} = \frac{16+8\sqrt{3}}{13+6\sqrt{3}}$. Rationalising,

$$\frac{(16+8\sqrt{3})(13-6\sqrt{3})}{61} = \frac{208-96\sqrt{3}+104\sqrt{3}-48\cdot 3}{61} = \frac{208-144+8\sqrt{3}}{61} = \frac{64+8\sqrt{3}}{61} = 1.2763345.$$

As a consistency check, $E_s = \frac{R_1^2+3R_2^2}{4} = \frac{0.1709964+3\cdot 1.2763345}{4} = \frac{4.0000000}{4} = 1$. ✓

□

Remark 26.5: Why APSK exists, if QAM has larger minimum distance. The comparison at $M = 16$ and $E_s = 1$ is sharp and must be stated without sugar-coating:

	16-QAM	optimal 4 + 12-APSK
$d_{\min}$	0.6324555	0.5848015
$d_{\min}$ in relative dB	+0.6804302	0
PAPR	1.8000000	1.2763345
PAPR in dB	2.5527251	1.0596452

On a linear Gaussian channel QAM wins, by 0.6804302 dB in minimum distance. APSK is therefore not an absolutely better modulation: it is better when the channel is not linear. A power amplifier aboard a satellite operates near saturation so as not to waste energy, and in that regime its characteristic compresses large moduli and rotates their phase; a constellation with PAPR 1.2763345 (1.0596452 dB) passes through that nonlinearity much better than one with PAPR 1.8 (2.5527251 dB), and it also has only two distinct moduli instead of three, which makes compensation simple. The gain of 1.4930799 dB in PAPR is paid for with 0.6804302 dB of minimum distance: the balance is favourable exactly in the regime in which satellites operate. The constellation of Theorem 26.5 was built here from the optimisation of $d_{\min}$, not taken from any standardisation document; real systems use radius ratios chosen with different criteria (and generally dependent on the coding rate), and do not coincide with $\gamma^* = 1 + \sqrt{3}$.

26.5. Minimum-distance decision

The receiver observes a complex number and must guess which symbol was transmitted. The rule everyone uses — "choose the closest symbol" — is not a convention or a heuristic: under precise hypotheses, it is the rule that *minimises the error probability*. This section states those hypotheses and proves the claim.

Definition 26.8: Additive white Gaussian noise channel in baseband. Let $\mathcal{A}$ be a constellation of order M . The **additive white Gaussian noise channel** (AWGN) for one use, of one-sided spectral density $N_0 > 0$, is the model

$$r = a + n,$$

where a is the transmitted symbol and n is a complex random variable, independent of a , with *independent* real and imaginary parts, each Gaussian with zero mean and variance $N_0/2$. The joint density of n with respect to Lebesgue measure on $\mathbb{R}^2 \cong \mathbb{C}$ is therefore

$$p_n(z) = \frac{1}{2\pi \cdot \frac{N_0}{2}} \exp\left(-\frac{(\Re z)^2 + (\Im z)^2}{2 \cdot \frac{N_0}{2}}\right) = \frac{1}{\pi N_0} e^{-|z|^2/N_0}, \quad z \in \mathbb{C}.$$

Such a variable is called **circularly symmetric complex Gaussian** of variance N_0 , because $\mathbb{E}[|n|^2] = N_0$ and the density depends only on the modulus.

Figure 26.4: On the left, the 16-QAM of Definition 26.6 with $\Delta = 0.5$ cm: the sixteen points lie at $(\pm 0.5, \pm 0.5)$, $(\pm 0.5, \pm 1.5)$, $(\pm 1.5, \pm 0.5)$, $(\pm 1.5, \pm 1.5)$, and the minimum-distance decision lines are $I, Q \in \{-1, 0, 1\}$, i.e. the midpoints between adjacent levels (Theorem 26.7). On the right, the optimal 4 + 12-APSK of Theorem 26.5, drawn with $R_2 = 2$ cm and hence $R_1 = 2/\gamma^* = 2/(1 + \sqrt{3}) = 0.7321$ cm: the four inner points lie at $45^\circ + k \cdot 90^\circ$, with coordinates $0.7321 \cdot \frac{\sqrt{2}}{2} = 0.5176$, and the twelve outer ones at $j \cdot 30^\circ$, with coordinates $2 \cos 30^\circ = 1.7321$, $2 \cos 60^\circ = 1$, 2 and 0 . The two green segments are the two distances that at the optimum become equal: this is the coincidence $h_1 = h_2$ of the proof. All coordinates are computed from the formulas, not measured.

Remark 26.6: The two conventions on N_0 . Definition 26.8 assigns variance $N_0/2$ to each of the two real components and N_0 to the complex one. This is the digital communications convention, in which N_0 is the one-sided spectral density (all the noise power is counted on positive frequencies) and $N_0/2$ the two-sided one. Readers of signal theory texts often find the opposite convention, with σ^2 per component and no reference to N_0 : the formulas change accordingly, and the error probability of BPSK, which here is $Q(\sqrt{2E_b/N_0})$, then becomes $Q(\sqrt{E_b}/\sigma)$. The two are translated by $\sigma^2 = N_0/2$. Whenever a numerical result of this chapter is compared with a source, the first thing to check is which of the two conventions it uses: it is the most common source of 3 dB discrepancies.

Definition 26.9: Decision rule and decision regions. A **decision rule** is a measurable function $\delta: \mathbb{C} \rightarrow \mathcal{A}$. Its **decision regions** are the sets $\mathcal{R}_j = \delta^{-1}(\{a_j\})$, $j = 0, \dots, M - 1$, which form a partition of $\mathbb{C}$. The **error probability** of the rule is

$$P_e(\delta) = \Pr[\delta(r) \neq a] = \frac{1}{M} \sum_{j=0}^{M-1} \Pr[r \notin \mathcal{R}_j \mid a = a_j].$$

The rule is called **maximum likelihood** (ML) if $\delta(r) \in \arg \max_j p_n(r - a_j)$, **maximum a posteriori** (MAP) if $\delta(r) \in \arg \max_j \Pr[a = a_j] p_n(r - a_j)$, and **minimum distance** if $\delta(r) \in \arg \min_j |r - a_j|$.

Theorem 26.6: Minimum distance, maximum likelihood, minimum error probability. Consider the channel of Definition 26.8 with equiprobable symbols. Then:

- (i) the MAP rule coincides with the ML rule;

(ii) the ML rule coincides with the minimum-distance rule:

$$\arg \max_j p_n(r - a_j) = \arg \min_j |r - a_j| \quad \text{for every } r \in \mathbb{C};$$

(iii) every MAP rule minimises the error probability among all decision rules;

(iv) two minimum-distance rules that differ only in the choice made in case of a tie have the same error probability.

Proof. (i). By definition the MAP rule maximises $\Pr[a = a_j] p_n(r - a_j)$. If the symbols are equiprobable, $\Pr[a = a_j] = 1/M$ for every j , and multiplying all the quantities to be compared by the same positive constant $1/M$ does not change the set of maximisers. Hence the two sets of maximising arguments coincide.

(ii). From Definition 26.8,

$$p_n(r - a_j) = \frac{1}{\pi N_0} e^{-|r - a_j|^2 / N_0}.$$

The function $x \mapsto \frac{1}{\pi N_0} e^{-x/N_0}$ is strictly decreasing on $[0, +\infty)$, because $N_0 > 0$ and its derivative equals $-\frac{1}{\pi N_0^2} e^{-x/N_0} < 0$. A strictly decreasing function reverses order, hence

$$p_n(r - a_j) \geq p_n(r - a_l) \iff |r - a_j|^2 \leq |r - a_l|^2 \iff |r - a_j| \leq |r - a_l|,$$

the last step because $t \mapsto t^2$ is strictly increasing on $[0, +\infty)$. Maximising the likelihood is therefore equivalent to minimising the distance, and the two sets of optimal arguments coincide.

(iii). Let δ be any decision rule, with regions $\mathcal{R}_j$. The probability of correct decision is

$$P_c(\delta) = \sum_{j=0}^{M-1} \Pr[a = a_j] \int_{\mathcal{R}_j} p_n(r - a_j) dr = \int_{\mathbb{C}} \sum_{j=0}^{M-1} \mathbf{1}_{\mathcal{R}_j}(r) \Pr[a = a_j] p_n(r - a_j) dr,$$

where interchanging the finite sum and the integral is legitimate because the integrands are nonnegative. For each fixed r , the inner sum equals $\Pr[a = a_{j(r)}] p_n(r - a_{j(r)})$, where $j(r)$ is the unique index with $r \in \mathcal{R}_{j(r)}$ (the regions form a partition); hence

$$\sum_j \mathbf{1}_{\mathcal{R}_j}(r) \Pr[a = a_j] p_n(r - a_j) \leq \max_{0 \leq j \leq M-1} \Pr[a = a_j] p_n(r - a_j) =: F(r),$$

and integrating, $P_c(\delta) \leq \int_{\mathbb{C}} F(r) dr$. The bound is an equality if and only if for almost every r the index $j(r)$ attains the maximum, i.e. if and only if δ is (almost everywhere) a MAP rule. Since a MAP rule exists — the maximum over a finite set is always attained, and one can choose the smallest such index, which gives a measurable function because each choice set is a finite intersection of measurable sets — the value $\int F$ is attained, and $P_e = 1 - P_c$ is minimal exactly for MAP rules.

(iv). Two minimum-distance rules differ only on the set

$$\mathcal{T} = \bigcup_{j \neq l} \{r \in \mathbb{C} : |r - a_j| = |r - a_l|\}.$$

For every pair $j \neq l$, the set $\{|r - a_j| = |r - a_l|\}$ is the perpendicular bisector of the segment $a_j a_l$: expanding $|r - a_j|^2 = |r - a_l|^2$ gives, with $r = x + iy$ and $a_j = \alpha_j + i\beta_j$,

$$-2\alpha_j x - 2\beta_j y + |a_j|^2 = -2\alpha_l x - 2\beta_l y + |a_l|^2,$$

i.e. a linear equation in (x, y) not identically zero (the coefficients $2(\alpha_l - \alpha_j)$ and $2(\beta_l - \beta_j)$ are not both zero, because $a_j \neq a_l$): it is a line, of zero Lebesgue measure in $\mathbb{R}^2$. The finite union $\mathcal{T}$ therefore has zero measure, and since the law of r is absolutely continuous (it has density $p_n(\cdot - a_j)$ conditionally on $a = a_j$), $\Pr[r \in \mathcal{T}] = 0$. The two rules therefore coincide with probability 1 and have the same error probability. $\square$

Theorem 26.7: The decision regions are convex Voronoi cells. For the minimum-distance rule on a constellation $\mathcal{A}$, the region associated with a_j , taken in its closed form

$$\overline{\mathcal{R}}_j = \{r \in \mathbb{C} : |r - a_j| \leq |r - a_l| \quad \forall l \neq j\},$$

is the intersection of $M - 1$ closed half-planes:

$$\overline{\mathcal{R}}_j = \bigcap_{l \neq j} \left\{ r \in \mathbb{C} : 2\Re[r \overline{(a_l - a_j)}] \leq |a_l|^2 - |a_j|^2 \right\}.$$

In particular $\overline{\mathcal{R}}_j$ is closed, convex, and contains a_j ; it is therefore a convex polygon, possibly unbounded.

Proof. For $r, a \in \mathbb{C}$, $|r - a|^2 = (r - a)\overline{(r - a)} = |r|^2 - r\bar{a} - \bar{r}a + |a|^2$, and $r\bar{a} + \bar{r}a = 2\Re(r\bar{a})$. Hence

$$|r - a_j|^2 \leq |r - a_l|^2 \iff |r|^2 - 2\Re(r\bar{a}_j) + |a_j|^2 \leq |r|^2 - 2\Re(r\bar{a}_l) + |a_l|^2.$$

The term $|r|^2$ cancels; moving the terms in r to the left and the moduli to the right, and using the real linearity of $\Re$,

$$2\Re(r\bar{a}_l) - 2\Re(r\bar{a}_j) = 2\Re[r \overline{(a_l - a_j)}] \leq |a_l|^2 - |a_j|^2.$$

For each fixed l the condition has the form $\langle v, w_l \rangle_{\mathbb{R}^2} \leq c_l$ with w_l a nonzero real vector (corresponding to $2\overline{(a_l - a_j)} \neq 0$): it is a closed half-plane. As an intersection of closed half-planes, $\overline{\mathcal{R}}_j$ is closed and convex (the intersection of convex sets is convex, the intersection of closed sets is closed). It contains a_j because $|a_j - a_j| = 0 \leq |a_j - a_l|$ for every l . That it is a polygon, possibly unbounded, is precisely the definition of a finite intersection of half-planes. $\square$

Corollary 26.4: Symmetry of the error probability in M-PSK. For the M-PSK constellation (Definition 26.4) with minimum-distance decision on the AWGN channel, the conditional error probability $\Pr[\delta(r) \neq a_j \mid a = a_j]$ does not depend on j , and hence coincides with the symbol error probability P_s .

Proof. Let $\rho = e^{i2\pi/M}$. By Definition 26.4, $a_{k+1} = \rho a_k$ with indices modulo M , so multiplication by ρ is a bijection of $\mathcal{A}$ onto itself. By Theorem 26.7, $\overline{\mathcal{R}}_j$ is defined by conditions involving only the moduli $|r - a_l|$; since $|\rho z| = |z|$ for every z ,

$$|\rho r - \rho a_{l+1}| = |\rho r - \rho a_l| = |\rho| |r - a_l| = |r - a_l|,$$

and hence $r \in \overline{\mathcal{R}}_j \iff \rho r \in \overline{\mathcal{R}}_{j+1}$: the rotation by $2\pi/M$ carries the region of a_j to that of a_{j+1} . Now,

$$\Pr[r \notin \overline{\mathcal{R}}_j \mid a = a_j] = \int_{\mathbb{C} \setminus \overline{\mathcal{R}}_j} p_n(r - a_j) dr.$$

In the change of variable $r = \rho u$ — a rotation of the plane, whose Jacobian determinant has modulus 1 and carries $\mathbb{C} \setminus \overline{\mathcal{R}}_j$ to $\mathbb{C} \setminus \overline{\mathcal{R}}_{j-1}$ read backwards — one uses $p_n(\rho u - a_j) = \frac{1}{\pi N_0} e^{-|\rho u - \rho a_{j-1}|^2/N_0} = \frac{1}{\pi N_0} e^{-|u - a_{j-1}|^2/N_0} = p_n(u - a_{j-1})$, obtaining

$$\Pr[r \notin \overline{\mathcal{R}}_j \mid a = a_j] = \int_{\mathbb{C} \setminus \overline{\mathcal{R}}_{j-1}} p_n(u - a_{j-1}) du = \Pr[r \notin \overline{\mathcal{R}}_{j-1} \mid a = a_{j-1}].$$

Iterating, all the conditional probabilities are equal to one another; since $P_s = \frac{1}{M} \sum_j \Pr[\cdot \mid a = a_j]$ is their average, it coincides with the common value. $\square$

Figure 26.5: The decision regions of Theorem 26.7 for the three-point constellation $a_1 = -2 - i$, $a_2 = 2 - i$, $a_3 = 2i$ (units: centimetres). Each boundary is the perpendicular bisector of a segment, i.e. the edge of the half-plane in the statement; the three bisectors meet at the circumcentre of the triangle, which lies on $I = 0$ by symmetry and has ordinate determined by $4 + (y+1)^2 = (y-2)^2$, i.e. $6y = -1$, $y = -\frac{1}{6} = -0.1667$. The region $\mathcal{R}_3$ is the intersection of two half-planes and is an unbounded angular sector; the other two are obtained by reflection. No region is bounded: this is the general case for points lying on the convex hull of the constellation.

Remark 26.7: What happens if the symbols are not equiprobable. Point (i) of Theorem 26.6 is the only one using equiprobability, and it uses it essentially. If $\Pr[a = a_j] = \pi_j$ with the π_j not all equal, the optimal rule is still MAP, which maximises $\pi_j e^{-|r-a_j|^2/N_0}$; taking the (strictly increasing) logarithm and changing sign, it minimises

$$|r - a_j|^2 - N_0 \ln \pi_j,$$

i.e. a distance corrected by a bias term that favours the more probable symbols. The boundaries remain lines — the additional term is constant with respect to r — but they no longer pass through the midpoints: they shift towards the less probable symbol by an amount $\frac{N_0 \ln(\pi_j/\pi_l)}{2|a_j - a_l|}$. The regions are still Voronoi cells, but weighted. In classical modulations the symbols are made equiprobable by construction (by the source encoder and a scrambler), and this case does not arise; it does arise, instead, in probabilistic shaping techniques, in which the inequality between the probabilities is introduced on purpose.

26.6. The matched filter

Before deciding one must measure, and the way of measuring is not indifferent. The useful signal occupies an interval of time and a bandwidth; the noise occupies everything. A linear filter that collects the observation into a single number can be chosen in infinitely many ways, and the choice changes the signal-to-noise ratio of that number by several decibels. This section proves that an optimal choice exists, that it is unique up to a multiplicative constant, and that the signal-to-noise ratio it attains depends only on the *energy* of the signal — not on its shape.

Definition 26.10: White Gaussian noise as a family of integrals. Let $N_0 > 0$. A **white Gaussian noise** of two-sided spectral density $N_0/2$ is a family $\{\mathcal{N}(g)\}_{g \in L^2(\mathbb{R}, \mathbb{R})}$ of real random variables, defined on the same probability space, such that:

(N1) $g \mapsto \mathcal{N}(g)$ is linear: $\mathcal{N}(\lambda g + \mu h) = \lambda \mathcal{N}(g) + \mu \mathcal{N}(h)$ almost surely, for every $\lambda, \mu \in \mathbb{R}$;
(N2) each $\mathcal{N}(g)$ is Gaussian with zero mean;
(N3) $\mathbb{E}[\mathcal{N}(g)\mathcal{N}(h)] = \frac{N_0}{2} \langle g, h \rangle = \frac{N_0}{2} \int_{\mathbb{R}} g(t)h(t) dt$.
One suggestively writes $\mathcal{N}(g) = \int_{\mathbb{R}} g(t) w(t) dt$, but the notation is a *name*: no function w realises those integrals, and the well-defined object is the family, not its integrand.

Remark 26.8: What is imported. The **existence** of a family with properties (N1)–(N3) is **imported** and not proved in this treatise. What is missing, precisely, is the construction of a Gaussian measure on a probability space that simultaneously realises all the $\mathcal{N}(g)$ for $g \in L^2$: it is obtained with Kolmogorov’s extension theorem applied to the coherent family of multivariate Gaussians with covariance matrix $\frac{N_0}{2}(\langle g_i, g_j \rangle)_{i,j}$ (which is positive semidefinite because it is a Gram matrix), or by completing the isometry $g \mapsto \mathcal{N}(g)$ from a countable orthonormal system. Both routes require measure-theoretic tools that the treatise does not develop. It must be stressed that nothing in what follows uses anything other than (N1)–(N3): Theorem 26.8 is proved starting from those axioms, and is therefore valid for any realisation of them. The model and its consequences are found in Wozencraft and Jacobs and in Proakis and Salehi (Sources [4] and [1]).

Lemma 26.3: Cauchy–Schwarz inequality with the equality case. Let $u, v \in L^2(\mathbb{R}, \mathbb{R})$. Then

$$\left(\int_{\mathbb{R}} u(t)v(t) dt \right)^2 \leq \left(\int_{\mathbb{R}} u(t)^2 dt \right) \left(\int_{\mathbb{R}} v(t)^2 dt \right),$$

i.e. $\langle u, v \rangle^2 \leq \|u\|^2 \|v\|^2$. Equality holds if and only if u and v are proportional, i.e. if and only if there exists $\lambda \in \mathbb{R}$ with $u = \lambda v$ almost everywhere, or $v = 0$ almost everywhere.

Proof. If $\|v\| = 0$ then $v = 0$ almost everywhere, both sides vanish and equality holds: this is the degenerate case allowed by the statement. Suppose therefore $\|v\| > 0$ and consider, for $\lambda \in \mathbb{R}$,

$$q(\lambda) = \|u - \lambda v\|^2 = \int_{\mathbb{R}} (u(t) - \lambda v(t))^2 dt = \|u\|^2 - 2\lambda \langle u, v \rangle + \lambda^2 \|v\|^2,$$

expanding the square and using linearity of the integral (all integrals are finite because $u, v \in L^2$ and, by the inequality $2|uv| \leq u^2 + v^2$, also $uv \in L^1$). The function q is a second-degree polynomial in λ with leading coefficient $\|v\|^2 > 0$, and $q(\lambda) \geq 0$ for every λ , because it is the integral of a square. A second-degree polynomial with positive leading coefficient is nonnegative on all of $\mathbb{R}$ if and only if its discriminant is ≤ 0 :

$$\Delta = 4\langle u, v \rangle^2 - 4\|u\|^2 \|v\|^2 \leq 0 \iff \langle u, v \rangle^2 \leq \|u\|^2 \|v\|^2.$$

This is the inequality.

Equality case. $\langle u, v \rangle^2 = \|u\|^2 \|v\|^2$ holds if and only if $\Delta = 0$, i.e. if and only if the polynomial q has a real (double) root $\lambda_0 = \langle u, v \rangle / \|v\|^2$. But $q(\lambda_0) = \|u - \lambda_0 v\|^2 = 0$ means $\int (u - \lambda_0 v)^2 = 0$; the integrand is nonnegative, hence it vanishes almost everywhere (if a set of positive measure had $(u - \lambda_0 v)^2 > 0$, by continuity from above there would exist $\varepsilon > 0$ and a set of positive measure on which $(u - \lambda_0 v)^2 \geq \varepsilon$, and the integral would be positive). Hence $u = \lambda_0 v$ almost everywhere. Conversely, if $u = \lambda v$ almost everywhere then $\langle u, v \rangle = \lambda \|v\|^2$ and $\|u\|^2 = \lambda^2 \|v\|^2$, and both sides equal $\lambda^2 \|v\|^4$. $\square$

Definition 26.11: Linear filter, sampling and signal-to-noise ratio. Let $s \in L^2(\mathbb{R}, \mathbb{R})$ be a pulse of energy $E = \|s\|^2 > 0$, transmitted in the presence of white noise (Definition 26.10), and let $h \in L^2(\mathbb{R}, \mathbb{R})$ be the impulse response of a linear filter, with $g(\tau) = h(T - \tau)$ not identically zero. The **output sampled at instant T** is the random variable

$$y = \underbrace{\int_{\mathbb{R}} h(T - \tau) s(\tau) d\tau}_{y_s = \langle s, g \rangle} + \mathcal{N}(g),$$

and its **signal-to-noise ratio** is

$$\text{SNR}(h) = \frac{y_s^2}{\text{Var}[\mathcal{N}(g)]} = \frac{\langle s, g \rangle^2}{\frac{N_0}{2} \|g\|^2}.$$

The filter is called **matched** to s (at instant T) if $h(t) = c s(T - t)$ for some constant $c \neq 0$.

Theorem 26.8: The matched filter maximises the signal-to-noise ratio. With the notation of Definition 26.11, for every admissible filter

$$\text{SNR}(h) \leq \frac{2E}{N_0},$$

and equality holds **if and only if** h is matched to s , i.e. $h(t) = c s(T - t)$ almost everywhere for some $c \neq 0$. The maximum therefore depends only on the energy of the pulse and not on its shape.

Proof. Step 1 — the variance of the noise term. By property (N3) of Definition 26.10 with $h = g$, and since $\mathcal{N}(g)$ has zero mean by (N2),

$$\text{Var}[\mathcal{N}(g)] = \mathbb{E}[\mathcal{N}(g)^2] = \frac{N_0}{2} \|g\|^2 > 0,$$

positive because g is not identically zero. The ratio of Definition 26.11 is therefore well defined.

Step 2 — the bound. We apply Lemma 26.3 to the pair (s, g) :

$$\langle s, g \rangle^2 \leq \|s\|^2 \|g\|^2 = E \|g\|^2.$$

Dividing by the positive quantity $\frac{N_0}{2} \|g\|^2$,

$$\text{SNR}(h) = \frac{\langle s, g \rangle^2}{\frac{N_0}{2} \|g\|^2} \leq \frac{E \|g\|^2}{\frac{N_0}{2} \|g\|^2} = \frac{2E}{N_0},$$

where $\|g\|^2$ cancels because it is nonzero. Note that the bound is *independent of g* : whatever filter is chosen, the ratio does not exceed $2E/N_0$.

Step 3 — the equality case. The inequality of Step 2 is an equality if and only if the Cauchy–Schwarz inequality applied to (s, g) is. By the equality case of Lemma 26.3, and since $g \neq 0$ by hypothesis, this occurs if and only if there exists $c \in \mathbb{R}$ with

$$s = \frac{1}{c} g \quad \text{almost everywhere, i.e.} \quad g(\tau) = c s(\tau) \quad \text{almost everywhere,}$$

with $c \neq 0$ (if $c = 0$ then $g = 0$, excluded). Recalling that $g(\tau) = h(T - \tau)$, the condition is rewritten $h(T - \tau) = c s(\tau)$, i.e. setting $t = T - \tau$ and hence $\tau = T - t$,

$$h(t) = c s(T - t) \quad \text{almost everywhere,}$$

which is exactly the definition of a matched filter. Finally, by direct check, a matched filter attains the maximum: with $g = cs$, $\langle s, g \rangle = c\|s\|^2 = cE$ and $\|g\|^2 = c^2E$, hence

$$\text{SNR} = \frac{c^2 E^2}{\frac{N_0}{2} c^2 E} = \frac{2E}{N_0}. \quad \checkmark$$

□

Corollary 26.5: *The matched filter is a correlator, and its output is the AWGN channel.* Let $p \in L^2(\mathbb{R}, \mathbb{R})$ be a pulse of unit energy, $\|p\|^2 = 1$, and transmit in complex baseband the signal $ap(t)$ with $a \in \mathcal{A}$. Let the noise be the sum $w = w_I + iw_Q$ of two independent white noises of two-sided density $N_0/2$ each. If the receiver computes

$$z = \int_{\mathbb{R}} (ap(t) + w(t)) p(t) dt = a + (\mathcal{N}_I(p) + i\mathcal{N}_Q(p)),$$

then $z = a + n$ with n circularly symmetric complex Gaussian of variance N_0 : i.e. exactly the channel of Definition 26.8. Moreover the value z is obtained from the filter matched to p sampled at $t = 0$, and it attains for each component the ratio $2E/N_0$ of Theorem 26.8.

Proof. The deterministic part gives $\int ap(t)p(t) dt = a\|p\|^2 = a$. The two random parts are $\mathcal{N}_I(p)$ and $\mathcal{N}_Q(p)$: by (N2) they are Gaussian with zero mean, by (N3) they have variance $\frac{N_0}{2}\|p\|^2 = \frac{N_0}{2}$, and they are independent by hypothesis. The joint density of $n = \mathcal{N}_I(p) + i\mathcal{N}_Q(p)$ is therefore the product of the two Gaussian densities, i.e.

$$\frac{1}{\sqrt{2\pi\frac{N_0}{2}}} e^{-x^2/N_0} \cdot \frac{1}{\sqrt{2\pi\frac{N_0}{2}}} e^{-y^2/N_0} = \frac{1}{\pi N_0} e^{-(x^2+y^2)/N_0},$$

which is the density of Definition 26.8; and $\mathbb{E}[|n|^2] = \frac{N_0}{2} + \frac{N_0}{2} = N_0$. That this is the matched filter is Definition 26.11 with $T = 0$ and $c = 1$: there $h(t) = s(-t)$ and the sampled output is $\int h(-\tau)s(\tau)d\tau = \int s(\tau)^2 d\tau$; here p has energy 1 and the computation is the same, component by component. □

Example 26.5: Rectangular pulse: the integrator and the cost of the wrong filter.

Let $s(t) = A$ for $t \in [0, T]$ and $s(t) = 0$ elsewhere, with $A = 0.5$ V and $T = 2 \cdot 10^{-6}$ s. The energy is

$$E = \int_0^T A^2 dt = A^2 T = 0.25 \cdot 2 \cdot 10^{-6} = 5.0000000 \cdot 10^{-7} \text{ V}^2\text{s}.$$

The matched filter has $h(t) = s(T - t)$, which for a rectangle coincides with s itself: the filter matched to a rectangular pulse is the *integrator* over the symbol interval. With $N_0 = 5 \cdot 10^{-8}$ V²/Hz,

$$\text{SNR}_{\max} = \frac{2E}{N_0} = \frac{2 \cdot 5 \cdot 10^{-7}}{5 \cdot 10^{-8}} = 20.0000000, \quad 10 \log_{10} 20 = 13.0102999 \text{ dB}.$$

The cost of the wrong filter. Suppose one mistakenly integrates only over the first half of the interval, i.e. takes $g = \mathbf{1}_{[0, T/2]}$. Then

$$\langle s, g \rangle = A \cdot \frac{T}{2}, \quad \|g\|^2 = \frac{T}{2},$$

and by Definition 26.11

$$\text{SNR} = \frac{A^2 T^2 / 4}{\frac{N_0}{2} \cdot \frac{T}{2}} = \frac{A^2 T}{N_0} = \frac{E}{N_0} = 10.0000000,$$

exactly half of the maximum: one loses $10 \log_{10} 2 = 3.0102999$ dB. The loss can also be read directly from Lemma 26.3, whose ratio $\langle s, g \rangle^2 / (\|s\|^2 \|g\|^2)$ here equals

$$\frac{(AT/2)^2}{(A^2T)(T/2)} = \frac{A^2T^2/4}{A^2T^2/2} = \frac{1}{2},$$

i.e. the squared cosine of the angle between s and g in L^2 : g "sees" only half of the pulse, and collects half its energy.

Independent check. The two ratios equal $2E/N_0 = 20$ and $E/N_0 = 10$: their quotient is 2, and $10 \log_{10} 20 - 10 \log_{10} 10 = 13.0102999 - 10 = 3.0102999$, which coincides with $10 \log_{10} 2$.
✓

Remark 26.9: Why the maximum does not depend on the shape of the pulse. Theorem 26.8 says that $2E/N_0$ is attainable with any pulse of energy E : rectangular, Gaussian, raised-cosine, or of arbitrarily irregular shape. The shape of the pulse therefore does not serve to improve the signal-to-noise ratio, but to control two different things: the bandwidth occupation (Section 26.8) and the interference between consecutive symbols (Theorem 26.11). This is why no real system uses the rectangular pulse of Example 26.5, even though it is optimal from the point of view of the signal-to-noise ratio: its spectrum is a sinc function (Proposition 19.2), which decays only as $1/|f|$ and occupies bandwidth unacceptably.

26.7. The error probability of BPSK and QPSK

Now the errors are counted. The whole section rests on a single function, the tail of the standard Gaussian, and on two elementary geometries: a line separating two points (BPSK) and two orthogonal lines separating four points (QPSK). The final result — that BPSK and QPSK have the *same* error probability per bit — is the reason why, in real systems, QPSK is almost always preferred: it doubles the rate at no cost.

Definition 26.12: The Q function. The Q function is the right tail of the standard Gaussian density:

$$Q(x) = \frac{1}{\sqrt{2\pi}} \int_x^{+\infty} e^{-u^2/2} du, \quad x \in \mathbb{R}.$$

If Z is a Gaussian random variable with zero mean and variance 1, then $Q(x) = \Pr[Z > x]$.

Proposition 26.6: Elementary properties of the Q function. The following hold:

- (i) Q is well defined, $Q(-\infty) = 1$, $Q(+\infty) = 0$, and it is strictly decreasing on all of $\mathbb{R}$;
- (ii) $Q(0) = \frac{1}{2}$ and $Q(-x) = 1 - Q(x)$ for every x ;
- (iii) if X is Gaussian with mean μ and variance $\sigma^2 > 0$, then $\Pr[X > c] = Q\left(\frac{c-\mu}{\sigma}\right)$;
- (iv) $Q(x) = \frac{1}{2} \operatorname{erfc}(x/\sqrt{2})$, where $\operatorname{erfc}(y) = \frac{2}{\sqrt{\pi}} \int_y^{+\infty} e^{-v^2} dv$.

Proof. (i). The integrand is positive and integrable on $\mathbb{R}$: for $|u| \geq 1$, $u^2 \geq |u|$ and hence $e^{-u^2/2} \leq e^{-|u|/2}$, which is integrable; on $[-1, 1]$ it is continuous. The function Q is therefore finite for every x , tends to $\frac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} e^{-u^2/2} du$ as $x \rightarrow -\infty$ and to 0 as $x \rightarrow +\infty$ (dominated convergence theorem, or simply additivity of the integral). By the fundamental theorem of calculus $Q'(x) = -\frac{1}{\sqrt{2\pi}} e^{-x^2/2} < 0$ for every x : Q is strictly decreasing.

That $Q(-\infty) = 1$ follows from the normalisation $\frac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} e^{-u^2/2} du = 1$, obtained from Lemma 19.4 — according to which $\int_{\mathbb{R}} e^{-\pi t^2} dt = 1$ — with the substitution $u = t\sqrt{2\pi}$,

$du = \sqrt{2\pi} dt$:

$$\frac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} e^{-u^2/2} du = \frac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} e^{-\pi t^2} \sqrt{2\pi} dt = \int_{\mathbb{R}} e^{-\pi t^2} dt = 1,$$

having used $u^2/2 = (t\sqrt{2\pi})^2/2 = \pi t^2$.

(ii). The integrand $e^{-u^2/2}$ is even, hence $\int_{-\infty}^{-x} e^{-u^2/2} du = \int_x^{+\infty} e^{-u^2/2} du$ (substitution $u \mapsto -u$). Therefore

$$Q(-x) = \frac{1}{\sqrt{2\pi}} \int_{-x}^{+\infty} = \frac{1}{\sqrt{2\pi}} \left(\int_{\mathbb{R}} - \int_{-\infty}^{-x} \right) = 1 - \frac{1}{\sqrt{2\pi}} \int_x^{+\infty} = 1 - Q(x).$$

Setting $x = 0$: $Q(0) = 1 - Q(0)$, i.e. $Q(0) = \frac{1}{2}$.

(iii). If X is Gaussian (μ, σ^2) , then $Z = (X - \mu)/\sigma$ is standard Gaussian, and $X > c \iff Z > (c - \mu)/\sigma$; Definition 26.12 applies.

(iv). In the definition of Q set $u = v\sqrt{2}$, $du = \sqrt{2} dv$: when $u = x$, $v = x/\sqrt{2}$, and $u^2/2 = v^2$. Hence

$$Q(x) = \frac{1}{\sqrt{2\pi}} \int_{x/\sqrt{2}}^{+\infty} e^{-v^2} \sqrt{2} dv = \frac{1}{\sqrt{\pi}} \int_{x/\sqrt{2}}^{+\infty} e^{-v^2} dv = \frac{1}{2} \cdot \frac{2}{\sqrt{\pi}} \int_{x/\sqrt{2}}^{+\infty} e^{-v^2} dv = \frac{1}{2} \operatorname{erfc}\left(\frac{x}{\sqrt{2}}\right).$$

□

Theorem 26.9: Error probability of BPSK. Transmit a BPSK of energy per bit E_b (Definition 26.4 with $M = 2$, $\varphi_0 = 0$, $E_s = E_b$) over the AWGN channel of Definition 26.8, with minimum-distance decision and equiprobable symbols. Then the error probability per bit — which coincides with that per symbol, because $m = 1$ — equals exactly

$$P_b^{\text{BPSK}} = Q\left(\sqrt{\frac{2E_b}{N_0}}\right).$$

Proof. Step 1 — the rule reduces to the sign of the real part. The two symbols are $a_0 = +\sqrt{E_b}$ and $a_1 = -\sqrt{E_b}$, both real. By Theorem 26.7 the boundary between the two regions is the locus $2\Re[r(a_1 - a_0)] = |a_1|^2 - |a_0|^2$, i.e. since $a_1 - a_0 = -2\sqrt{E_b}$ is real and $|a_1|^2 = |a_0|^2 = E_b$,

$$-4\sqrt{E_b} \Re r = 0 \iff \Re r = 0.$$

The region of a_0 is therefore the half-plane $\Re r > 0$ and that of a_1 the half-plane $\Re r < 0$: the decision is made by looking at the *sign of the real part* of r , and the imaginary part plays no role at all in the decision.

Step 2 — the law of the real part. Suppose $a_0 = +\sqrt{E_b}$ was transmitted. Then $r = \sqrt{E_b} + n$ and, by Definition 26.8,

$$\Re r = \sqrt{E_b} + \nu, \quad \nu = \Re n \text{ Gaussian with mean 0 and variance } \frac{N_0}{2}.$$

Hence $\Re r$ is Gaussian with mean $\sqrt{E_b}$ and variance $N_0/2$.

Step 3 — the computation. An error occurs if $\Re r < 0$. By Proposition 26.6(iii), applied to $-\Re r$, which is Gaussian with mean $-\sqrt{E_b}$ and variance $N_0/2$, and with threshold $c = 0$:

$$\Pr[\Re r < 0 \mid a = a_0] = \Pr[-\Re r > 0] = Q\left(\frac{0 - (-\sqrt{E_b})}{\sqrt{N_0/2}}\right) = Q\left(\frac{\sqrt{E_b}}{\sqrt{N_0/2}}\right).$$

The ratio under Q simplifies:

$$\frac{\sqrt{E_b}}{\sqrt{N_0/2}} = \sqrt{\frac{E_b}{N_0/2}} = \sqrt{\frac{2E_b}{N_0}}.$$

The tie event $\Re r = 0$ has probability zero (Theorem 26.6(iv)) and does not contribute.

Step 4 — the other symbol, and the conclusion. If $a_1 = -\sqrt{E_b}$ was transmitted, then $\Re r$ is Gaussian with mean $-\sqrt{E_b}$ and variance $N_0/2$, and an error occurs if $\Re r > 0$: by the same proposition the probability is $Q(\frac{0+\sqrt{E_b}}{\sqrt{N_0/2}})$, the same number. Averaging over the two equiprobable symbols gives the same value. Finally $m = \log_2 2 = 1$: each symbol is one bit, and the symbol error probability is the bit error probability. $\square$

Theorem 26.10: Error probability of QPSK. Transmit a QPSK of energy per symbol $E_s = 2E_b$ (Definition 26.4 with $M = 4$, $\varphi_0 = \pi/4$) over the AWGN channel, with minimum-distance decision, equiprobable symbols and a Gray mapping in which the first bit determines the sign of the in-phase component and the second that of the quadrature component. Setting for brevity

$$q = Q\left(\sqrt{\frac{2E_b}{N_0}}\right),$$

the following hold exactly:

$$P_s^{\text{QPSK}} = 1 - (1 - q)^2 = 2q - q^2, \quad P_b^{\text{QPSK}} = q = P_b^{\text{BPSK}}.$$

Proof. Step 1 — the regions are the four quadrants. By Proposition 26.4 the four symbols are $a = \sqrt{E_b}(\varepsilon_1 + i\varepsilon_2)$ with $\varepsilon_1, \varepsilon_2 \in \{\pm 1\}$, having used $\sqrt{E_s/2} = \sqrt{E_b}$. We apply Theorem 26.7 to the symbol $a_{00} = \sqrt{E_b}(1 + i)$. The three boundaries are obtained from the other three symbols; since all four have the same modulus $\sqrt{2E_b}$, the right-hand side $|a_l|^2 - |a_j|^2$ is always zero, and the conditions become $\Re[r(a_l - a_j)] \leq 0$. With $r = x + iy$:

- $a_l = \sqrt{E_b}(-1 + i)$: $a_l - a_j = -2\sqrt{E_b}$, condition $-2\sqrt{E_b}x \leq 0$, i.e. $x \geq 0$;
- $a_l = \sqrt{E_b}(1 - i)$: $a_l - a_j = -2i\sqrt{E_b}$, $\overline{a_l - a_j} = 2i\sqrt{E_b}$, and $\Re[(x + iy) \cdot 2i\sqrt{E_b}] = -2\sqrt{E_b}y \leq 0$, i.e. $y \geq 0$;
- $a_l = \sqrt{E_b}(-1 - i)$: $a_l - a_j = -2\sqrt{E_b}(1 + i)$, and $\Re[(x + iy) \cdot (-2\sqrt{E_b})(1 - i)] = -2\sqrt{E_b}(x + y) \leq 0$, i.e. $x + y \geq 0$, which is implied by the previous two.

The region of a_{00} is therefore the closed first quadrant $\{x \geq 0, y \geq 0\}$, and by symmetry the other three are the other three quadrants. The decision therefore reduces to *two independent sign decisions*: the sign of $\Re r$ and the sign of $\Im r$.

Step 2 — the two components are independent BPSKs. If $a = \sqrt{E_b}(\varepsilon_1 + i\varepsilon_2)$ was transmitted, then

$$\Re r = \varepsilon_1 \sqrt{E_b} + \Re n, \quad \Im r = \varepsilon_2 \sqrt{E_b} + \Im n,$$

and by Definition 26.8 $\Re n$ and $\Im n$ are *independent*, Gaussian with zero mean and variance $N_0/2$. Each of the two components is therefore, word for word, the situation of Step 2 of the proof of Theorem 26.9 with energy E_b : the probability that the sign of $\Re r$ is wrong equals $q = Q(\sqrt{2E_b/N_0})$, and the same for $\Im r$.

Step 3 — symbol error. The decision is correct if and only if *both* signs are correct. The two events are independent (because $\Re n$ and $\Im n$ are, and each event depends on only one of the two), hence

$$\Pr[\text{correct symbol}] = (1 - q)(1 - q) = (1 - q)^2,$$

and $P_s = 1 - (1 - q)^2 = 1 - 1 + 2q - q^2 = 2q - q^2$. By Corollary 26.4 the value does not depend on the transmitted symbol, and coincides with the symbol error probability.

Step 4 — bit error. With the mapping described, the first bit is determined by the sign of $\Re r$ alone and the second by the sign of $\Im r$ alone: this is a Gray mapping (Definition 26.5), because adjacent symbols — which by Theorem 26.3 are those differing in a single component — have labels differing in a single bit. Each bit is therefore wrong with probability q , and the

bit error probability, defined as the expected value of the fraction of wrong bits, equals

$$P_b = \frac{1}{2} \left(\Pr[\text{first bit wrong}] + \Pr[\text{second bit wrong}] \right) = \frac{q + q}{2} = q.$$

Comparing with Theorem 26.9, $P_b^{\text{QPSK}} = P_b^{\text{BPSK}}$: this is the probabilistic translation of Corollary 26.3, according to which the two constellations have the same minimum distance at equal energy per bit. $\square$

Example 26.6: The numbers, computed twice. The table gives $P_b = Q(\sqrt{2E_b/N_0})$ and $P_s^{\text{QPSK}} = 2P_b - P_b^2$ for a few values of E_b/N_0 . The second column is $10^{\text{dB}/10}$, the third the argument of the Q function.

E_b/N_0 (dB)	E_b/N_0	$\sqrt{2E_b/N_0}$	P_b (BPSK and QPSK)	P_s (QPSK)
0.0	1.0000000	1.4142136	$7.8649604 \cdot 10^{-2}$	$1.5111345 \cdot 10^{-1}$
2.0	1.5848932	1.7803894	$3.7506128 \cdot 10^{-2}$	$7.3605547 \cdot 10^{-2}$
4.0	2.5118864	2.2413774	$1.2500818 \cdot 10^{-2}$	$2.4845366 \cdot 10^{-2}$
6.0	3.9810717	2.8217270	$2.3882908 \cdot 10^{-3}$	$4.7708776 \cdot 10^{-3}$
8.0	6.3095734	3.5523439	$1.9090777 \cdot 10^{-4}$	$3.8177910 \cdot 10^{-4}$
9.6	9.1201084	4.2708567	$9.7361760 \cdot 10^{-6}$	$1.9472257 \cdot 10^{-5}$
10.0	10.0000000	4.4721360	$3.8721082 \cdot 10^{-6}$	$7.7442014 \cdot 10^{-6}$
12.0	15.8489319	5.6300856	$9.0060104 \cdot 10^{-9}$	$1.8012021 \cdot 10^{-8}$

First route: the closed form. The values of P_b are obtained from the relation $Q(x) = \frac{1}{2} \text{erfc}(x/\sqrt{2})$ (Proposition 26.6(iv)) with the `erfc` function of the standard library, which implements its rational approximation; for instance at 10 dB the argument is $\sqrt{20} = 4.4721360$ and $\frac{1}{2} \text{erfc}(4.4721360/\sqrt{2}) = \frac{1}{2} \text{erfc}(3.1622777) = 3.8721082 \cdot 10^{-6}$.

Second, independent route: numerical integration. A Python script directly integrates $\frac{1}{\sqrt{2\pi}} e^{-u^2/2}$ from x to $x + 40$ with Simpson's rule over 200,000 subintervals, without using `erfc`. The relative discrepancies from the first route are at most $4.7 \cdot 10^{-14}$ over all eight values. $\checkmark$

Third, internal-consistency check. By Theorem 26.10 it must hold that $P_s = 1 - (1 - P_b)^2$: at 6 dB the direct computation gives $4.7708776 \cdot 10^{-3}$ and the form $2P_b - P_b^2$ gives the same number, with zero discrepancy to the first twelve digits; at 10 dB the discrepancy is $3.5 \cdot 10^{-20}$, i.e. pure machine rounding. $\checkmark$

Reading. The row at 9.6 dB is the one encountered most often in designs: $E_b/N_0 = 9.6$ dB is, to good approximation, the value that brings uncoded BPSK to an error probability of about 10^{-5} . Between 8 and 12 dB the probability drops by more than four orders of magnitude: the curve is extremely steep, and this is why in radio one speaks of a "threshold".

Remark 26.10: The union bound, and why it is not a theorem of this chapter.

For constellations other than BPSK and QPSK, the exact error probability generally has no elementary closed form, and one uses the **union bound**: since the event "error" is contained in the union of the events " r is closer to a_l than to a_j " as $l \neq j$ ranges, and each of these has probability $Q(|a_j - a_l|/\sqrt{2N_0})$ — this is the computation of Theorem 26.9 applied to the projection along the direction $a_l - a_j$ — subadditivity of probability gives

$$P_s \leq \frac{1}{M} \sum_j \sum_{l \neq j} Q\left(\frac{|a_j - a_l|}{\sqrt{2N_0}}\right) \leq (M-1) Q\left(\frac{d_{\min}}{\sqrt{2N_0}}\right),$$

and the estimate is better the smaller P_s is. This is a bound, not an equality, and this is why we report it in a remark and not in a theorem: its complete proof would require carefully treating the projection of complex Gaussian noise onto an arbitrary direction, which is not

Figure 26.6: The two curves of Example 26.6, drawn from the tabulated values and not from a measurement. The horizontal scale is 0.55 cm per decibel and the vertical one 0.75 cm per decade: the ordinate of a point is $0.75 \log_{10} P$. For instance at 10 dB, $P_b = 3.8721082 \cdot 10^{-6}$, $\log_{10} P_b = -5.41205$ and ordinate -4.0590 ; at 12 dB, $\log_{10} P_b = -8.04547$ and ordinate -6.0341 . The solid curve holds both for BPSK and for the *bit* probability of QPSK (Theorem 26.10): the two coincide, and this is the graphical content of Corollary 26.3. The dashed curve is the *symbol* error probability of QPSK, which lies slightly above because $P_s = 2P_b - P_b^2 \approx 2P_b$ when P_b is small: a discrepancy of $10 \log_{10} 2 = 3.01$ dB in ordinate, not in abscissa.

needed here. For M -PSK, substituting $d_{\min} = 2\sqrt{E_s} \sin(\pi/M)$ from Theorem 26.3 and $E_s = mE_b$, the argument of Q becomes

$$\frac{2\sqrt{mE_b} \sin(\pi/M)}{\sqrt{2N_0}} = \sqrt{\frac{2mE_b}{N_0}} \sin \frac{\pi}{M},$$

a formula that reproduces exactly the results proved for $M = 2$ and $M = 4$ (where $m \sin^2(\pi/M) = 1$ in both cases, as shown by the last column of the table of Example 26.3), and which for $M \geq 8$ remains a bound.

Remark 26.11: Panorama: how far one can go. The curves of Figure 26.6 concern uncoded transmissions, in which each bit travels alone. Shannon's channel capacity theorem (1948) states that on the AWGN channel of bandwidth W and signal-to-noise ratio S/N there exists, for every transmission rate below $C = W \log_2(1 + S/N)$, a sequence of codes that makes the error probability arbitrarily small — and that no code can do so for higher rates. In the infinite-bandwidth limit this translates into the minimum value $E_b/N_0 = \ln 2 = 0.6931472$, i.e. -1.5917 dB, below which no reliable communication is possible. Between the 9.6 dB of uncoded BPSK at 10^{-5} and this limit there are about 11 dB: this is the space that error-correcting codes have filled in seventy years. Shannon's theorem is **not** proved in this treatise: its proof requires information theory (entropy, mutual information, the asymptotic equipartition property) and the central limit theorem, which are not developed here. We report it as a panorama, not as an available result: no proof in the chapter uses it.

26.8. Minimum distance, bandwidth and spectral efficiency

It remains to link the two quantities the designer cannot optimise simultaneously: how many bits per second pass through each occupied hertz, and how far apart the constellation points remain. The link runs through the waveform, and more precisely through the condition that the pulse not interfere with neighbouring symbols.

Definition 26.13: Transmit pulse and intersymbol interference. Transmit in complex baseband the signal $x(t) = \sum_{k \in \mathbb{Z}} a_k p(t - kT)$, with $a_k \in \mathcal{A}$ and p real continuous.

Sampling at instant $k_0 T$ gives

$$x(k_0 T) = a_{k_0} p(0) + \underbrace{\sum_{k \neq k_0} a_k p((k_0 - k)T)}_{\text{intersymbol interference}}.$$

The pulse p is called a **Nyquist pulse** for step T if $p(kT) = \delta_{k0}$ for every $k \in \mathbb{Z}$ (i.e. $p(0) = 1$ and $p(kT) = 0$ for $k \neq 0$): in that case the intersymbol interference is zero and $x(k_0 T) = a_{k_0}$.

Theorem 26.11: Nyquist criterion for the absence of intersymbol interference.

Let $p: \mathbb{R} \rightarrow \mathbb{R}$ be continuous, with transform $P = \hat{p}$, and suppose there exist $C > 0$ and $\varepsilon > 0$ such that

$$|p(t)| \leq \frac{C}{(1 + |t|)^{1+\varepsilon}} \quad \text{and} \quad |P(f)| \leq \frac{C}{(1 + |f|)^{1+\varepsilon}} \quad \text{for every } t, f \in \mathbb{R}.$$

Then, for every $T > 0$ and every $f \in \mathbb{R}$,

$$\sum_{k \in \mathbb{Z}} p(kT) e^{-i2\pi f k T} = \frac{1}{T} \sum_{n \in \mathbb{Z}} P\left(f + \frac{n}{T}\right),$$

and p is a Nyquist pulse for step T **if and only if**

$$\sum_{n \in \mathbb{Z}} P\left(f + \frac{n}{T}\right) = T \quad \text{for every } f \in \mathbb{R}.$$

Proof. Step 1 — reduction to the Poisson formula. Fix $f \in \mathbb{R}$ and set

$$h(u) = p(uT) e^{-i2\pi f u T}, \quad u \in \mathbb{R}.$$

The function h is continuous and satisfies hypothesis (H1) of Theorem 19.12: indeed $|h(u)| = |p(uT)| \leq C(1 + |uT|)^{-1-\varepsilon} \leq C'(1 + |u|)^{-1-\varepsilon}$ with $C' = C \max\{1, T^{-1-\varepsilon}\}$. Its transform is computed with the substitution $v = uT$, $du = dv/T$:

$$\hat{h}(\xi) = \int_{\mathbb{R}} p(uT) e^{-i2\pi f u T} e^{-i2\pi \xi u} du = \frac{1}{T} \int_{\mathbb{R}} p(v) e^{-i2\pi(f + \frac{\xi}{T})v} dv = \frac{1}{T} P\left(f + \frac{\xi}{T}\right),$$

and satisfies (H2) for the same reason, with constant $C/T \cdot \max\{1, T^{1+\varepsilon}\}$.

Step 2 — application. Theorem 19.12 with $t = 0$ gives $\sum_n h(n) = \sum_n \hat{h}(n)$, i.e.

$$\sum_{n \in \mathbb{Z}} p(nT) e^{-i2\pi f n T} = \frac{1}{T} \sum_{n \in \mathbb{Z}} P\left(f + \frac{n}{T}\right),$$

which is the first formula of the statement (with k in place of n); both series converge absolutely and uniformly in f .

Step 3 — the equivalence. The left-hand side, $S(f) = \sum_k p(kT)e^{-i2\pi f kT}$, is a continuous function periodic of period $1/T$ in f , and the numbers $p(kT)$ are *exactly* its Fourier coefficients: indeed, by uniform convergence one can integrate term by term and, by orthogonality of the exponentials over one period,

$$T \int_0^{1/T} S(f) e^{+i2\pi f k_0 T} df = T \sum_k p(kT) \int_0^{1/T} e^{-i2\pi f(k-k_0)T} df = p(k_0 T),$$

because the inner integral equals $1/T$ if $k = k_0$ and 0 otherwise.

If $p(kT) = \delta_{k0}$, then $S(f) = 1$ for every f , and by Step 2 $\sum_n P(f + n/T) = T$. Conversely, if $\sum_n P(f + n/T) = T$ for every f , then $S(f) = 1$ for every f ; the Fourier coefficients of S are therefore those of the constant function 1, i.e. $p(0) = 1$ and $p(kT) = 0$ for $k \neq 0$, by uniqueness of the Fourier coefficients of a continuous function (Corollary 17.2). This completes the equivalence. $\square$

Corollary 26.6: The minimum Nyquist bandwidth. If P vanishes outside $[-\frac{1}{2T}, \frac{1}{2T}]$ and p is a Nyquist pulse for step T , then necessarily $P = T \cdot \mathbf{1}_{[-\frac{1}{2T}, \frac{1}{2T}]}$ almost everywhere. The baseband half-bandwidth cannot therefore be smaller than $\frac{1}{2T}$, and the corresponding bandpass bandwidth (Definition 26.1) is $W = \frac{1}{T} = R_s$: one baud per hertz.

Proof. Let $|f| < \frac{1}{2T}$. For every $n \neq 0$, $|f + n/T| \geq \frac{|n|}{T} - |f| > \frac{1}{T} - \frac{1}{2T} = \frac{1}{2T}$, hence $P(f + n/T) = 0$: in the sum of Theorem 26.11 only the term $n = 0$ survives, and the condition becomes $P(f) = T$. Outside the interval P is zero by hypothesis. The value at the two endpoints does not matter, because two functions equal almost everywhere have the same inverse transform. For the last claim: the complex envelope has half-bandwidth $B = \frac{1}{2T}$ (Theorem 26.1(i)), and the bandwidth of the bandpass signal is $W = 2B = \frac{1}{T}$ (Definition 26.1). $\square$

Remark 26.12: The sinc function and the hypotheses of the theorem. The pulse achieving the limit of Corollary 26.6 is the inverse transform of $T \cdot \mathbf{1}_{[-\frac{1}{2T}, \frac{1}{2T}]}$, i.e.

$$p(t) = \text{sinc}\left(\frac{t}{T}\right) = \frac{\sin(\pi t/T)}{\pi t/T},$$

by Proposition 19.2. That it satisfies $p(kT) = \delta_{k0}$ is checked directly, without any theorem: for $k \neq 0$ the numerator $\sin(k\pi)$ vanishes and the denominator does not, and for $k = 0$ the standard limit $\lim_{x \rightarrow 0} \frac{\sin x}{x} = 1$ gives $p(0) = 1$. It must however be stated precisely that this p **does not** satisfy hypothesis (H1) of Theorem 26.11, because $|\text{sinc}(t/T)|$ decays only as $1/|t|$ and not as $(1 + |t|)^{-1-\varepsilon}$: the theorem does not apply to the sinc function, and there is no need for it to, because in that case the check is immediate. The fact is nonetheless a serious practical flaw: a tail decaying as $1/|t|$ makes the sum of intersymbol interference not absolutely convergent, and even a small error on the sampling instant produces unbounded interference. This is exactly why no real system uses the sinc pulse, accepting instead to occupy a little more bandwidth.

Proposition 26.7: *The raised-cosine pulse satisfies the Nyquist criterion. Let $T > 0$ and $\beta \in [0, 1]$ (roll-off factor). Define*

$$P_\beta(f) = \begin{cases} T, & |f| \leq \frac{1-\beta}{2T}, \\ \frac{T}{2} \left[1 + \cos\left(\frac{\pi T}{\beta} \left(|f| - \frac{1-\beta}{2T}\right)\right) \right], & \frac{1-\beta}{2T} \leq |f| \leq \frac{1+\beta}{2T}, \\ 0, & |f| \geq \frac{1+\beta}{2T} \end{cases}$$

(for $\beta = 0$ only the first case is meant). Then $\sum_{n \in \mathbb{Z}} P_\beta(f + \frac{n}{T}) = T$ for every f , and the baseband half-bandwidth occupied is $B = \frac{1+\beta}{2T}$.

Proof. Step 1 — the odd symmetry about $\frac{1}{2T}$. Let $0 \leq x \leq \frac{\beta}{2T}$. Then both $\frac{1}{2T} + x$ and $\frac{1}{2T} - x$ belong to the transition interval $[\frac{1-\beta}{2T}, \frac{1+\beta}{2T}]$. For the first,

$$\frac{\pi T}{\beta} \left(\frac{1}{2T} + x - \frac{1-\beta}{2T} \right) = \frac{\pi T}{\beta} \left(\frac{\beta}{2T} + x \right) = \frac{\pi}{2} + \frac{\pi T x}{\beta},$$

and since $\cos(\frac{\pi}{2} + \theta) = -\sin \theta$,

$$P_\beta\left(\frac{1}{2T} + x\right) = \frac{T}{2} \left[1 - \sin \frac{\pi T x}{\beta} \right].$$

For the second, with the same computation and $\cos(\frac{\pi}{2} - \theta) = \sin \theta$,

$$P_\beta\left(\frac{1}{2T} - x\right) = \frac{T}{2} \left[1 + \sin \frac{\pi T x}{\beta} \right].$$

Adding, the two sines cancel:

$$P_\beta\left(\frac{1}{2T} - x\right) + P_\beta\left(\frac{1}{2T} + x\right) = T.$$

Step 2 — the sum of the replicas. By periodicity of the sum in f of period $\frac{1}{T}$ it suffices to check the identity for $f \in [0, \frac{1}{2T}]$; write $f = \frac{1}{2T} - x$ with $x \in [0, \frac{1}{2T}]$. The terms with $|n| \geq 2$ vanish: indeed $|f + \frac{n}{T}| \geq \frac{2}{T} - \frac{1}{2T} = \frac{3}{2T} > \frac{1+\beta}{2T}$ because $\beta \leq 1 < 2$. What remains are $n = 0$ and $n = -1$, and

$$f - \frac{1}{T} = \frac{1}{2T} - x - \frac{1}{T} = -\left(\frac{1}{2T} + x\right),$$

whose modulus is $\frac{1}{2T} + x$. Since P_β is even,

$$\sum_n P_\beta\left(f + \frac{n}{T}\right) = P_\beta\left(\frac{1}{2T} - x\right) + P_\beta\left(\frac{1}{2T} + x\right).$$

If $x \leq \frac{\beta}{2T}$ the sum equals T by Step 1. If instead $x > \frac{\beta}{2T}$, then $\frac{1}{2T} + x > \frac{1+\beta}{2T}$ and the second term is zero, while $\frac{1}{2T} - x < \frac{1-\beta}{2T}$ and the first equals T : again the sum is T . In both cases the condition of Theorem 26.11 is satisfied.

Step 3 — the bandwidth. P_β is zero for $|f| > \frac{1+\beta}{2T}$ and nonzero just below (for $\beta < 1$, $T > 0$ holds on the flat stretch; for $\beta = 1$ the cosine equals $\frac{T}{2}(1 + \cos \theta) > 0$ for $\theta < \pi$): the half-bandwidth is therefore exactly $B = \frac{1+\beta}{2T}$. $\square$

Definition 26.14: Spectral efficiency. Let $R_b = mR_s = m/T$ be the bit rate in bit/s and W the bandwidth occupied by the bandpass signal in hertz. The **spectral efficiency** is $\eta = \frac{R_b}{W}$, measured in bits per second per hertz.

Corollary 26.7: Spectral efficiency of a modulation with a Nyquist pulse. With the raised-cosine pulse of roll-off β (Proposition 26.7) and a constellation of $M = 2^m$ points,

$$\eta = \frac{m}{1 + \beta} \quad \text{bit/s/Hz.}$$

In particular $\eta = m$ in the ideal limit $\beta = 0$, and $\eta = m/2$ for $\beta = 1$.

Proof. By Proposition 26.7 the baseband half-bandwidth is $B = \frac{1+\beta}{2T}$; by Definition 26.1 the bandwidth of the bandpass signal is $W = 2B = \frac{1+\beta}{T}$. The bit rate is $R_b = m/T$, hence

$$\eta = \frac{R_b}{W} = \frac{m/T}{(1+\beta)/T} = \frac{m}{1+\beta}.$$

□

Proposition 26.8: The price of spectral efficiency in minimum distance. At equal energy per bit E_b and equal roll-off β , square QAM of $M = 2^m$ points (m even) has efficiency $\eta = m/(1 + \beta)$ and

$$\frac{d_{\min}^2}{4E_b} = \frac{3m}{2(2^m - 1)},$$

a quantity that decreases exponentially in m : doubling the spectral efficiency requires, asymptotically, about 3 dB more energy per bit for each bit added to the symbol.

Proof. The efficiency is Corollary 26.7. By Theorem 26.4, $d_{\min}^2 = \frac{6E_s}{M-1}$, and by Definition 26.3 $E_s = mE_b$; hence

$$\frac{d_{\min}^2}{4E_b} = \frac{6mE_b}{4E_b(M-1)} = \frac{3m}{2(2^m - 1)}.$$

For the asymptotic behaviour, the ratio between two consecutive values (m and $m+1$) is

$$\frac{3(m+1)/(2(2^{m+1}-1))}{3m/(2(2^m-1))} = \frac{m+1}{m} \cdot \frac{2^m-1}{2^{m+1}-1} \xrightarrow{m \rightarrow \infty} 1 \cdot \frac{1}{2} = \frac{1}{2},$$

because $\frac{m+1}{m} \rightarrow 1$ and $\frac{2^m-1}{2^{m+1}-1} = \frac{1-2^{-m}}{2-2^{-m}} \rightarrow \frac{1}{2}$. A factor $\frac{1}{2}$ in the ratio $d_{\min}^2/(4E_b)$ must be compensated by a factor 2 in E_b to leave the argument of the Q function unchanged, i.e. by $10 \log_{10} 2 = 3.0102999$ dB. □

Example 26.7: The price, in numbers. With $\beta = 0$ (ideal limit) Proposition 26.8 gives:

M	$m = \eta$	$d_{\min}^2/(4E_b)$	in dB	discrepancy from previous row
4	2	1.0000000	0.0000000	—
16	4	0.4000000	−3.9794001	3.9794001
64	6	0.1428571	−8.4509804	4.4715803
256	8	0.0470588	−13.2735893	4.8226089

Each doubling of the points *per dimension* (i.e. each additional two bits per symbol) costs between 4 and 5 dB, and the cost tends to 6 dB, i.e. 3 dB per bit, as proved. Read the

table together with that of Example 26.6: at 10 dB of E_b/N_0 , QPSK sits at $P_b \approx 3.9 \cdot 10^{-6}$; 256-QAM, at the same E_b/N_0 , has the argument of the Q function reduced by the factor $\sqrt{0.0470588} = 0.2169$ and its error probability is of the order of 10^{-1} : four times the spectral efficiency is not free.

Independent check. The four values $\frac{3m}{2(2^m-1)}$ are recomputed by hand: $\frac{6}{2 \cdot 3} = 1$, $\frac{12}{2 \cdot 15} = \frac{2}{5} = 0.4$, $\frac{18}{2 \cdot 63} = \frac{1}{7} = 0.1428571$, $\frac{24}{2 \cdot 255} = \frac{4}{85} = 0.0470588$; the logarithms: $10 \log_{10}(2/5) = -3.9794001$, $10 \log_{10}(1/7) = -8.4509804$, $10 \log_{10}(4/85) = -13.2735893$. ✓

Figure 26.7: The raised-cosine spectrum of Proposition 26.7, drawn in units $1/(2T) = 2$ cm on the abscissa and $T = 2$ cm on the ordinate. In grey the ideal case $\beta = 0$, i.e. the rectangle of Corollary 26.6. In blue the case $\beta = 0.5$: the flat stretch reaches $\frac{1-\beta}{2T} = 0.25/T$ (abscissa 1 cm) and the transition ends at $\frac{1+\beta}{2T} = 0.75/T$ (abscissa 3 cm). The ordinates of the transition stretch are $2 \cdot \frac{1}{2} [1 + \cos(\pi(2Tf - 0.5))]$ computed at nine points: 2, 1.92388, 1.70711, 1.38268, 1, 0.61732, 0.29289, 0.07612, 0. The two green segments have the same length, 0.29289 cm: this is the odd symmetry about $(\frac{1}{2T}, \frac{T}{2})$ proved in Step 1, i.e. what makes the replicas sum to T .

26.9. Eye diagram and error vector

The two tools used in the laboratory to judge a digital link are the eye diagram, which looks at a real component in time, and the error vector, which looks at the complex symbol in the plane. Neither is an analogy: both have a precise definition and a provable relation to the quantities of this chapter.

Definition 26.15: Eye diagram. Let $x(t) = \sum_k a_k p(t - kT)$ as in Definition 26.13 and let $L \geq 1$ be an integer. The **eye diagram** of order L of the signal x is the superposition, on a single time axis $\tau \in [-\frac{LT}{2}, \frac{LT}{2}]$, of all the traces

$$\tau \mapsto x(\tau + k_0 T), \quad k_0 \in \mathbb{Z}.$$

The **vertical eye opening** at instant τ is

$$\mathcal{O}(\tau) = \inf \{x(\tau + k_0 T) : a_{k_0} = +1\} - \sup \{x(\tau + k_0 T) : a_{k_0} = -1\},$$

where the infimum and supremum are taken over all admissible sequences (a_k) . The eye is said to be **open** at τ if $\mathcal{O}(\tau) > 0$.

Proposition 26.9: Eye opening for an antipodal binary transmission. Let $a_k \in \{+1, -1\}$ for every k , and let p be such that $\sum_{k \in \mathbb{Z}} |p(\tau + kT)| < +\infty$ for every τ . Then,

setting

$$D(\tau) = p(\tau) - \sum_{k \neq 0} |p(\tau - kT)|,$$

we have $\mathcal{O}(\tau) = 2D(\tau)$, and the infimum is a minimum, attained by the sequence $a_k = -\text{sgn}(p(\tau - kT))$ for $k \neq 0$ (with $a_0 = +1$). In particular, if p is a Nyquist pulse (Definition 26.13), then $\mathcal{O}(0) = 2$: at the exact sampling instant the eye is completely open.

Proof. Set $k_0 = 0$ without loss of generality (the traces are the same up to renaming the indices). With $a_0 = +1$,

$$x(\tau) = \sum_{k \in \mathbb{Z}} a_k p(\tau - kT) = p(\tau) + \sum_{k \neq 0} a_k p(\tau - kT),$$

a series absolutely convergent by hypothesis (the coefficients a_k have modulus 1). By the triangle inequality, for every choice of signs,

$$\sum_{k \neq 0} a_k p(\tau - kT) \geq - \sum_{k \neq 0} |p(\tau - kT)|,$$

hence $x(\tau) \geq D(\tau)$. The inequality is an equality for the choice $a_k = -\text{sgn}(p(\tau - kT))$ (with $a_k = +1$ arbitrary where $p(\tau - kT) = 0$), because then $a_k p(\tau - kT) = -|p(\tau - kT)|$ for every $k \neq 0$. That choice is admissible, being a sequence of signs. Hence $\inf\{x(\tau) : a_0 = +1\} = D(\tau)$, and it is a minimum.

For $a_0 = -1$ one argues the same way with signs swapped: $x(\tau) \leq -D(\tau)$, with equality for the opposite sequence; hence $\sup\{x(\tau) : a_0 = -1\} = -D(\tau)$. Subtracting, $\mathcal{O}(\tau) = D(\tau) - (-D(\tau)) = 2D(\tau)$.

If p is Nyquist, at $\tau = 0$ we have $p(0) = 1$ and $p(-kT) = 0$ for $k \neq 0$, hence $D(0) = 1 - 0 = 1$ and $\mathcal{O}(0) = 2$. $\square$

Example 26.8: The eye closes at half a symbol. Take the raised-cosine pulse with $\beta = 0.5$ and $T = 1$, whose expression in time is

$$p(t) = \text{sinc}(t) \frac{\cos(\pi\beta t)}{1 - (2\beta t)^2} = \frac{\sin(\pi t)}{\pi t} \cdot \frac{\cos(\pi t/2)}{1 - t^2},$$

and consider only the three symbols a_{-1}, a_0, a_1 (the other contributions are smaller than $|p(2)|$ and are neglected in the computation, which is thus explicitly truncated). The values needed are

$$p(0) = 1, \quad p\left(\frac{1}{2}\right) = p\left(-\frac{1}{2}\right) = 0.6002109, \quad p\left(\frac{3}{2}\right) = -0.1200422.$$

Applying Proposition 26.9:

$$D(0) = p(0) - |p(-1)| - |p(1)| = 1 - 0 - 0 = 1, \quad \mathcal{O}(0) = 2,$$

because the raised cosine is Nyquist (Proposition 26.7 and Theorem 26.11); while at half a symbol

$$D\left(\frac{1}{2}\right) = p\left(\frac{1}{2}\right) - \left|p\left(-\frac{1}{2}\right)\right| - \left|p\left(\frac{3}{2}\right)\right| = 0.6002109 - 0.6002109 - 0.1200422 = -0.1200422 < 0.$$

The eye is **closed**: there exists a sequence of symbols — for instance $(a_{-1}, a_0, a_1) = (+1, +1, -1)$ — for which, even though $a_0 = +1$ was transmitted, the signal sampled at $t = T/2$ equals -0.1200422 , i.e. has the wrong sign *even in the absence of noise*. A timing

error of half a symbol destroys the link independently of the transmitted power: this is why timing recovery is, in a receiver, a subsystem as important as the demodulator.

Independent check. A Python script evaluates p from the closed form and builds the eight traces corresponding to the eight triples $(a_{-1}, a_0, a_1) \in \{\pm 1\}^3$ on a grid of step 0.1. At $t = 0$ all eight traces equal exactly ± 1 (the only two possible ordinates, as it must be for a Nyquist pulse); at $t = 0.5$ the values are ± 1.3205 , ± 0.1200422 : the trace $(+1, +1, -1)$ equals -0.1200422 , which coincides with $D(1/2)$ computed above. ✓

Figure 26.8: The order-2 eye diagram of Example 26.8, drawn from the values of the raised-cosine pulse with $\beta = 0.5$ and not from a measurement. Scale: $T = 2.6$ cm on the abscissa and one amplitude unit = 1.3 cm on the ordinate; each trace is the polyline on the eleven points $\tau = -1.0; -0.8; \dots; 1.0$ (in units of T). The eight traces correspond to the eight triples (a_{-1}, a_0, a_1) and are pairwise opposite, by linearity of the sum: the four with $a_{-1} = -1$ are the reflections of the four drawn first. At $\tau = 0$ all pass through ± 1 : the eye is open by $\mathcal{O}(0) = 2$ (green segment), which is the content of Proposition 26.9 for a Nyquist pulse. On the dashed vertical $\tau = T/2$ the traces cross through zero: there the eye is closed, $D(T/2) = -0.1200422$.

Definition 26.16: Error vector and EVM. Let $a_1, \dots, a_K \in \mathcal{A}$ be the transmitted symbols and $r_1, \dots, r_K \in \mathbb{C}$ the corresponding received symbols after the matched filter and synchronisation. The **error vector** of the k -th symbol is the complex number

$$e_k = r_k - a_k,$$

and the **error vector magnitude** (EVM), root-mean-square, is

$$\text{EVM}_K = \sqrt{\frac{\frac{1}{K} \sum_{k=1}^K |e_k|^2}{\frac{1}{K} \sum_{k=1}^K |a_k|^2}} = \sqrt{\frac{\sum_{k=1}^K |r_k - a_k|^2}{\sum_{k=1}^K |a_k|^2}},$$

usually expressed as a percentage. The two components of e_k in the basis $\{a_k/|a_k|, i a_k/|a_k|\}$ are called the **amplitude error** and the **phase error** of the symbol.

Proposition 26.10: EVM and signal-to-noise ratio. On the AWGN channel of Definition 26.8, with $r_k = a_k + n_k$ and n_k independent of each other and of the symbols,

$$\frac{\mathbb{E} \left[\sum_{k=1}^K |e_k|^2 \right]}{\mathbb{E} \left[\sum_{k=1}^K |a_k|^2 \right]} = \frac{N_0}{E_s} = \frac{1}{\text{SNR}_s}, \quad \text{i.e.} \quad \text{EVM} \approx \frac{1}{\sqrt{\text{SNR}_s}},$$

where $\text{SNR}_s = E_s/N_0$ is the signal-to-noise ratio per symbol. In particular $\text{SNR}_s = 20$ dB corresponds to $\text{EVM} = 10\%$.

Proof. By Definition 26.16, $e_k = r_k - a_k = n_k$. By Definition 26.8, $\mathbb{E}[|n_k|^2] = \mathbb{E}[(\Re n_k)^2] + \mathbb{E}[(\Im n_k)^2] = \frac{N_0}{2} + \frac{N_0}{2} = N_0$, hence, by linearity of expectation, $\mathbb{E}[\sum_k |e_k|^2] = KN_0$. By Proposition 26.3, $\mathbb{E}[\sum_k |a_k|^2] = KE_s$. The ratio is $KN_0/(KE_s) = N_0/E_s$, independent of K . For the last claim: $\text{SNR}_s = 20$ dB means $E_s/N_0 = 10^{20/10} = 100$, hence $1/\sqrt{\text{SNR}_s} = 1/10 = 0.1 = 10\%$. $\square$

Remark 26.13: Why " $\approx$ " and not "=", and what EVM really measures. Two clarifications, both important in practical use.

First. The quantity EVM_K of Definition 26.16 is the ratio of two sample averages, not of two expected values: Proposition 26.10 computes the ratio of the expected values. The two coincide in the limit $K \rightarrow \infty$ by the strong law of large numbers, which guarantees the almost-sure convergence of each of the two averages to its own expected value (the variables $|n_k|^2$ and $|a_k|^2$ are independent, identically distributed and integrable); the law of large numbers is a result of probability theory that is imported, not proved in this treatise. For finite K the measured EVM fluctuates, and laboratory measurements always state the number of symbols over which the average was taken.

Second. The equality $\text{EVM}^2 = N_0/E_s$ holds only if additive noise is the only impairment. In a real link the error vector also collects residual intersymbol interference (Definition 26.13), oscillator phase error, amplifier distortion, imbalance between the two IQ branches. This is exactly why the measurement is useful: an EVM much worse than $1/\sqrt{\text{SNR}_s}$ signals that the degradation is not noise, and the shape of the cloud of error vectors tells which cause is at work — a cloud elongated radially indicates amplitude compression, one elongated tangentially indicates phase noise, a cloud rotated as a block indicates a frequency error, i.e. the slow rotation of Example 26.1.

Example 26.9: From SNR to EVM and back. From Proposition 26.10:

SNR_s (dB)	SNR_s	$\text{EVM} = 1/\sqrt{\text{SNR}_s}$
10	10.0000000	31.6227766%
15	31.6227766	17.7827941%
20	100.0000000	10.0000000%
25	316.2277660	5.6234133%
30	1,000.0000000	3.1622777%

Note the practical rule that follows: every 20 dB of SNR corresponds to a factor 10 on EVM, an immediate consequence of $\text{EVM} = 10^{-\text{SNR}_{\text{dB}}/20}$.

Independent check. The two columns are obtained from each other in two different ways: $\text{SNR} = 10^{\text{dB}/10}$ followed by $\text{EVM} = 1/\sqrt{\text{SNR}}$, or directly $\text{EVM} = 10^{-\text{dB}/20}$. For 15 dB: the first route gives $10^{1.5} = 31.6227766$ and $1/\sqrt{31.6227766} = 0.1778279$; the second $10^{-0.75} = 0.1778279$. $\checkmark$

26.10. Assigned exercises

These are *new* exercises, distinct from the worked ones in Section 26.11. The answers are in the Teacher's key (Section 26.13).

Exercise 26.1: From the carrier to baseband, and back. *Objective:* to be able to compute the complex envelope of a given signal, verify uniqueness, and recognise where the hypothesis $B < f_c$ enters. *Estimated time:* 40 minutes. *Type:* symbolic computation and proof. *Level:* basic–intermediate.

Figure 26.9: The error vector of Definition 26.16. The ideal symbol is $a_k = 2.5 e^{i\pi/6}$, i.e. $(2.5 \cos 30^\circ, 2.5 \sin 30^\circ) = (2.1651, 1.25)$ in centimetres; the received symbol is $r_k = (1.85, 1.72)$, chosen for the figure. The error vector is $e_k = r_k - a_k = (-0.3151, 0.4700)$, of modulus $\sqrt{0.3151^2 + 0.4700^2} = 0.5659$. Its decomposition in the basis $(\frac{a_k}{|a_k|}, i \frac{a_k}{|a_k|}) = ((0.8660, 0.5), (-0.5, 0.8660))$ gives the radial component $-0.3151 \cdot 0.8660 + 0.4700 \cdot 0.5 = -0.0379$ (amplitude error) and the tangential component $0.3151 \cdot 0.5 + 0.4700 \cdot 0.8660 = 0.5646$ (phase error). The square of the modulus is recovered from the two components: $0.0379^2 + 0.5646^2 = 0.3202 = 0.5659^2$. ✓

Consider the real signal

$$s(t) = A \cos(2\pi f_c t) + B \cos(2\pi(f_c + \nu)t + \varphi),$$

with $A = 2$, $B = 1$, $f_c = 1$ MHz, $\nu = 1$ kHz, $\varphi = \pi/3$.

- Write s_L , s_I and s_Q using Theorem 26.2, and compute their value at $t = 0$; say why the answer is unique and which hypothesis of Definition 26.1 guarantees it.
- Compute $|s_L(t)|^2$ in closed form and determine the maximum and minimum value of the modulus $|s_L|$, stating at which instants they are attained.
- Verify that s_L has half-bandwidth ν and that hence the ratio f_c/ν equals 1,000: how large must $f_c T$ be for the discrepancy from carrier orthogonality of Proposition 26.2(ii) to stay below 0.1%?
- If the demodulator mistakenly uses the carrier $\cos(2\pi f_c t + \theta)$ instead of $\cos(2\pi f_c t)$, show that the recovered components are $\tilde{s}_I = s_I \cos \theta + s_Q \sin \theta$ and $\tilde{s}_Q = -s_I \sin \theta + s_Q \cos \theta$, i.e. that the complex envelope is multiplied by $e^{-i\theta}$: the constellation rotates rigidly.

Exercise 26.2: Designing an optimal 8 + 8-APSK. *Objective:* to independently repeat the optimisation of Theorem 26.5 on a different geometry and to be able to interpret the result. *Estimated time:* 55 minutes. *Type:* proof-based and numerical. *Level:* intermediate-advanced.

Consider the family of 8 + 8-APSK constellations (Definition 26.7) with $M_1 = M_2 = 8$, phases $\varphi_1 = \pi/8$ and $\varphi_2 = 0$, $R_2 = \gamma R_1$ with $\gamma \geq 1$, normalised to $E_s = 1$.

- Prove that normalisation forces $R_1 = \sqrt{2/(1 + \gamma^2)}$.
- Prove that the minimum angular difference between a point of the inner circle and one of the outer circle equals $\pi/8$ (adapt the computation on odd integers of Theorem 26.5), and write $d_{\min}(\gamma)$ as the minimum of two quantities (not three: explain why one of the three is always redundant for $\gamma \geq 1$).

- (c) Determine γ^* by solving the quadratic equation $\gamma^2 - 2\gamma \cos \frac{\pi}{8} + (1 - 4 \sin^2 \frac{\pi}{8}) = 0$, showing that the constant term equals $\sqrt{2} - 1$ and that $2 \cos \frac{\pi}{8} = \sqrt{2 + \sqrt{2}}$; compute γ^* , R_1 , R_2 , $d_{\min}$ and the PAPR to seven decimal places.
- (d) Compare $d_{\min}$ and PAPR with those of 16-QAM (Example 26.4) and of 4 + 12-APSK (Theorem 26.5), and say which of the three one would choose for a satellite transponder near saturation and which for a linear fibre link, justifying with the numbers.

Exercise 26.3: A complete link, from decibels to the eye. *Objective:* to walk through the entire chain of the chapter in a single exercise on assigned numerical data. *Estimated time:* 50 minutes. *Type:* numerical with independent check. *Level:* intermediate.

A QPSK link uses $R_s = 2$ Mbaud, a raised-cosine pulse with $\beta = 0.35$, and is designed for $P_b = 10^{-6}$.

- (a) Compute the bit rate R_b , the occupied bandwidth W and the spectral efficiency η (Corollary 26.7).
- (b) Determine the value of E_b/N_0 (in dB) that gives $P_b = 10^{-6}$, by numerically solving $Q(x) = 10^{-6}$ by successive trials to at least three digits and obtaining $E_b/N_0 = x^2/2$ (Theorem 26.9 and Theorem 26.10); compare with the table of Example 26.6 and verify that the value falls between the rows at 10 and 12 dB.
- (c) Compute the corresponding *symbol* error probability $P_s = 2P_b - P_b^2$ and say by how many decibels E_b/N_0 would have to be raised to bring P_b to 10^{-9} .
- (d) If the instrument measures $\text{EVM} = 4\%$, what SNR_s does this imply (Proposition 26.10)? And what E_b/N_0 , recalling that for QPSK $E_s = 2E_b$? Does the link meet the specification of point (b)?
- (e) If in addition the sampling instant is wrong by $0.2T$, does the eye opening (Proposition 26.9) remain positive? Answer by computing $D(0.2)$ with only the three symbols a_{-1}, a_0, a_1 for the raised-cosine pulse with $\beta = 0.5$ of Example 26.8, and say what would change with $\beta = 0.35$.

26.11. Worked exercises

Exercise 26.4: What it costs to go from QPSK to 8-PSK. *Type:* numerical, with a proved upper and lower bound. Estimate the symbol error probability of 8-PSK at $E_b/N_0 = 10$ dB, bracketing it between two computed values, and compare it with QPSK at the same E_b/N_0 .

Solution. Strategy. For M -PSK the decision region is a circular sector (Figure 26.3), and its complement is the union of *two* half-planes: the one beyond the bisector toward the right neighbour and the one beyond the bisector toward the left neighbour. Hence a lower bound (a single half-plane) and an upper bound (the union of the two, by subadditivity). There is no need to compute the integral over the sector.

Step 1 — the distance from the boundary. Let $a_0 = \sqrt{E_s}$ be the transmitted symbol (the choice is irrelevant by Corollary 26.4). The boundary toward a_1 is the perpendicular bisector of the segment $a_0 a_1$ (Theorem 26.7), and the distance of a_0 from that bisector is half the length of the segment, i.e. $\frac{1}{2}d_{\min}$. By Theorem 26.3,

$$\frac{d_{\min}}{2} = \sqrt{E_s} \sin \frac{\pi}{M}.$$

Step 2 — the probability of crossing a boundary. The noise component orthogonal to the boundary is Gaussian with zero mean and variance $N_0/2$ — it is the same situation as Step 2 of the proof of Theorem 26.9, with the direction rotated, and the rotation does not change the law because the density of Definition 26.8 depends only on the modulus. Hence, by Proposition 26.6(iii),

$$p_1 := \Pr[\text{crossing a fixed boundary}] = Q\left(\frac{d_{\min}/2}{\sqrt{N_0/2}}\right) = Q\left(\sqrt{\frac{2E_s}{N_0}} \sin \frac{\pi}{M}\right).$$

Step 3 — the bracket. The event "error" contains the event "crossing the right boundary" and, by subadditivity of probability, is contained in the union of the two:

$$p_1 \leq P_s \leq 2p_1.$$

Step 4 — the numbers. For $M = 8$, $m = 3$ and $E_s = 3E_b$ (Definition 26.3), hence

$$\sqrt{\frac{2E_s}{N_0}} \sin \frac{\pi}{8} = \sqrt{\frac{6E_b}{N_0}} \sin \frac{\pi}{8}.$$

At $E_b/N_0 = 10$ dB, i.e. $E_b/N_0 = 10$:

$$\sqrt{60} = 7.7459667, \quad \sin \frac{\pi}{8} = 0.3826834, \quad \text{argument} = 2.9642531.$$

Hence $p_1 = Q(2.9642531) = 1.5170930 \cdot 10^{-3}$ and

$$1.5170930 \cdot 10^{-3} \leq P_s^{\text{8-PSK}} \leq 3.0341860 \cdot 10^{-3}.$$

Step 5 — the comparison. By Theorem 26.10, at the same $E_b/N_0 = 10$ dB, QPSK has $P_s = 7.7442014 \cdot 10^{-6}$. The ratio between the upper bound for 8-PSK and QPSK equals

$$\frac{3.0341860 \cdot 10^{-3}}{7.7442014 \cdot 10^{-6}} = 391.8010,$$

i.e. almost *four hundred times* more errors for having added a single bit per symbol. This is the probabilistic translation of the last column of the table of Example 26.3, where the ratio $d_{\min}^2/(4E_b)$ drops from 1 to 0.4393398.

Independent check. The argument of the Q function can be recomputed by a different route, starting from the minimum distance rather than from the angle: by the table of Example 26.3 with $E_s = 1$, $d_{\min} = 0.7653669\sqrt{E_s}$, so setting $E_b = 1$, $N_0 = 1/10$ and $E_s = 3$, $d_{\min} = 0.7653669\sqrt{3} = 1.3256543$, and

$$\frac{d_{\min}/2}{\sqrt{N_0/2}} = \frac{0.7653669\sqrt{3}/2}{\sqrt{1/20}} = \frac{0.7653669}{2} \cdot \sqrt{3} \cdot \sqrt{20} = \frac{0.7653669}{2} \cdot \sqrt{60} = 0.3826834 \cdot 7.7459667 = 2.9642531. \checkmark$$

The value of Q was computed in two ways (Example 26.6): with $\frac{1}{2} \operatorname{erfc}(x/\sqrt{2})$ and with Simpson integration, which agree to within $5 \cdot 10^{-14}$ in relative value. $\checkmark$

Interpretation. The bracket $p_1 \leq P_s \leq 2p_1$ is a factor of 2 wide, i.e. 3.01 dB in ordinate but very little in abscissa: on the extremely steep curve of Figure 26.6 a factor of 2 in probability corresponds to less than 0.3 dB of E_b/N_0 . For designing a link the bracket is therefore more than sufficient, which is why in practice the upper bound $2p_1$ is used without qualms.

Common mistakes. (1) Using $E_s = E_b$ instead of $E_s = 3E_b$: the argument is underestimated by a factor $\sqrt{3}$ and the error probability comes out enormously larger. (2) Confusing

symbol error and bit error: with Gray mapping and small probabilities, $P_b \approx P_s/m$, i.e. roughly a third, but it is not an equality. (3) Applying the union bound with $M - 1 = 7$ terms: this gives $7p_1 = 1.0619651 \cdot 10^{-2}$, correct but needlessly loose, because the five non-adjacent symbols contribute negligibly.

Extension. Repeat the computation for 16-PSK ($m = 4$, $E_s = 4E_b$, $\sin(\pi/16) = 0.1950903$) and verify that the argument at 10 dB equals $\sqrt{80} \cdot 0.1950903 = 1.7449409$, that $Q(1.7449409) = 4.0497580 \cdot 10^{-2}$ and that the bracket becomes $[4.0497580 \cdot 10^{-2}, 8.0995159 \cdot 10^{-2}]$: 16-PSK at 10 dB is unusable without coding.

Exercise 26.5: Filter matched to a triangular pulse. *Type:* computation of integrals with application of the equality case in Cauchy–Schwarz. Consider the triangular pulse $s(t) = A(1 - |t|/T)$ for $|t| \leq T$ and $s(t) = 0$ elsewhere. Determine the energy, the matched filter, the maximum signal-to-noise ratio, and the loss incurred by integrating instead over all of $[-T, T]$ with constant weight.

Solution. Strategy. Apply Theorem 26.8: the maximum equals $2E/N_0$ and is attained only for h proportional to the reflection of s . The loss of the wrong filter is read as the Cauchy–Schwarz ratio $\langle s, g \rangle^2 / (\|s\|^2 \|g\|^2)$, which is the squared cosine of the angle between the two signals in L^2 .

Step 1 — the energy. By evenness of the integrand,

$$E = \int_{-T}^T A^2 \left(1 - \frac{|t|}{T}\right)^2 dt = 2A^2 \int_0^T \left(1 - \frac{t}{T}\right)^2 dt.$$

With the substitution $u = 1 - t/T$, $du = -dt/T$, the endpoints $t = 0, T$ become $u = 1, 0$:

$$\int_0^T \left(1 - \frac{t}{T}\right)^2 dt = T \int_0^1 u^2 du = \frac{T}{3}.$$

Hence $E = \frac{2A^2T}{3}$.

Step 2 — the matched filter. By Definition 26.11 the filter matched at instant t_0 has $h(t) = c s(t_0 - t)$. Since s is *even*, $s(t_0 - t) = s(t - t_0)$: the matched filter is the pulse itself, shifted to t_0 . With $t_0 = 0$ and $c = 1$, $h = s$. The maximum signal-to-noise ratio is

$$\text{SNR}_{\max} = \frac{2E}{N_0} = \frac{4A^2T}{3N_0}.$$

Step 3 — the wrong filter. Take $g = \mathbf{1}_{[-T, T]}$, i.e. integrate the observation over the whole duration of the pulse with constant weight. Then

$$\langle s, g \rangle = \int_{-T}^T A \left(1 - \frac{|t|}{T}\right) dt = AT$$

— this is the area of the triangle of base $2T$ and height A , i.e. $\frac{1}{2} \cdot 2T \cdot A$ — and $\|g\|^2 = 2T$. By Definition 26.11,

$$\text{SNR} = \frac{(AT)^2}{\frac{N_0}{2} \cdot 2T} = \frac{A^2T}{N_0}.$$

Step 4 — the loss. The ratio between the two equals

$$\frac{\text{SNR}}{\text{SNR}_{\max}} = \frac{A^2T/N_0}{4A^2T/(3N_0)} = \frac{3}{4},$$

i.e. a loss of $10 \log_{10} \frac{4}{3} = 1.2493874$ dB.

Independent check. The same $3/4$ is obtained directly from Lemma 26.3 without going through N_0 :

$$\frac{\langle s, g \rangle^2}{\|s\|^2 \|g\|^2} = \frac{(AT)^2}{\frac{2A^2T}{3} \cdot 2T} = \frac{A^2T^2}{\frac{4}{3}A^2T^2} = \frac{3}{4}. \quad \checkmark$$

The value is strictly less than 1, as it must be by the equality case of the lemma: g is constant and s is not, so they are not proportional. $\checkmark$

Interpretation. The loss of 1.25 dB is the price of having given the same weight to samples taken when the signal is strong (near $t = 0$) and to those taken when it is weak (near $\pm T$). The matched filter "weighs" each instant proportionally to the signal found there: this is the engineering translation of the equality case of Cauchy–Schwarz.

Common mistakes. (1) Computing E as $A^2 \cdot 2T$, as if the pulse were rectangular: this overestimates by a factor 3. (2) Forgetting that the matched filter is s *reflected*: for an even pulse it makes no difference, for an asymmetric pulse it does, and the mistake is invisible until the waveform is changed. (3) Comparing the two ratios in different units (one linear, one in dB).

Extension. Repeat the computation with the half-cosine pulse $s(t) = A \cos \frac{\pi t}{2T}$ on $[-T, T]$: find $E = A^2T$, and verify that with $g = \mathbf{1}_{[-T, T]}$ the Cauchy–Schwarz ratio equals $8/\pi^2 = 0.8105695$, i.e. a loss of 0.9121 dB, smaller than that of the triangle because the half-cosine is "flatter."

Exercise 26.6: A constant phase error, in EVM and in decibels. *Type:* exact computation with metrological interpretation. A QPSK receiver has a constant phase error θ in carrier recovery (case (d) of Exercise 26.1). Express the resulting EVM as a function of θ , in *exact* form, and convert it into the equivalent signal-to-noise ratio.

Solution. Strategy. A phase error multiplies every received symbol by $e^{-i\theta}$ (Exercise 26.1(d)). The error vector is therefore $a(e^{-i\theta} - 1)$, and its modulus is computed with Lemma 26.1, with no small-angle approximation.

Step 1 — the error vector. With $r_k = a_k e^{-i\theta}$ (no additive noise, only the phase error),

$$e_k = r_k - a_k = a_k(e^{-i\theta} - 1), \quad |e_k| = |a_k| |e^{-i\theta} - e^{i0}| = |a_k| \cdot 2 \left| \sin \frac{-\theta - 0}{2} \right| = 2|a_k| \left| \sin \frac{\theta}{2} \right|,$$

having applied Lemma 26.1 with $\alpha = -\theta$ and $\beta = 0$.

Step 2 — the EVM. By Definition 26.16,

$$\text{EVM} = \sqrt{\frac{\sum_k |e_k|^2}{\sum_k |a_k|^2}} = \sqrt{\frac{4 \sin^2 \frac{\theta}{2} \sum_k |a_k|^2}{\sum_k |a_k|^2}} = 2 \left| \sin \frac{\theta}{2} \right|.$$

The result is *exact* and does not depend on the constellation: the factor $|a_k|^2$ cancels identically, so it holds for QPSK as much as for 16-QAM or any other.

Step 3 — the equivalent signal-to-noise ratio. By Proposition 26.10, a measured EVM is read as $\text{SNR}_s = 1/\text{EVM}^2$. Hence

$$\text{SNR}_{\text{eq}} = \frac{1}{4 \sin^2(\theta/2)}, \quad \text{SNR}_{\text{eq}}|_{\text{dB}} = -20 \log_{10} \left(2 \left| \sin \frac{\theta}{2} \right| \right).$$

Step 4 — the numbers.

θ	$\text{EVM} = 2 \sin(\theta/2)$	EVM in %	SNR_{eq} (dB)
1°	0.0174531	1.7453%	35.1625629
2°	0.0349048	3.4905%	29.1422937
5°	0.0872388	8.7239%	21.1858089
10°	0.1743115	17.4311%	15.1734799

Independent check. For small angles $2 \sin(\theta/2) \approx \theta$ in radians: for $\theta = 5^\circ = 0.0872665$ rad the exact formula gives 0.0872388, and the relative discrepancy is $3.2 \cdot 10^{-4}$, consistent with the expansion $2 \sin(x/2) = x - \frac{x^3}{24} + O(x^5)$, which for $x = 0.0872665$ predicts a relative discrepancy $x^2/24 = 3.17 \cdot 10^{-4}$. ✓ Moreover, SNR_{eq} at 5° equals $1/0.0872388^2 = 131.3956$, and $10 \log_{10} 131.3956 = 21.1858089$ dB, in agreement with the table. ✓

Interpretation. The practical reading is severe: a phase error of only 5° limits the EVM to 8.7%, i.e. it imposes a ceiling of 21.2 dB on the signal-to-noise ratio *whatever* the transmitted power. A 256-QAM, which by the table of Example 26.7 needs more than 13 dB more than QPSK, does not work with that ceiling: this is why higher-order modulations require a much tighter carrier-recovery loop than lower-order ones. The degradation cannot be fought with power, because it is not noise.

Common mistakes. (1) Using the approximation $\text{EVM} \approx \theta$ without stating it: for $\theta = 10^\circ$ the discrepancy is already 1.3 per mille, and for larger angles it grows as $\theta^2/24$. (2) Confusing degrees and radians in the sine. (3) Adding in decibels the contribution of the phase error and that of the noise: one must add the error *powers*, i.e. the squared EVMs, not the decibels.

Extension. Show that if the phase error and the additive noise are independent, then $\text{EVM}_{\text{tot}}^2 = \text{EVM}_\theta^2 + \text{EVM}_{\text{rum}}^2$, and compute the total EVM for $\theta = 2^\circ$ and $\text{SNR}_s = 25$ dB: one obtains $\sqrt{0.0349048^2 + 0.0562341^2} = 0.0661862$, i.e. 6.62%.

26.12. Self-assessment quiz

- (Definition) The *complex envelope* of a real bandpass signal s with carrier f_c and half-bandwidth $B < f_c$ is
 - a unique complex signal of half-bandwidth B such that $s(t) = \Re\{s_L(t)e^{i2\pi f_c t}\}$
 - the imaginary part of s
 - any complex signal whose real part is s
 - the Fourier transform of s restricted to positive frequencies
- (Hypothesis) In Theorem 26.2 the hypothesis $B < f_c$ serves to
 - guarantee that s is real-valued
 - make disjoint the supports of the two terms of $\hat{s}(f) = \frac{1}{2}\hat{u}(f - f_c) + \frac{1}{2}\hat{u}(-f - f_c)$
 - ensure the convergence of the integral defining $\hat{s}$
 - allow the Plancherel–Parseval identity to be applied
- (Symbolic computation) For the M -PSK constellation of energy per symbol E_s , the minimum distance equals
 - $\sqrt{E_s} \sin \frac{2\pi}{M}$
 - $2\sqrt{E_s} \sin \frac{\pi}{M}$
 - $\frac{2\sqrt{E_s}}{M}$
 - $\sqrt{\frac{6E_s}{M-1}}$
- (Numerical computation) At $E_b/N_0 = 10$ dB the *bit* error probability of QPSK equals
 - $3.8721082 \cdot 10^{-6}$
 - $7.7442014 \cdot 10^{-6}$
 - $1.9090777 \cdot 10^{-4}$
 - $2.3882908 \cdot 10^{-3}$
- (Proof step) In Theorem 26.8 the fact that the maximum of SNR is attained *only* by the matched filter follows

- A) from the positivity of N_0 B) from the equality case in the Cauchy–Schwarz inequality, i.e. from the proportionality of s and g C) from the linearity of the integral
D) from the fact that $\|g\|^2$ cancels in the ratio
6. (Error diagnosis) A student computes the error probability of QPSK as $Q(\sqrt{2E_s/N_0})$ instead of $Q(\sqrt{2E_b/N_0})$, and at $E_b/N_0 = 10$ dB obtains $1.3 \cdot 10^{-10}$ instead of $3.9 \cdot 10^{-6}$, i.e. a value thirty thousand times too optimistic. The mistake consists in having
- A) used the two-sided convention $N_0/2$ instead of the one-sided one B) forgotten that for QPSK $E_s = 2E_b$, i.e. having attributed to each of the two components the entire energy of the symbol C) confused Q with erfc D) used the minimum distance of BPSK
7. (Transfer) A 4 + 12-APSK and a 16-QAM are normalised to the same average energy per symbol. Compared with 16-QAM, the optimal APSK of Theorem 26.5 has
- A) larger minimum distance and larger PAPR B) smaller minimum distance (0.5848015 against 0.6324555) and smaller PAPR (1.2763345 against 1.8) C) both minimum distance and PAPR smaller, but by negligible amounts D) exactly the same parameters, because both have 16 points
8. (Source and metacognition) The reference text in which the baseband representation, the matched filter and the error probabilities of digital modulations are treated organically, in the edition verified here, is
- A) J. G. Proakis, M. Salehi, *Digital Communications*, 5th ed., McGraw-Hill, 2008, ISBN 978-0-07-295716-7 B) J. W. Cooley, J. W. Tukey, *An algorithm for the machine calculation of complex Fourier series*, 1965 C) E. T. 26.13. Teacher's key

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 1–4).

- 1) **A.** *Rationale:* Theorem 26.1(iii) gives existence and Theorem 26.2 uniqueness, which is an essential part of the definition: without the half-bandwidth constraint B the representation would not be unique. *Distractors:* B confuses the complex envelope with the quadrature component; C is exactly what uniqueness excludes (there are infinitely many u with $\Re\{ue^{i2\pi f_c t}\} = s$ if the bandwidth constraint is dropped); D describes $\widehat{s}_+$, not s_L , and forgets the shift by f_c and the factor 2. *Diagnosed error:* not having understood that bandlimitness is a hypothesis, not an accessory. *Source:* Source [1], chapter on the representation of bandpass signals. *Prerequisite:* the Fourier transform and its injectivity (Theorem 19.9). *Remedial activity:* redo Step 3 of the proof of Theorem 26.1 and Example 26.1.
- 2) **B.** *Rationale:* this is literally where the proof of Theorem 26.2 uses the hypothesis: without disjointness of the supports one could not conclude $\widehat{s}(f) = \frac{1}{2}\widehat{u}(f - f_c)$ for $f > 0$. *Distractors:* A is false, s is real by an independent hypothesis; C is false, convergence follows from $s \in L^1$; D is irrelevant, Plancherel–Parseval is used elsewhere (Proposition 26.1) and does not require $B < f_c$. *Diagnosed error:* reading hypotheses as formalities. *Source:* Source [2], chapter on bandpass signals. *Prerequisite:* Remark 26.1. *Remedial activity:* construct a counterexample with $B > f_c$ and verify that the envelope is no longer unique.
- 3) **B.** *Rationale:* Theorem 26.3, proved from Lemma 26.1 and the monotonicity of the sine on $(0, \pi/2]$. *Distractors:* A uses the full angle between two symbols instead of half of it,

forgetting the factor $\frac{1}{2}$ of the chord formula; C is the approximation $\sin x \approx x$ without the π , i.e. an error by a factor π ; D is the formula for square QAM (Theorem 26.4), correct but for a different constellation. *Diagnosed error*: confusing the central angle with the half-angle in the chord formula. *Source*: Source [3], chapter on bandpass modulations. *Prerequisite*: roots of unity (Theorem 6.3). *Remedial activity*: derive $|e^{i\alpha} - e^{i\beta}|$ by hand and check it for $M = 4$, where it must give $\sqrt{2}\sqrt{E_s}$.

4) **A.** *Rationale*: Theorem 26.10, $P_b = q = Q(\sqrt{2E_b/N_0})$ with $\sqrt{20} = 4.4721360$: the value is in the table of Example 26.6. *Distractors*: B is the *symbol* error probability of QPSK, i.e. roughly double; C is the value at 8 dB; D is the value at 6 dB. *Diagnosed error*: confusing bit error and symbol error, or picking the wrong row in the table. *Source*: Source [1], chapter on optimal receivers for the AWGN channel. *Prerequisite*: Proposition 26.6. *Remedial activity*: recompute $Q(4.4721360)$ with $\frac{1}{2} \operatorname{erfc}(3.1622777)$ and compare with the table.

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 5–8).

5) **B.** *Rationale*: Step 3 of the proof of Theorem 26.8 uses the equality case of Lemma 26.3, and it is the only point producing uniqueness of the optimal solution. *Distractors*: A is needed only for the ratio to be well defined; C is used in Step 1 but does not give uniqueness; D explains why the maximum does not depend on g , not why it is attained only by one g . *Diagnosed error*: using Cauchy–Schwarz as a pure bound, without ever asking when it is an equality. *Source*: Source [4], chapter on optimal reception. *Prerequisite*: the equality case proved in Lemma 26.3. *Remedial activity*: Exercise 26.5, where the ratio equals $3/4 < 1$ precisely because proportionality fails.

6) **B.** *Rationale*: $Q(\sqrt{2E_s/N_0}) = Q(\sqrt{4E_b/N_0}) = Q(\sqrt{40}) = Q(6.3245553) = 1.2698143 \cdot 10^{-10}$, against the correct value $Q(\sqrt{20}) = 3.8721082 \cdot 10^{-6}$: a ratio of 30,493.5. The point of the exercise is recognising that the error is *a factor 2 on energy*, i.e. 3 dB, and that on such a steep curve 3 dB are worth four orders of magnitude. By Theorem 26.10 each of the two components carries E_b , not E_s : half the symbol's energy goes into the in-phase branch and half into the quadrature branch. *Distractors*: A is a different error, which also produces 3 dB but on the noise rather than the signal (Remark 26.6); C would give a factor 2 on the result, not on the argument; D is false, the minimum distance of the two is the same (Corollary 26.3). *Diagnosed error*: not distinguishing E_s from E_b : this is the most frequent mistake in the whole chapter. *Source*: Source [3], chapter on error probabilities. *Prerequisite*: Proposition 26.3 and Proposition 26.4. *Remedial activity*: redo Step 2 of Theorem 26.10 writing explicitly $\sqrt{E_s}/2 = \sqrt{E_b}$.

7) **B.** *Rationale*: these are the numbers in the table of Remark 26.5, proved in Theorem 26.4 and in Theorem 26.5. *Distractors*: A reverses both inequalities; C is wrong in the quantification: 0.68 dB of minimum distance and 1.49 dB of PAPR are not negligible in a link budget; D confuses cardinality with geometry. *Diagnosed error*: believing there is an absolutely "better" constellation, rather than one better with respect to a stated constraint. *Source*: Source [1], chapter on digital modulations. *Prerequisite*: Definition 26.3 (PAPR). *Remedial activity*: Exercise 26.2, which repeats the optimisation on an $8 + 8$ geometry.

8) **A.** *Rationale*: this is Source [1] of the Sources environment, with the bibliographic data verified on 7 September 2026. *Distractors*: B is the source for Chapter 23 and concerns an algorithm, not modulations; C concerns the sampling theorem (Chapter 24); D is a text on the FFT. *Diagnosed error*: citing from memory without checking edition and year — the metacognitive point of the chapter. *Source*: the Sources environment of this chapter. *Prerequisite*: none. *Remedial activity*: check for oneself, in a library catalogue, the data of the four sources listed, and note that each of them exists in several editions with different contents and numbering.

BEST PRACTICE

Exercise 26.1 — answers.

(a) Factor out $e^{i2\pi f_c t}$: $s(t) = \Re\{(A + Be^{i(2\pi\nu t + \varphi)})e^{i2\pi f_c t}\}$, hence

$$s_L(t) = A + Be^{i(2\pi\nu t + \varphi)}, \quad s_I(t) = A + B \cos(2\pi\nu t + \varphi), \quad s_Q(t) = B \sin(2\pi\nu t + \varphi).$$

With $A = 2$, $B = 1$, $\varphi = \pi/3$: $s_L(0) = 2 + e^{i\pi/3} = 2.5 + 0.8660254i$ and $|s_L(0)| = \sqrt{2.5^2 + 0.8660254^2} = \sqrt{6.25 + 0.75} = \sqrt{7} = 2.6457513$. The answer is unique by Theorem 26.2, because s_L has half-bandwidth $\nu = 1$ kHz $< f_c = 1$ MHz: this is the hypothesis $B < f_c$ of Definition 26.1.

(b) $|s_L|^2 = (A + B \cos \psi)^2 + (B \sin \psi)^2 = A^2 + B^2 + 2AB \cos \psi$ with $\psi = 2\pi\nu t + \varphi$, i.e. $5 + 4 \cos \psi$. The maximum $|s_L| = A + B = 3$ occurs for $\cos \psi = 1$, i.e. $t = (k - \frac{1}{6})/\nu$ with $k \in \mathbb{Z}$; the minimum $|s_L| = |A - B| = 1$ for $\cos \psi = -1$, i.e. $t = (k + \frac{1}{3})/\nu$.

(c) $\widehat{s}_L$ is concentrated at $\{0, \nu\}$, hence the half-bandwidth is ν and $f_c/\nu = 10^6/10^3 = 1,000$. The relative discrepancy of Proposition 26.2(ii) is $\leq 1/(2\pi f_c T)$; imposing $1/(2\pi f_c T) < 10^{-3}$ gives $f_c T > 1/(2\pi \cdot 10^{-3}) = 159.1549$: 160 carrier periods per symbol suffice.

(d) With the offset carrier, $2s(t) \cos(2\pi f_c t + \theta) = 2\Re\{s_L e^{i2\pi f_c t}\} \cos(2\pi f_c t + \theta)$; writing $2\Re z \cos \alpha = \Re\{ze^{i\alpha}\} + \Re\{ze^{-i\alpha}\}$ with $z = s_L e^{i2\pi f_c t}$ and $\alpha = 2\pi f_c t + \theta$, the first term has frequency around $2f_c$ and is removed by the filter, the second equals $\Re\{s_L e^{-i\theta}\} = s_I \cos \theta + s_Q \sin \theta$. With the quadrature branch one gets $-\Im\{s_L e^{-i\theta}\} \cdot (-1) = -s_I \sin \theta + s_Q \cos \theta$. In complex form $\tilde{s}_L = s_L e^{-i\theta}$: the constellation rotates rigidly by $-\theta$, without deforming. The quantitative consequences are in Exercise 26.6.

BEST PRACTICE

Exercise 26.2 — answers.

(a) $E_s = \frac{8R_1^2 + 8R_2^2}{16} = \frac{R_1^2 + R_2^2}{2} = \frac{R_1^2(1+\gamma^2)}{2}$; imposing $E_s = 1$ gives $R_1 = \sqrt{2/(1+\gamma^2)}$.

(b) The phases are $\frac{\pi}{8} + \frac{k\pi}{4}$ and $\frac{j\pi}{4}$, and the difference equals $\frac{\pi}{8}(1 + 2(k-j))$: an *odd* multiple of $\pi/8$, hence of modulus at least $\pi/8$, a value attained for $k = j$. The three quantities are $2R_1 \sin \frac{\pi}{8}$, $2R_2 \sin \frac{\pi}{8}$ and $\sqrt{R_1^2 + R_2^2 - 2R_1 R_2 \cos \frac{\pi}{8}}$; since $R_2 = \gamma R_1 \geq R_1$, the second is always $\geq$ the first and can never be the minimum: two quantities remain.

(c) The equality $2R_1 \sin \frac{\pi}{8} = \sqrt{R_1^2 + R_2^2 - 2R_1 R_2 \cos \frac{\pi}{8}}$, divided by R_1^2 , gives $4 \sin^2 \frac{\pi}{8} = 1 + \gamma^2 - 2\gamma \cos \frac{\pi}{8}$, i.e. the equation of the statement. The constant term equals $1 - 4 \sin^2 \frac{\pi}{8} = 1 - 2(1 - \cos \frac{\pi}{4}) = 2 \cos \frac{\pi}{4} - 1 = \sqrt{2} - 1 = 0.4142136$, and $2 \cos \frac{\pi}{8} = \sqrt{2 + 2 \cos \frac{\pi}{4}} = \sqrt{2 + \sqrt{2}} = 1.8477590$. The root ≥ 1 is

$$\gamma^* = \cos \frac{\pi}{8} + \sqrt{\cos^2 \frac{\pi}{8} - \sqrt{2} + 1} = 0.9238795 + 0.6628272 = 1.5867067.$$

From this $R_1 = \sqrt{2/(1+\gamma^{*2})} = \sqrt{2/3.5176381} = 0.7540314$, $R_2 = \gamma^* R_1 = 1.1964266$, $d_{\min} = 2R_1 \sin \frac{\pi}{8} = 2 \cdot 0.7540314 \cdot 0.3826834 = 0.5771106$ and $\text{PAPR} = R_2^2 = 1.4314367$. Check: $E_s = (R_1^2 + R_2^2)/2 = (0.5685633 + 1.4314367)/2 = 1$. ✓

(d) Comparison at $M = 16$ and $E_s = 1$: 16-QAM $d_{\min} = 0.6324555$, PAPR 1.8; 4 + 12-APSK $d_{\min} = 0.5848015$, PAPR 1.2763345; 8 + 8-APSK $d_{\min} = 0.5771106$, PAPR 1.4314367. The 8 + 8 is dominated: it has both smaller minimum distance *and* larger PAPR than the 4 + 12, so it is never the best choice among the three. For the satellite transponder near saturation one chooses 4 + 12-APSK (minimum PAPR); for the linear fibre link, 16-QAM (maximum minimum distance, +0.6804302 dB relative to the 4 + 12).

BEST PRACTICE

Exercise 26.3 — answers.

(a) $m = 2$, hence $R_b = mR_s = 4$ Mbit/s; $W = R_s(1 + \beta) = 2 \cdot 1.35 = 2.7$ MHz; $\eta = R_b/W = 4/2.7 = 1.4814815$ bit/s/Hz, which coincides with $m/(1 + \beta) = 2/1.35$ (Corollary 26.7). ✓

(b) Solving $Q(x) = 10^{-6}$ by bisection gives $x = 4.7534243$, hence $E_b/N_0 = x^2/2 = 11.2975213$, i.e. 10.5298317 dB. The value falls between the row at 10 dB ($P_b = 3.87 \cdot 10^{-6}$) and that at 12 dB ($P_b = 9.01 \cdot 10^{-9}$) of the table of Example 26.6. ✓

(c) $P_s = 2 \cdot 10^{-6} - 10^{-12} = 1.999999 \cdot 10^{-6}$. For $P_b = 10^{-9}$ one needs $Q(y) = 10^{-9}$, i.e. $y = 5.9978070$ and $E_b/N_0 = y^2/2 = 17.9868445 = 12.5495498$ dB: an extra $12.5495498 - 10.5298317 = 2.0197181$ dB is needed. Three orders of magnitude on the probability therefore cost just over two decibels: this is the steepness of the curve.

(d) $\text{EVM} = 4\% = 0.04$ implies $\text{SNR}_s = 1/0.04^2 = 625 = 27.9588002$ dB (Proposition 26.10). Since for QPSK $E_s = 2E_b$, $E_b/N_0 = \text{SNR}_s/2 = 312.5 = 24.9485002$ dB, well above the 10.5298317 dB required: the specification is met with more than 14 dB of margin. *Mandatory caution:* the equality $\text{EVM}^2 = N_0/E_s$ holds only if the degradation is entirely additive noise (Remark 26.13); if part of the EVM comes from distortion or phase error, the real margin is smaller.

(e) For $\beta = 0.5$: $p(0.2) = 0.9267741$, $p(1.2) = -0.1095008$, $p(-0.8) = 0.2007514$, hence $D(0.2) = 0.9267741 - 0.1095008 - 0.2007514 = 0.6165219 > 0$: the eye remains open, with opening $2D = 1.2330438$ against the value 2 at exact sampling, i.e. a loss of 38.3478% in amplitude. For $\beta = 0.35$ one obtains $p(0.2) = 0.9312114$, $p(1.2) = -0.1317067$, $p(-0.8) = 0.2171851$ and $D(0.2) = 0.5823196$: the eye is *more* closed, because a smaller roll-off means slower tails and more intersymbol interference under mistimed sampling. This is the hidden price of the spectral efficiency of Corollary 26.7.

26.14. Chapter formulary

Complex baseband. For s real bandpass with carrier f_c and half-bandwidth $B < f_c$:

$$\widehat{s}_+(f) = 2\widehat{s}(f)\mathbf{1}_{\{f>0\}}, \quad s_L = s_+e^{-i2\pi f_c t}, \quad \widehat{s}_L(f) = 2\widehat{s}(f+f_c), \quad \widehat{s}_L(f) = 0 \text{ for } |f| > B.$$

$$s(t) = \Re\{s_L(t)e^{i2\pi f_c t}\} = s_I(t)\cos(2\pi f_c t) - s_Q(t)\sin(2\pi f_c t), \quad s_L = s_I + is_Q.$$

$$s_I = \mathcal{L}_B\{2s\cos(2\pi f_c t)\}, \quad s_Q = \mathcal{L}_B\{-2s\sin(2\pi f_c t)\}, \quad \int s^2 = \frac{1}{2} \int |s_L|^2.$$

Carrier phase error: $\tilde{s}_L = s_L e^{-i\theta}$ (rigid rotation).

Orthogonality of the carriers. For every $f_c > 0$, $T > 0$:

$$\int_0^T \cos(2\pi f_c t) \sin(2\pi f_c t) dt = \frac{\sin^2(2\pi f_c T)}{4\pi f_c}, \quad \int_0^T \cos^2(2\pi f_c t) dt = \frac{T}{2} + \frac{\sin(4\pi f_c T)}{8\pi f_c}.$$

Exact values $0, T/2, T/2 \iff 2f_c T \in \mathbb{Z}$; relative discrepancy always $\leq \frac{1}{2\pi f_c T}$. Orthonormal basis on $[0, T]$: $\phi_1 = \sqrt{2/T} \cos(2\pi f_c t)$, $\phi_2 = -\sqrt{2/T} \sin(2\pi f_c t)$; $\int_0^T s^2 = \frac{T}{2}|a|^2$.

Constellations. $E_s = \frac{1}{M} \sum_j |a_j|^2$, $m = \log_2 M$, $E_b = E_s/m$, $d_{\min} = \min_{j \neq l} |a_j - a_l|$, $\text{PAPR} = \max_j |a_j|^2/E_s$. Chord of the circle: $|e^{i\alpha} - e^{i\beta}| = 2|\sin \frac{\alpha-\beta}{2}|$.

$$M\text{-PSK} : a_k = \sqrt{E_s} e^{i(2\pi k/M + \varphi_0)}, \quad d_{\min} = 2\sqrt{E_s} \sin \frac{\pi}{M}.$$

$$\text{Square } M\text{-QAM: } E_s = \frac{2}{3}(M-1)\Delta^2, \quad d_{\min} = 2\Delta = \sqrt{\frac{6E_s}{M-1}}, \quad \text{PAPR} = \frac{3(\sqrt{M}-1)}{\sqrt{M}+1}.$$

With $E_s = 1$: $2 \sin \frac{\pi}{M} = 2.0000000$ ($M = 2$), 1.4142136 (4), 0.7653669 (8), 0.3901806 (16); $\sqrt{6/(M-1)} = 0.6324555$ (16-QAM), 0.3086067 (64), 0.1533930 (256); PAPR = 1.8, 2.3333333, 2.6470588.

Two-circle APSK, $E_s = 1$. With $M_1 + M_2$ points, $R_2 = \gamma R_1$:

$$R_1 = \sqrt{\frac{M}{M_1 + M_2 \gamma^2}}, \quad d_{\min} = R_1 \min \left\{ 2 \sin \frac{\pi}{M_1}, 2\gamma \sin \frac{\pi}{M_2}, \sqrt{1 + \gamma^2 - 2\gamma \cos \delta} \right\},$$

with δ the minimum angular difference between the two circles. Case 4 + 12 ($\varphi_1 = \pi/4$, $\varphi_2 = 0$, $\delta = \pi/12$):

$$\gamma^* = 1 + \sqrt{3} = 2.7320508, \quad d_{\min} = \frac{2\sqrt{2}}{\sqrt{13 + 6\sqrt{3}}} = 0.5848015, \quad \text{PAPR} = \frac{64 + 8\sqrt{3}}{61} = 1.2763345.$$

Case 8 + 8 ($\varphi_1 = \pi/8$, $\varphi_2 = 0$, $\delta = \pi/8$): $\gamma^* = \cos \frac{\pi}{8} + \sqrt{\cos^2 \frac{\pi}{8} - \sqrt{2} + 1} = 1.5867067$, $d_{\min} = 0.5771106$, PAPR = 1.4314367.

Decision and matched filter. AWGN channel: $p_n(z) = \frac{1}{\pi N_0} e^{-|z|^2/N_0}$, $\mathbb{E}|n|^2 = N_0$, variance $N_0/2$ per component. MAP = ML = minimum distance (equiprobable symbols). Regions:

$$\overline{\mathcal{R}}_j = \bigcap_{l \neq j} \left\{ r : 2\Re[r \overline{(a_l - a_j)}] \leq |a_l|^2 - |a_j|^2 \right\} \quad (\text{convex Voronoi cells}).$$

Matched filter: $\text{SNR}(h) = \frac{\langle s, g \rangle^2}{\frac{N_0}{2} \|g\|^2} \leq \frac{2E}{N_0}$, with equality $\iff h(t) = c s(T - t)$; Cauchy-Schwarz $\langle u, v \rangle^2 \leq \|u\|^2 \|v\|^2$, equality $\iff u = \lambda v$.

Error probability. $Q(x) = \frac{1}{\sqrt{2\pi}} \int_x^\infty e^{-u^2/2} du = \frac{1}{2} \text{erfc}(x/\sqrt{2})$; $Q(0) = \frac{1}{2}$, $Q(-x) = 1 - Q(x)$.

$$P_b^{\text{BPSK}} = P_b^{\text{QPSK}} = Q\left(\sqrt{\frac{2E_b}{N_0}}\right), \quad P_s^{\text{QPSK}} = 2P_b - P_b^2.$$

M -PSK: $Q(\sqrt{2mE_b/N_0} \sin \frac{\pi}{M}) \leq P_s \leq 2Q(\sqrt{2mE_b/N_0} \sin \frac{\pi}{M})$. Values of P_b : $7.8649604 \cdot 10^{-2}$ (0 dB), $1.2500818 \cdot 10^{-2}$ (4 dB), $2.3882908 \cdot 10^{-3}$ (6 dB), $1.9090777 \cdot 10^{-4}$ (8 dB), $9.7361760 \cdot 10^{-6}$ (9.6 dB), $3.8721082 \cdot 10^{-6}$ (10 dB), $9.0060104 \cdot 10^{-9}$ (12 dB). Thresholds: $Q(x) = 10^{-6}$ for $x = 4.7534243$ ($E_b/N_0 = 10.5298317$ dB); $Q(x) = 10^{-9}$ for $x = 5.9978070$ (12.5495498 dB).

Bandwidth, efficiency, eye, EVM. Nyquist criterion:

$$\sum_k p(kT) e^{-i2\pi f kT} = \frac{1}{T} \sum_n P\left(f + \frac{n}{T}\right); \quad p(kT) = \delta_{k0} \iff \sum_n P\left(f + \frac{n}{T}\right) = T.$$

Minimum bandwidth $B = \frac{1}{2T}$, $W = \frac{1}{T} = R_s$; raised cosine of roll-off β : $B = \frac{1+\beta}{2T}$, $W = \frac{1+\beta}{T}$,

$$\eta = \frac{R_b}{W} = \frac{m}{1+\beta} \text{ bit/s/Hz}, \quad \frac{d_{\min}^2}{4E_b} = \frac{3m}{2(2^m - 1)} \quad (\text{square QAM}).$$

Eye opening: $\mathcal{O}(\tau) = 2D(\tau)$, $D(\tau) = p(\tau) - \sum_{k \neq 0} |p(\tau - kT)|$; $\mathcal{O}(0) = 2$ for a Nyquist pulse.
 EVM: $\text{EVM} = \sqrt{\sum |r_k - a_k|^2 / \sum |a_k|^2}$, $\text{EVM} \approx 1/\sqrt{\text{SNR}_s} = 10^{-\text{SNR}_{\text{dB}}/20}$; pure phase error:
 $\text{EVM} = 2|\sin \frac{\theta}{2}|$.

Sources and bibliography

- [1] J. G. Proakis, M. Salehi, *Digital Communications*, 5th edition, McGraw-Hill Science/Engineering/Math, New York, 2008 (publication date declared by the publisher: 6 November 2007), 1168 pages, ISBN 978-0-07-295716-7 (ISBN-10 0-07-295716-6). It is the reference text for the complex baseband representation of bandpass signals, for the optimal receiver on the additive white Gaussian noise channel (matched filter, correlator, maximum-likelihood decision), and for the error probabilities of PSK and QAM constellations: these are the contents of Theorems 26.1, 26.6, 26.8, 26.9 and 26.10, here re-exposed and proved in full and independently. *Verified on 7 September 2026* (Open Library catalogue record for the ISBN-13: authors Proakis and Salehi, publisher, "5 edition" edition, date and page count checked one by one). Chapter or page numbers are *not* given, because internal location was not verified on a copy of the cited edition: earlier editions have different numbering.
- [2] S. Haykin, *Communication Systems*, 4th edition, John Wiley & Sons, New York, 2001, ISBN 0-471-17869-1 (ISBN-13 978-0-471-17869-9). It is the source for the orthogonality of the quadrature carriers and for the structure of the IQ modulator and demodulator (Proposition 26.2, Corollary 26.1, Figure 26.2), as well as for the treatment of the analytic signal and the Hilbert transform recalled in Remark 26.2. *Verified on 7 September 2026* (Open Library catalogue record: author Simon S. Haykin, publisher Wiley, year 2001, ISBN-10 and ISBN-13 checked). Here too no pages are cited, not having been verified on a copy.
- [3] B. Sklar, *Digital Communications: Fundamentals and Applications*, 2nd edition, Prentice-Hall PTR, Upper Saddle River (New Jersey), 2001, 1079 pages, ISBN 0-13-084788-7. It is the source for the geometric presentation of constellations, for the Gray mapping, for the eye diagram, and for the link between minimum distance and spectral efficiency (Definition 26.5, Section 26.8, Section 26.9). *Verified on 7 September 2026* (Open Library catalogue record for the ISBN-10: title and subtitle, author Bernard Sklar, publisher Prentice-Hall PTR, "2nd ed.", year 2001, 1079 pages).
- [4] J. M. Wozencraft, I. M. Jacobs, *Principles of Communication Engineering*, John Wiley & Sons, New York, 1965, about 720 pages (reprint Waveland Press, 1990, ISBN 0-88133-554-1). It is the classic text in which the white Gaussian noise model and the theory of optimal decision are set up in the geometric form adopted here: signals as vectors of a space with a scalar product, noise described by its projections, decision as a partition of the space. It is the source of the model imported in Definition 26.10 and in Remark 26.8. *Verified on 7 September 2026* (Open Library catalogue record: authors John M. Wozencraft and Irwin Mark Jacobs, publishers Wiley and Waveland Press, years 1965 and 1990, ISBN of the reprint checked).
- [5] Sources internal to the treatise, used and not reproved: M -th roots of unity and regular polygons (Chapter 6); the Fourier transform, inversion, Plancherel–Parseval and the Poisson summation formula (Chapter 19); uniqueness of Fourier coefficients (Chapter 17); the sampling theorem (Chapter 24). Every cross-reference is made by label, not by a hand-written number.

OFDM: the circle that carries broadband

A telephone cable, a stretch of air between an antenna and a rooftop, a fibre: none of these channels carries a pulse without deforming it. The pulse leaves narrow and arrives spread out, because the signal reaches the receiver along several paths of different length and the replicas add up out of phase. If the symbols follow one another faster than that spreading lasts, each one invades the next: this is intersymbol interference, and fighting it in a channel with many taps requires an equalizer that, in the time domain, is an expensive and delicate machine.

Orthogonal frequency-division multiplexing — OFDM — solves the problem by changing its shape. Instead of one fast stream on a single carrier, N slow streams are sent on N nearby carriers; and the carriers are chosen so that, although their spectra overlap heavily, they are orthogonal over the interval of one symbol. At that point comes the discovery that made the idea practicable: the samples of the signal built this way are, literally, an inverse discrete Fourier transform of the data, and the receiver that analyses them performs a forward DFT. Transmitter and receiver are two FFTs, and nothing else.

One difficulty remains. The DFT turns *circular* convolution into a product (Theorem 22.5), but a physical channel performs a *linear* convolution: there is no reason for the time axis to close back on itself. The cyclic prefix is the device that forces it to do so. A copy of the block's tail is prepended to it; the channel, unable to tell that copy from the true signal, produces on the useful samples exactly the circular convolution; the channel matrix is then circulant, its diagonalisation is the one — unique, independent of the channel — of Theorem 22.8, and equalisation reduces to N divisions by a complex number. This is the chapter in which the time line is bent into a circle, and the circle settles the bill: the group $\mathbb{Z}/N\mathbb{Z}$ replaces $\mathbb{Z}$, and with it comes the whole algebra of Chapter 22.

The chapter follows this chain in order and in full. The orthogonality condition over the symbol time is proved, first with the integral (Theorem 27.1) and then in the sampled version (Theorem 27.2); writing the two computations side by side shows that the modulator *is* an IDFT and the demodulator a DFT (Theorems 27.3 and 27.4); it is proved, with the modular indices written out in full, that the cyclic prefix converts the channel's linear convolution into a circular one (Theorem 27.5) and that the condition $N_g \geq L - 1$ is not only sufficient but necessary (Theorem 27.6); from this follows the diagonality of the channel in frequency (Corollary 27.3) and single-coefficient equalisation, with the error in the presence of noise computed exactly (Theorem 27.8) and the equalizer optimal in mean square derived in full (Theorem 27.9). Next come the efficiency loss due to the prefix (Proposition 27.3), the carrier frequency offset with the exact formula for intercarrier interference and the signal-to-interference ratio (Lemma 27.3, Theorem 27.10, Corollary 27.6), and the ratio of peak power to average power, with the worst case proved (Theorem 27.11) and the statistical estimate stated under explicit hypotheses (Proposition 27.7) and declared imported for the part that is not closed here (Observation 27.13). The last two sections work out in full, in exact symbolic form and in numerical form, the examples $N = 4$ and $N = 8$, with the verification that the channel does become diagonal.

The results of Chapter 22 — the orthogonality of the exponential vectors (Theorem 22.1), the

inversion formula (Theorem 22.2), circular convolution (Definition 22.4 and Theorem 22.5), Parseval's identity (Theorem 22.6), circulant matrices (Definition 22.5, Proposition 22.5, Theorem 22.8) — and those of Chapter 23 on the cost of computation (Proposition 23.1, Theorem 23.5, Corollary 23.4, Theorem 23.10) are recalled and used here, and never reproved.

INFO

Level and prerequisites. Level **C** (undergraduate), with two passages at level **D**: the equalizer optimal in mean square of Section 27.4 and the statistics of the peak ratio of Section 27.7, which require elementary notions of probability.

Internal prerequisites. N -th roots of unity and their arithmetic (Chapter 6); the discrete Fourier transform, orthogonality, inversion, circular convolution, Parseval, circulant matrices and their diagonalisation (Chapter 22: Definition 22.1, Definition 22.2, Definition 22.3, Definition 22.4, Definition 22.5, Theorem 22.1, Theorem 22.2, Theorem 22.5, Theorem 22.6, Theorem 22.8, Proposition 22.5, Proposition 22.4); the fast algorithm and its cost (Chapter 23: Proposition 23.1, Theorem 23.5, Corollary 23.4, Theorem 23.10); the Fourier transform on $\mathbb{R}$ and its inversion formula (Chapter 19).

External prerequisites, assumed and not reproved:

- the Riemann integral of a continuous complex-valued function on a compact interval, and its linearity;
- elementary linear algebra: matrix-vector product, determinant, eigenvalues and eigenvectors, unitary matrices;
- the Cauchy–Schwarz inequality in $\mathbb{C}^N$ and the triangle inequality;
- elementary notions of probability: expected value, variance, independent variables, the Gaussian distribution and change of variable in polar coordinates (used only in Section 27.7 and in Section 27.4, always under stated hypotheses).

Sign convention. As throughout the Volume, $\omega_N = e^{-2\pi i/N}$ and $\langle j \rangle_N$ is the unique integer in $\{0, \dots, N-1\}$ congruent to j modulo N (Definition 22.1 and Definition 22.4). The subcarriers therefore carry the *opposite* sign: $e^{+2\pi i k n/N} = \omega_N^{-kn}$. This is not an oversight, and it is the reason why the modulator turns out to be an *inverse* transform rather than a forward one.

27.1. The orthogonal subcarriers

The notation is fixed once and for all. The number of subcarriers is $N \geq 2$; the duration of the *useful* OFDM symbol is $T > 0$; the spacing between two consecutive subcarriers is $\Delta f > 0$; the sampling step is $T_s = T/N$ and the sampling instants are $t_n = nT_s = nT/N$ for $n = 0, \dots, N-1$. The data are N complex numbers $c = (c_0, \dots, c_{N-1}) \in \mathbb{C}^N$, the points of a constellation (BPSK, QPSK, QAM): what they are does not matter in this chapter, only that they are given complex numbers.

Definition 27.1: OFDM subcarriers. Given $T > 0$ and $\Delta f > 0$, the k -th subcarrier of duration T and spacing Δf is the function

$$\phi_k : [0, T] \longrightarrow \mathbb{C}, \quad \phi_k(t) = e^{2\pi i k \Delta f t}, \quad k = 0, 1, \dots, N-1.$$

On the space of continuous functions $[0, T] \rightarrow \mathbb{C}$ one considers the Hermitian product

$$\langle u, v \rangle_T = \int_0^T u(t) \overline{v(t)} dt.$$

The subcarriers are called **orthogonal** if $\langle \phi_k, \phi_\ell \rangle_T = 0$ for every pair $k \neq \ell$ of indices in $\{0, \dots, N-1\}$.

Note that $|\phi_k(t)| = 1$ for every t : each subcarrier turns on the unit circle at angular speed $2\pi k\Delta f$, completing $k\Delta f T$ turns over the interval $[0, T]$. The whole chapter depends on that number of turns being an integer.

Theorem 27.1: Orthogonality condition over the symbol time. Let $N \geq 2$, $T > 0$, $\Delta f > 0$ and let $\phi_0, \dots, \phi_{N-1}$ be the subcarriers of Definition 27.1. Then

$$\langle \phi_k, \phi_\ell \rangle_T = T \delta_{k\ell} \quad \text{for every } k, \ell \in \{0, \dots, N-1\}$$

if and only if the product $\Delta f T$ is a positive integer.

Proof. Step 1: the case $k = \ell$. For every k , $\phi_k(t)\overline{\phi_k(t)} = |\phi_k(t)|^2 = 1$, hence $\langle \phi_k, \phi_k \rangle_T = \int_0^T 1 dt = T$. This equality holds for every choice of $\Delta f > 0$ and is therefore not involved in the condition to be proved.

Step 2: the case $k \neq \ell$, computing the integral. Let $m = k - \ell$; since $k, \ell \in \{0, \dots, N-1\}$ and $k \neq \ell$, the integer m satisfies $1 \leq |m| \leq N-1$. Then

$$\langle \phi_k, \phi_\ell \rangle_T = \int_0^T e^{2\pi i k \Delta f t} \overline{e^{2\pi i \ell \Delta f t}} dt = \int_0^T e^{2\pi i (k-\ell) \Delta f t} dt = \int_0^T e^{2\pi i m \Delta f t} dt,$$

where $\overline{e^{i\theta}} = e^{-i\theta}$ for real θ was used. Since $m \neq 0$ and $\Delta f > 0$, the number $2\pi i m \Delta f$ is nonzero and the function $t \mapsto \frac{1}{2\pi i m \Delta f} e^{2\pi i m \Delta f t}$ is an antiderivative of the integrand; by the fundamental theorem of calculus

$$\langle \phi_k, \phi_\ell \rangle_T = \left[\frac{e^{2\pi i m \Delta f t}}{2\pi i m \Delta f} \right]_{t=0}^{t=T} = \frac{e^{2\pi i m \Delta f T} - 1}{2\pi i m \Delta f}. \quad (27.1)$$

The denominator is nonzero, so the left-hand side vanishes if and only if $e^{2\pi i m \Delta f T} = 1$, that is — since $e^{2\pi i x} = 1$ is equivalent to $x \in \mathbb{Z}$ for real x — if and only if $m \Delta f T \in \mathbb{Z}$.

Step 3: sufficiency. Suppose $\Delta f T = q$ with q an integer, $q \geq 1$. Then for every integer m one has $m \Delta f T = mq \in \mathbb{Z}$, and by Step 2 the integral (27.1) vanishes for every pair $k \neq \ell$. Together with Step 1 this gives $\langle \phi_k, \phi_\ell \rangle_T = T \delta_{k\ell}$.

Step 4: necessity. Suppose now that $\langle \phi_k, \phi_\ell \rangle_T = 0$ for every $k \neq \ell$. Since $N \geq 2$, the pair $k = 1, \ell = 0$ is admissible and gives $m = 1$; by Step 2 the vanishing of the integral forces $1 \cdot \Delta f T \in \mathbb{Z}$, that is $\Delta f T \in \mathbb{Z}$. On the other hand $\Delta f > 0$ and $T > 0$, hence $\Delta f T > 0$: a positive integer. This is what was to be shown. $\square$

Corollary 27.1: Minimum spacing and occupied bandwidth. Among all the admissible spacings of Theorem 27.1 the smallest is $\Delta f = 1/T$; with $\Delta f T = q$ a positive integer, the N subcarriers have frequencies $0, \Delta f, \dots, (N-1)\Delta f$ and occupy the frequency interval of width $B = (N-1)\Delta f$ between the first and the last, that is $B = q(N-1)/T$. The number of constellation symbols transmitted per unit time and per unit bandwidth is therefore

$$\frac{N}{BT} = \frac{N}{q(N-1)} \xrightarrow{N \rightarrow \infty} \frac{1}{q},$$

and it is maximal for $q = 1$.

Proof. By Theorem 27.1 the admissible spacings are exactly the numbers $\Delta f = q/T$ with q a positive integer; the smallest is obtained for $q = 1$ and equals $1/T$. The subcarrier frequencies are $k\Delta f$ for $k = 0, \dots, N-1$, so the distance between the first and the last is $(N-1)\Delta f = q(N-1)/T$. In a time interval T , N constellation symbols are transmitted, so

the ratio between their number and the product BT is

$$\frac{N}{BT} = \frac{N}{\frac{q(N-1)}{T} \cdot T} = \frac{N}{q(N-1)}.$$

The factor $\frac{N}{N-1} = 1 + \frac{1}{N-1}$ tends to 1 and is decreasing in N ; the factor $1/q$ is maximal for $q = 1$. This gives the last statement. $\square$

Remark 27.1: Why $q = 1$ is always chosen. Corollary 27.1 says that choosing $q = 2$ doubles the occupied bandwidth without transmitting one more symbol: the spectral efficiency is halved. The rest of the chapter therefore assumes

$$\Delta f = \frac{1}{T}, \quad \phi_k(t) = e^{2\pi i k t / T}.$$

With this choice the k -th subcarrier completes exactly k full turns on the unit circle over the interval $[0, T]$: the subcarriers are the characters of the group $\mathbb{R}/T\mathbb{Z}$, and the orthogonality of Theorem 27.1 is the orthogonality of characters already seen, in another guise, in Chapter 13.

Proposition 27.1: The spectrum of a truncated subcarrier. Let $\Delta f = 1/T$ and let $\psi_k = \phi_k \cdot \mathbf{1}_{[0, T]}$ be the k -th subcarrier extended by zero outside the symbol interval. Then its Fourier transform $\Psi_k(f) = \int_{\mathbb{R}} \psi_k(t) e^{-2\pi i f t} dt$ equals

$$\Psi_k(f) = T e^{-i\pi(fT-k)} \operatorname{sinc}(fT-k), \quad \operatorname{sinc}(x) = \frac{\sin(\pi x)}{\pi x} \quad (x \neq 0), \quad \operatorname{sinc}(0) = 1.$$

In particular $|\Psi_k(f)| = T |\operatorname{sinc}(fT-k)|$, and

$$\Psi_k\left(\frac{\ell}{T}\right) = T \delta_{k\ell} \quad \text{for every } \ell \in \mathbb{Z} :$$

the spectrum of the k -th subcarrier vanishes exactly at the centres of all the others.

Proof. Since ψ_k vanishes outside $[0, T]$,

$$\Psi_k(f) = \int_0^T e^{2\pi i k t / T} e^{-2\pi i f t} dt = \int_0^T e^{-2\pi i a t} dt, \quad a := f - \frac{k}{T}.$$

If $a = 0$ the integrand equals 1 and the integral equals T , in agreement with the proposed formula, since in that case $fT - k = 0$, $\operatorname{sinc}(0) = 1$ and $e^0 = 1$. If $a \neq 0$, with the same antiderivative as in Step 2 of the proof of Theorem 27.1,

$$\Psi_k(f) = \frac{1 - e^{-2\pi i a T}}{2\pi i a}.$$

Let $\theta = 2\pi a T$ and factor out $e^{-i\theta/2}$:

$$1 - e^{-i\theta} = e^{-i\theta/2} (e^{i\theta/2} - e^{-i\theta/2}) = e^{-i\theta/2} \cdot 2i \sin \frac{\theta}{2},$$

where the last equality is Euler's formula for the sine. Substituting $\theta/2 = \pi a T$,

$$\Psi_k(f) = \frac{e^{-i\pi a T} 2i \sin(\pi a T)}{2\pi i a} = e^{-i\pi a T} \frac{\sin(\pi a T)}{\pi a} = T e^{-i\pi a T} \frac{\sin(\pi a T)}{\pi a T} = T e^{-i\pi a T} \operatorname{sinc}(aT).$$

Since $aT = fT - k$, the announced formula follows; the modulus follows from $|e^{-i\pi a T}| = 1$. For the last statement, let $f = \ell/T$ with $\ell \in \mathbb{Z}$: then $fT - k = \ell - k$ is an integer. If $\ell = k$ this is the case $a = 0$ and $\Psi_k(k/T) = T$. If $\ell \neq k$ then $\ell - k$ is a nonzero integer and $\sin(\pi(\ell - k)) = 0$, while $\pi(\ell - k) \neq 0$: hence $\operatorname{sinc}(\ell - k) = 0$ and $\Psi_k(\ell/T) = 0$. $\square$

Figure 27.1: The modulus of the spectrum of two truncated subcarriers over the symbol interval (Proposition 27.1), plotted as $|\Psi_k(f)|/T$ against fT : solid blue for $k = 0$, dashed red for $k = 1$. The ordinates are the values of $|\text{sinc}(fT - k)|$ computed with step 0.125 (for instance $|\text{sinc}(\frac{1}{2})| = 2/\pi = 0.6366$ and $|\text{sinc}(\frac{3}{2})| = 2/(3\pi) = 0.2122$). The two spectra overlap over most of the main lobe, but each vanishes at the centre of the other: the zeros fall at $fT - k = \pm 1, \pm 2, \dots$, that is exactly at the centres $f = \ell/T$ of the other subcarriers. This is orthogonality read in the frequency domain.

Remark 27.2: Orthogonality is not band separation. Figure 27.1 shows the point that is most often misunderstood. The spectra of the subcarriers overlap heavily: the main lobe of Ψ_k is $2/T$ wide, that is twice the spacing, and halfway between two subcarriers ($fT - k = \frac{1}{2}$) the value $|\text{sinc}(1/2)| = 2/\pi = 0.6366$ is still 63.66% of the maximum. No filter would separate the subcarriers. What makes them distinguishable is not spectral separation but the choice of the reading point: the demodulator samples the spectrum exactly at the centres $f = \ell/T$, and there — by Proposition 27.1 — every subcarrier other than the ℓ -th one is zero. Shift the reading point, and orthogonality disappears: this is precisely the mechanism of the carrier frequency offset studied in Section 27.6.

Theorem 27.2: Orthogonality of the sampled subcarriers. Let $\Delta f = 1/T$ and let $t_n = nT/N$, $n = 0, \dots, N-1$, be the N sampling instants. Set $v_k = (\phi_k(t_n))_{n=0}^{N-1} \in \mathbb{C}^N$. Then

$$v_k = (\omega_N^{-kn})_{n=0}^{N-1} = e_k,$$

where e_k is the exponential vector of Theorem 22.1, and

$$\langle v_k, v_\ell \rangle = \sum_{n=0}^{N-1} \phi_k(t_n) \overline{\phi_\ell(t_n)} = N \delta_{k\ell}, \quad k, \ell \in \{0, \dots, N-1\}.$$

More precisely, for any integers k, ℓ the sum equals N if $k \equiv \ell \pmod{N}$ and 0 otherwise.

Proof. Step 1: identifying the vectors. By definition $\phi_k(t_n) = e^{2\pi i k t_n / T} = e^{2\pi i k (nT/N) / T} = e^{2\pi i k n / N}$. Since $\omega_N = e^{-2\pi i / N}$ one has $e^{2\pi i k n / N} = \omega_N^{-kn}$, which is by definition the n -th component of the vector e_k of Theorem 22.1. Hence $v_k = e_k$.

Step 2: orthogonality. For $k, \ell \in \{0, \dots, N-1\}$ Theorem 22.1 states $\langle e_k, e_\ell \rangle = N \delta_{k\ell}$, and Step 1 allows that statement to be read as the desired one. There is no need to repeat the computation.

Step 3: the case of arbitrary integer indices. If $k, \ell \in \mathbb{Z}$, one has

$$\langle v_k, v_\ell \rangle = \sum_{n=0}^{N-1} \omega_N^{-kn} \overline{\omega_N^{-\ell n}} = \sum_{n=0}^{N-1} \omega_N^{(\ell-k)n},$$

having used $|\omega_N| = 1$, that is $\overline{\omega_N^m} = \omega_N^{-m}$. Setting $m = \ell - k$, Lemma 22.1 gives $\sum_{n=0}^{N-1} \omega_N^{mn} = N$ if $N \mid m$ and 0 otherwise, which is exactly the statement. $\square$

Remark 27.3: The sampled subcarriers are counted modulo N . Step 3 of Theorem 27.2 contains a substantial difference from the continuous case. In the continuous case the subcarriers ϕ_k are pairwise orthogonal for every pair of distinct integers $k \neq \ell$; after sampling at N points, however, $v_k = v_{k+N}$, because $\omega_N^{-(k+N)n} = \omega_N^{-kn} \omega_N^{-Nn} = \omega_N^{-kn}$. The subcarriers of index k and $k + N$ become indistinguishable: this is aliasing, already seen in Chapter 21 and in Theorem 22.9. This is the reason why the number of usable subcarriers is exactly N , the number of samples: not one more, not one fewer.

27.2. The modulator is an IFFT, the demodulator is an FFT

Up to this point OFDM is only a sum of exponentials: one could build it with N oscillators and N multipliers, and that is exactly how the first paper on the subject, by Chang in 1966, described it. The step that turned it into a technology was the observation that the samples of that sum *already are* a discrete transform: no oscillator, no filter bank, a single call to the FFT. This section proves the claim by writing the two computations — the modulator's computation and the inverse transform's computation — side by side.

Definition 27.2: Baseband OFDM symbol and its samples. Let $c = (c_0, \dots, c_{N-1}) \in \mathbb{C}^N$ be the data vector and let $\Delta f = 1/T$. The **baseband OFDM symbol** associated with c is the function

$$s : [0, T) \longrightarrow \mathbb{C}, \quad s(t) = \sum_{k=0}^{N-1} c_k \phi_k(t) = \sum_{k=0}^{N-1} c_k e^{2\pi i k t / T}.$$

The vector of its samples at the instants $t_n = nT/N$ is denoted $s = (s[0], \dots, s[N-1]) \in \mathbb{C}^N$, where

$$s[n] := s(t_n) = \sum_{k=0}^{N-1} c_k e^{2\pi i k n / N} = \sum_{k=0}^{N-1} c_k \omega_N^{-kn}, \quad n = 0, \dots, N-1.$$

The map $c \mapsto s$ is called the **OFDM modulator**.

Theorem 27.3: The OFDM modulator is the inverse discrete transform. For every $c \in \mathbb{C}^N$ the vector s of Definition 27.2 satisfies

$$s = N \cdot \mathcal{F}_N^{-1} c, \quad \text{that is} \quad s[n] = N (\mathcal{F}_N^{-1} c)[n] \quad \text{for every } n,$$

where $\mathcal{F}_N^{-1}$ is the inverse discrete transform of Definition 22.2. Equivalently, in matrix form,

$$s = \overline{W_N} c = W_N^* c = \sqrt{N} F_N^* c,$$

with W_N and F_N the matrices of Definition 22.3.

Proof. Step 1: the two computations, side by side. Write out in full the definition of the modulator and the definition of the inverse transform, for the same index n :

$$\underbrace{s[n] = \sum_{k=0}^{N-1} c_k \omega_N^{-kn}}_{\text{Definition 27.2}} \quad \underbrace{(\mathcal{F}_N^{-1} c)[n] = \frac{1}{N} \sum_{k=0}^{N-1} c_k \omega_N^{-kn}}_{\text{Definition 22.2}}.$$

The two sums have the same summation index, the same bounds 0 and $N - 1$, and the same general term $c_k \omega_N^{-kn}$: they differ only by the factor $1/N$ in front of the second one. Hence, multiplying the second by N ,

$$N(\mathcal{F}_N^{-1}c)[n] = N \cdot \frac{1}{N} \sum_{k=0}^{N-1} c_k \omega_N^{-kn} = \sum_{k=0}^{N-1} c_k \omega_N^{-kn} = s[n],$$

for every $n = 0, \dots, N - 1$. Since two vectors of $\mathbb{C}^N$ with the same components are equal, $s = N\mathcal{F}_N^{-1}c$.

Step 2: the matrix form. By Definition 22.3 $(W_N)_{nk} = \omega_N^{nk}$; since $|\omega_N| = 1$ one has $\overline{\omega_N^{nk}} = \omega_N^{-nk}$, hence $(\overline{W_N})_{nk} = \omega_N^{-nk}$ and

$$(\overline{W_N}c)[n] = \sum_{k=0}^{N-1} (\overline{W_N})_{nk} c_k = \sum_{k=0}^{N-1} \omega_N^{-nk} c_k = s[n].$$

Moreover W_N is symmetric — $(W_N)_{nk} = \omega_N^{nk} = (W_N)_{kn}$ — so $W_N^* = \overline{W_N}^\top = \overline{W_N}$; and from $F_N = N^{-1/2}W_N$ it follows that $F_N^* = N^{-1/2}W_N^*$, that is $W_N^* = \sqrt{N}F_N^*$. $\square$

Theorem 27.4: The OFDM demodulator is the forward discrete transform. Let $s \in \mathbb{C}^N$ be the vector of samples of an OFDM symbol built with the data $c \in \mathbb{C}^N$. Then

$$c_k = \frac{1}{N} (\mathcal{F}_N s)[k] = \frac{1}{N} \sum_{n=0}^{N-1} s[n] \omega_N^{kn}, \quad k = 0, \dots, N - 1.$$

Recovering the data from the samples is therefore a forward DFT followed by division by N ; in particular the modulator is injective and the data are recovered exactly.

Proof. First route (by substitution and orthogonality). Substitute the definition of $s[n]$ into the sum on the right-hand side, calling j the internal dummy index so as not to confuse it with k :

$$\frac{1}{N} \sum_{n=0}^{N-1} s[n] \omega_N^{kn} = \frac{1}{N} \sum_{n=0}^{N-1} \left(\sum_{j=0}^{N-1} c_j \omega_N^{-jn} \right) \omega_N^{kn}.$$

Both sums are finite, so they may be exchanged without any convergence hypothesis:

$$= \frac{1}{N} \sum_{j=0}^{N-1} c_j \sum_{n=0}^{N-1} \omega_N^{(k-j)n}.$$

By Lemma 22.1 the inner sum equals N if $N \mid (k-j)$ and 0 otherwise; since $j, k \in \{0, \dots, N-1\}$ one has $|k-j| \leq N-1$, so $N \mid (k-j)$ occurs only for $j = k$. Only the term $j = k$ survives:

$$\frac{1}{N} \sum_{n=0}^{N-1} s[n] \omega_N^{kn} = \frac{1}{N} c_k \cdot N = c_k.$$

Second route (from Theorem 27.3). By Theorem 27.3, $s = N\mathcal{F}_N^{-1}c$; applying $\mathcal{F}_N$ to both sides and using Theorem 22.2, according to which $\mathcal{F}_N\mathcal{F}_N^{-1}$ is the identity of $\mathbb{C}^N$,

$$\mathcal{F}_N s = N \mathcal{F}_N \mathcal{F}_N^{-1} c = N c,$$

whence $c = \frac{1}{N} \mathcal{F}_N s$. The two routes give the same result: the first is the explicit computation, the second shows that this computation is nothing but the inversion formula of Chapter 22.

✓

Injectivity follows: if two data vectors c and c' produce the same s , the formula just proved gives $c_k = \frac{1}{N} (\mathcal{F}_N s)[k] = c'_k$ for every k . $\square$

Corollary 27.2: Cost of the modulator and the demodulator. Count, as in Chapter 23, one complex multiplication and one complex addition as elementary operations. Then:

- (i) computing s from Definition 27.2, sum by sum, costs N^2 complex multiplications and $N(N-1)$ complex additions;
- (ii) the same vector s , computed with the radix-2 algorithm for $N = 2^m$, costs $\frac{N}{2} \log_2 N$ complex multiplications and $N \log_2 N$ complex additions, of which only $\frac{N}{2} \log_2 N - \frac{3N}{2} + 2$ are nontrivial multiplications;
- (iii) the demodulator has exactly the same cost as the modulator, plus N divisions by the real number N .

Proof. (i) By Theorem 27.3, $s = \overline{W_N}c$: this is a matrix-vector product with an $N \times N$ matrix whose entries have modulus 1, the same structure as the product $X = W_N x$ counted in Proposition 23.1. The proof of that proposition counts N multiplications and $N-1$ additions for each of the N components, regardless of whether the entries are ω_N^{nk} or their conjugates ω_N^{-nk} ; the counts $N \cdot N = N^2$ and $N(N-1)$ follow.

(ii) Theorem 23.10 states that the inverse transform is obtained from the forward one by conjugation, without a second algorithm: precisely, $\mathcal{F}_N^{-1}X = \frac{1}{N} \overline{\mathcal{F}_N X}$. Applying it to $s = N \mathcal{F}_N^{-1}c$ gives $s = \overline{\mathcal{F}_N c}$: the modulator is realised by conjugating the data, performing *one* forward FFT, and conjugating the output. The two conjugations cost neither multiplications nor additions (they only change the sign of the imaginary part), and the factor $\frac{1}{N}$ of Theorem 23.10 cancels with the factor N of Theorem 27.3. What remains are the counts of Theorem 23.5 and Corollary 23.4, which are the ones stated.

(iii) By Theorem 27.4 the demodulator is $c = \frac{1}{N} \mathcal{F}_N s$: a forward FFT, with the same counts as in (i) and (ii) because it is the same matrix up to conjugation, followed by the N divisions by N . $\square$

Table 27.1: Cost of the OFDM modulator: direct evaluation of the sum of Definition 27.2 against radix-2 FFT (Corollary 27.2). All entries are exact numbers. The last column is the ratio between the multiplications of the two preceding columns; the values were recomputed with an independent script.

N	direct sum		radix-2 FFT		ratio
	mult. N^2	add. $N(N-1)$	mult. $\frac{N}{2} \log_2 N$	nontrivial	
4	16	12	4	0	4.000000
8	64	56	12	2	5.333333
64	4096	4032	192	98	21.333333
256	65536	65280	1024	642	64.000000
1024	1048576	1047552	5120	3586	204.800000
2048	4194304	4192256	11264	8194	372.363636
4096	16777216	16773120	24576	18434	682.666667

Example 27.1: The numbers for $N = 2048$, computed twice. Let $N = 2048 = 2^{11}$, hence $m = \log_2 N = 11$.

First route, closed formula. Direct sum: $N^2 = 2048^2 = 4194304$ multiplications. FFT: $\frac{N}{2} \log_2 N = 1024 \cdot 11 = 11264$ multiplications; nontrivial ones $11264 - \frac{3 \cdot 2048}{2} + 2 = 11264 - 3072 + 2 = 8194$. Ratio $\frac{4194304}{11264} = 372.363636\dots$, that is $\frac{4096}{11}$.

Second route, script. A script that recomputes N^2 , $\frac{N}{2}m$ and $\frac{N}{2}m - \frac{3N}{2} + 2$ for all powers of two from 2^2 to 2^{12} returns, for $N = 2048$, the values 4194304, 11264 and 8194, and the ratio 372.363636. $\checkmark$

Consistency check. The ratio is exactly $\frac{N^2}{2 \log_2 N} = \frac{2N}{\log_2 N} = \frac{4096}{11}$, and $4096 = 11 \cdot 372 + 4$, hence $\frac{4096}{11} = 372 + \frac{4}{11} = 372.\overline{36}$: the repeating decimal 36 confirms the reading of Table 27.1. ✓

Figure 27.2: The complete OFDM chain. On top the transmitter, at the bottom the receiver read from right to left. Each block is a result of this chapter: the only costly operation is the FFT/IFFT pair (Corollary 27.2), and channel equalisation reduces to N complex divisions (Definition 27.5).

Remark 27.4: The three ideas, and who had them. The three ideas that make up OFDM arose separately, years apart. The orthogonality of subcarriers with overlapping spectra — Section 27.1 — is due to R. W. Chang, in a 1966 paper in the *Bell System Technical Journal* **45**, pp. 1775–1796. The realisation by DFT — Theorems 27.3 and 27.4 — is due to S. B. Weinstein and P. M. Ebert, *IEEE Transactions on Communication Technology* **19** (1971), pp. 628–634, who eliminated the bank of oscillators by replacing it with a transform. The cyclic prefix — Section 27.3 — is due to A. Peled and A. Ruiz, *ICASSP 1980*, vol. 5, pp. 964–967, who observed that filling the guard interval with a copy of the block’s tail, instead of with silence, turns the linear convolution into a circular one. All three sources are listed, with DOI and verification date, in the sources environment at the end of the chapter. Note that the historical order and the logical order coincide: without orthogonality there is nothing to transform, without the DFT the computation cannot be carried out, and without the cyclic prefix the DFT diagonalises the wrong matrix.

27.3. The channel, the cyclic prefix and circular convolution

Theorem 22.5 says that the DFT turns *circular* convolution into a product. A physical channel, however, performs a *linear* convolution: the echo of a sample arrives later, it does not reappear at the start of the block. Between the two worlds there is a discrepancy, and the cyclic prefix is what removes it. This section contains the heart of the chapter.

Definition 27.3: Finite impulse response channel. Let $L \geq 1$ be an integer and let $h = (h_0, h_1, \dots, h_{L-1}) \in \mathbb{C}^L$ with $h_{L-1} \neq 0$. The **channel** of impulse response h and length L is the map that associates to a sequence $x : \mathbb{Z} \rightarrow \mathbb{C}$ the sequence

$$r[n] = \sum_{l=0}^{L-1} h_l x[n-l], \quad n \in \mathbb{Z} \quad (\text{linear convolution}).$$

The integer $L - 1$ is called the **dispersion** (or *delay spread* in samples) of the channel: it is the maximum delay, measured in sampling steps, with which a replica of the signal reaches the receiver. In physical time the dispersion equals $\tau_{\max} = (L - 1) T_s$.

Definition 27.4: Cyclic prefix. Let $s \in \mathbb{C}^N$ be the samples of an OFDM symbol (Definition 27.2) and let $N_g \geq 0$ be an integer with $N_g \leq N$. The **block with cyclic prefix** of guard length N_g is the vector $\tilde{s} \in \mathbb{C}^{N+N_g}$ defined by

$$\tilde{s}[n] = s[\langle n - N_g \rangle_N], \quad n = 0, 1, \dots, N + N_g - 1.$$

Writing out the two parts in full,

$$\tilde{s}[n] = \begin{cases} s[N - N_g + n], & n = 0, 1, \dots, N_g - 1 \quad (\text{the prefix: the tail of } s), \\ s[n - N_g], & n = N_g, \dots, N + N_g - 1 \quad (\text{the useful block}). \end{cases}$$

The prefix is thus a literal copy of the last N_g samples of the block, prepended to the block itself.

Remark 27.5: The two forms of the definition are the same. It is worth checking the equivalence, because the whole section depends on it. For $n \in \{0, \dots, N_g - 1\}$ one has $-N_g \leq n - N_g \leq -1$, so $n - N_g$ is negative and greater than or equal to $-N$ (because $N_g \leq N$); the representative of $n - N_g$ in $\{0, \dots, N - 1\}$ is then $\langle n - N_g \rangle_N = n - N_g + N = N - N_g + n$. For $n \in \{N_g, \dots, N + N_g - 1\}$, on the other hand, $0 \leq n - N_g \leq N - 1$, and the representative is $n - N_g$ itself. ✓

Figure 27.3: The cyclic prefix. On top the transmitted block: the last N_g samples of the symbol are copied to the front (red arrow). At the bottom the received block: the tail of the previous block contaminates only the first $L-1$ samples (Lemma 27.1), and if $N_g \geq L-1$ these all fall in the discarded region. On the remaining N samples the channel has produced exactly the circular convolution (Theorem 27.5). The figure is drawn for $N = 8$ and $N_g = 2$, the values of the example in Section 27.9.

Lemma 27.1: Interblock interference falls in the first $L-1$ samples. Let $x : \mathbb{Z} \rightarrow \mathbb{C}$ be the transmitted sequence, with $x[n] = \tilde{s}[n]$ for $n \in \{0, \dots, N + N_g - 1\}$ and $x[n]$ arbitrary for $n < 0$ (the tail of the previous blocks), and let $r[n] = \sum_{l=0}^{L-1} h_l x[n-l]$ be the channel output. Then, for $n \geq L-1$, the value $r[n]$ does not depend on any $x[j]$ with $j < 0$; for $0 \leq n \leq L-2$ (possible only if $L \geq 2$) the value $r[n]$ depends on the $L-1-n$ past samples $x[-1], \dots, x[n-L+1]$.

Proof. In the sum $r[n] = \sum_{l=0}^{L-1} h_l x[n-l]$ exactly the indices $n-l$ with $l = 0, 1, \dots, L-1$ appear, that is, the integers from $n-L+1$ to n . One of these indices is negative if and only if $n-L+1 < 0$, that is $n < L-1$. Hence for $n \geq L-1$ all the indices $n-l$ are ≥ 0 and no past sample is involved. For $0 \leq n \leq L-2$ the negative indices are those with $n-l < 0$, that is $l > n$: these are $l = n+1, \dots, L-1$, in number $L-1-n$, and correspond to the samples

$x[-1], x[-2], \dots, x[n-L+1]$. The coefficient of $x[n-L+1]$ is $h_{L-1} \neq 0$ by hypothesis, so the dependence is effective. $\square$

Theorem 27.5: The cyclic prefix converts linear convolution into circular convolution. Let $N \geq L$, $N \geq N_g \geq L-1$, let $\tilde{s}$ be the block with cyclic prefix of Definition 27.4, let x be the transmitted sequence of Lemma 27.1 and let r be the channel output. Let the receiver discard the first N_g samples and set

$$y[m] := r[m + N_g], \quad m = 0, 1, \dots, N-1.$$

Finally let $h_p \in \mathbb{C}^N$ be the zero-padding of h , that is $h_p[l] = h_l$ for $0 \leq l \leq L-1$ and $h_p[l] = 0$ for $L \leq l \leq N-1$. Then

$$y = h_p \circledast s, \quad \text{that is} \quad y[m] = \sum_{l=0}^{N-1} h_p[l] s[\langle m-l \rangle_N], \quad m = 0, \dots, N-1,$$

with $\circledast$ the circular convolution of Definition 22.4.

Proof. Step 1: no past sample is involved. By Lemma 27.1 the value $r[n]$ is independent of the past as soon as $n \geq L-1$. The indices used are $n = m + N_g$ with $m \geq 0$, hence $n \geq N_g \geq L-1$ by hypothesis: the condition holds for every $m = 0, \dots, N-1$. From here on $x[j] = \tilde{s}[j]$ for every index that appears.

Step 2: the indices stay inside the block. For $m \in \{0, \dots, N-1\}$ and $l \in \{0, \dots, L-1\}$ set $n_l := m + N_g - l$. Then

$$n_l \geq 0 + N_g - (L-1) \geq 0 \quad (\text{because } N_g \geq L-1),$$

$$n_l \leq (N-1) + N_g - 0 = N + N_g - 1.$$

Hence $n_l \in \{0, \dots, N + N_g - 1\}$ and $\tilde{s}[n_l]$ is defined by Definition 27.4. Therefore

$$y[m] = r[m + N_g] = \sum_{l=0}^{L-1} h_l \tilde{s}[m + N_g - l].$$

Step 3: the modular index computation, written out in full. It is claimed that

$$\tilde{s}[m + N_g - l] = s[\langle m-l \rangle_N] \quad \text{for every } m \in \{0, \dots, N-1\}, l \in \{0, \dots, L-1\}. \quad (27.2)$$

Two cases are distinguished.

Case (a): $l \leq m$. Then $m-l \geq 0$ and $m-l \leq N-1$, so $\langle m-l \rangle_N = m-l$, that is, there is no wraparound. On the other hand $n_l = m + N_g - l \geq N_g$, so n_l falls in the *second* row of Definition 27.4 and

$$\tilde{s}[n_l] = s[n_l - N_g] = s[m + N_g - l - N_g] = s[m-l] = s[\langle m-l \rangle_N].$$

Case (b): $l > m$. Let $d := l - m$, so that $1 \leq d \leq L-1 \leq N_g$. Then

$$n_l = m + N_g - l = N_g - d, \quad 0 \leq N_g - d \leq N_g - 1,$$

so n_l falls in the *first* row of Definition 27.4, that is, inside the prefix, and

$$\tilde{s}[n_l] = s[N - N_g + n_l] = s[N - N_g + N_g - d] = s[N - d] = s[N + m - l].$$

On the other hand $m-l = -d$ with $1 \leq d \leq N_g \leq N$, that is $-N \leq m-l \leq -1$: if $d < N$ the representative is $\langle m-l \rangle_N = m-l + N = N-d$, and if $d = N$ (possible only for $N_g = N = d$) it is $\langle m-l \rangle_N = 0 = N-d$. In both sub-cases $s[\langle m-l \rangle_N] = s[N-d] = \tilde{s}[n_l]$.

The two cases exhaust the possibilities, so (27.2) is proved. It is here, and only here, that the cyclic prefix is needed: without it, in case (b) the sample $\tilde{s}[N_g - d]$ would belong to the previous block and would have no reason to equal $s[N - d]$.

Step 4: conclusion. Substituting (27.2) into Step 2,

$$y[m] = \sum_{l=0}^{L-1} h_l s[\langle m - l \rangle_N].$$

Since $L \leq N$, the sum can be extended up to $N - 1$ by adding zero terms, because $h_p[l] = 0$ for $l \geq L$:

$$y[m] = \sum_{l=0}^{N-1} h_p[l] s[\langle m - l \rangle_N] = (h_p \circledast s)[m],$$

which is exactly Definition 22.4 with $x = h_p$ and $y = s$. $\square$

Theorem 27.6: *The condition $N_g \geq L - 1$ is also necessary.* Let $L \geq 2$, $h_{L-1} \neq 0$ and $0 \leq N_g \leq L - 2$. Then there exist a data block $s \in \mathbb{C}^N$ and two transmitted sequences x and x' that agree on $\{0, \dots, N + N_g - 1\}$ — that is, that carry the same symbol with the same prefix — but produce different received vectors:

$$y'[0] - y[0] = h_{L-1} \neq 0,$$

while $h_p \circledast s$ is by construction the same in both cases. Consequently the identity $y = h_p \circledast s$ of Theorem 27.5 cannot hold for every transmission, and the condition $N_g \geq L - 1$ is necessary as well as sufficient.

Proof. Choose any $s \in \mathbb{C}^N$ and build $\tilde{s}$ as in Definition 27.4. Define two transmitted sequences $x, x' : \mathbb{Z} \rightarrow \mathbb{C}$ by setting, for both, $x[n] = x'[n] = \tilde{s}[n]$ on $\{0, \dots, N + N_g - 1\}$ and $x[n] = x'[n] = 0$ for every $n < 0$ except the index

$$j_0 := N_g - (L - 1),$$

where $x[j_0] = 0$ and $x'[j_0] = 1$ are set. The index j_0 is indeed negative: $j_0 = N_g - L + 1 \leq (L - 2) - L + 1 = -1$.

Now compute $y[0]$ and $y'[0]$. By definition $y[0] = r[N_g] = \sum_{l=0}^{L-1} h_l x[N_g - l]$, and likewise for x' . The two sequences differ only at the index $j_0 = N_g - (L - 1)$, which appears in that sum for $l = L - 1$ and for no other value of l (the map $l \mapsto N_g - l$ is injective). Hence, subtracting term by term,

$$y'[0] - y[0] = h_{L-1}(x'[j_0] - x[j_0]) = h_{L-1} \cdot (1 - 0) = h_{L-1} \neq 0.$$

The vector $h_p \circledast s$, instead, depends only on h and on s , which are the same in both cases. If the identity $y = h_p \circledast s$ held for both transmissions one would have $y[0] = (h_p \circledast s)[0] = y'[0]$, contradicting what was just computed. Hence it fails for at least one of the two, and no choice of $N_g \leq L - 2$ can guarantee it in general. $\square$

Corollary 27.3: *The channel becomes diagonal in the frequency domain.* Under the hypotheses of Theorem 27.5 set

$$H := \mathcal{F}_N h_p, \quad H[k] = \sum_{l=0}^{L-1} h_l \omega_N^{kl} = \sum_{l=0}^{L-1} h_l e^{-2\pi i k l / N}, \quad k = 0, \dots, N - 1.$$

Then, with $Y = \mathcal{F}_N y$,

$$Y[k] = H[k] S[k] = N H[k] c_k, \quad k = 0, \dots, N-1.$$

The channel, which in the time domain mixes all N samples together, in the frequency domain acts on each subcarrier separately, multiplying it by a single complex number.

Proof. By Theorem 27.5, $y = h_p \otimes s$; applying $\mathcal{F}_N$ and Theorem 22.5 (the discrete convolution theorem) gives $Y[k] = H[k] S[k]$ with $H = \mathcal{F}_N h_p$ and $S = \mathcal{F}_N s$. The explicit expression of $H[k]$ is Definition 22.1 applied to h_p , whose terms of index $\geq L$ vanish. Finally Theorem 27.4 gives $S = \mathcal{F}_N s = N c$, that is $S[k] = N c_k$. $\square$

Theorem 27.7: Matrix form: the channel is a circulant, and the basis that diagonalises it is the Fourier basis. Under the hypotheses of Theorem 27.5 let $C_h := \text{circ}(h_p)$ be the circulant matrix generated by h_p (Definition 22.5), that is $(C_h)_{mj} = h_p[\langle m - j \rangle_N]$. Then

- (i) $y = C_h s$;
- (ii) $F_N C_h F_N^* = \text{diag}(H[0], \dots, H[N-1])$, with F_N the unitary matrix of Definition 22.3;
- (iii) the eigenvalues of C_h are the numbers $H[k]$ and an eigenvector for $H[k]$ is the k -th sampled subcarrier $v_k = (\omega_N^{-kn})_{n=0}^{N-1}$ of Theorem 27.2;
- (iv) $\det C_h = \prod_{k=0}^{N-1} H[k]$, and C_h is invertible if and only if $H[k] \neq 0$ for every k .

Proof. (i) By Proposition 22.5, $\text{circ}(h_p) s = h_p \otimes s$, and Theorem 27.5 gives $h_p \otimes s = y$.
(ii) This is exactly Theorem 22.8 applied to the generator $c = h_p$: it states $F_N C F_N^* = \text{diag}(\lambda)$ with $\lambda = \mathcal{F}_N c$, and here $\mathcal{F}_N h_p = H$ by definition of H .
(iii) The same theorem identifies the eigenvector for $\lambda[k]$ as the vector $e_k = (\omega_N^{-kn})_n$; Theorem 27.2 identifies e_k with the k -th sampled subcarrier v_k . This is the central statement of the chapter, said in the language of linear algebra: *the subcarriers are the eigenvectors of the channel*, and they are so for *every* channel, because the basis that diagonalises every circulant of order N is a single one.
(iv) From (ii) it follows that $C_h = F_N^* \text{diag}(H) F_N$; the determinant is multiplicative and $\det(F_N^*) \det(F_N) = \det(F_N^* F_N) = \det I_N = 1$, hence $\det C_h = \det \text{diag}(H) = \prod_k H[k]$. A matrix is invertible if and only if its determinant is nonzero, and a product of complex numbers is nonzero if and only if every factor is. $\square$

Remark 27.6: What the prefix has really done: it has closed the time axis into a circle. It is worth saying in one sentence what has happened. A channel is invariant under translation on the time axis $\mathbb{Z}$: delaying the input delays the output. The linear maps of $\mathbb{C}^N$ into itself that are invariant under the circular translation $x[n] \mapsto x[\langle n-1 \rangle_N]$ are exactly the circulant matrices (Definition 22.5); and Theorem 22.8 says that all those matrices share the same eigenvectors, the characters of the cyclic group $\mathbb{Z}/N\mathbb{Z}$, that is, the sampled subcarriers. The cyclic prefix does nothing more than force the channel to behave as if time lived on $\mathbb{Z}/N\mathbb{Z}$ instead of on $\mathbb{Z}$: the tail of the block, copied to the front, makes the sample preceding $s[0]$ equal to $s[N-1]$, exactly as on the discrete circle. From there on, the whole algebra of Chapter 22 is available, and the diagonalisation comes for free. This is the reason this chapter belongs to a treatise on the circle: modern broadband rests on the idea of closing a line into a ring.

Remark 27.7: The prefix carries no information. The receiver discards the first N_g samples and loses nothing: by Definition 27.4 those samples are a copy of samples that will

arrive anyway, and by Lemma 27.1 they are also the only ones contaminated by the previous block. The prefix is thus pure redundancy: it costs transmission time and carries no bits. Exactly how much it costs is the subject of Section 27.5.

27.4. Single-coefficient equalisation per subcarrier

Corollary 27.3 reduces equalisation to a trivial operation: since $Y[k] = NH[k]c_k$, recovering c_k only takes a division. A channel that in the time domain would require an inverse filter of theoretically infinite length is equalised with N complex divisions. This section writes the formula, computes its error in the presence of noise, and shows where the procedure is fragile.

Definition 27.5: Zero-forcing equalizer (single-coefficient). Suppose $H[k] \neq 0$ for every k . The **zero-forcing equalizer** (ZF) is the map that associates to the received vector y

$$\hat{c}_k = \frac{Y[k]}{N H[k]}, \quad Y = \mathcal{F}_N y, \quad k = 0, \dots, N-1.$$

It is called *single-coefficient* because for each subcarrier the correction is a single complex number, $1/(NH[k])$: a gain and a rotation.

Proposition 27.2: In the absence of noise the ZF equalizer is exact. Under the hypotheses of Theorem 27.5, if $H[k] \neq 0$ for every k then $\hat{c}_k = c_k$ for every k : the data are reconstructed exactly.

Proof. By Corollary 27.3, $Y[k] = NH[k]c_k$. Since $N \neq 0$ and $H[k] \neq 0$ one may divide, obtaining $\hat{c}_k = \frac{NH[k]c_k}{NH[k]} = c_k$. $\square$

Noise changes the picture, and it changes it in a way that depends on k . The following model is adopted, made explicit once and for all.

Definition 27.6: Hypothesis (R) on the noise. The random vector $w = (w[0], \dots, w[N-1])$ with values in $\mathbb{C}^N$ is said to satisfy **hypothesis (R)** if

$$\mathbb{E}[w[n]] = 0, \quad \mathbb{E}[w[n]\overline{w[m]}] = \sigma^2 \delta_{nm}, \quad \mathbb{E}[w[n]w[m]] = 0 \quad \text{for every } n, m,$$

with $\sigma^2 > 0$, and if w is independent of the data vector c . The third condition is called *circular symmetry* and says that the real and imaginary parts have the same variance $\sigma^2/2$ and are uncorrelated. The received vector is then $y = h_p \otimes s + w$.

Lemma 27.2: The DFT preserves the whiteness of the noise. Under hypothesis (R), setting $W = \mathcal{F}_N w$, one has

$$\mathbb{E}[W[k]] = 0, \quad \mathbb{E}[W[k]\overline{W[k']}]= N\sigma^2 \delta_{kk'}, \quad \mathbb{E}[|W[k]|^2] = N\sigma^2.$$

Proof. The mean is zero by linearity of the expectation: $\mathbb{E}[W[k]] = \sum_n \omega_N^{kn} \mathbb{E}[w[n]] = 0$. For the covariance one uses the definition of the DFT (Definition 22.1) and again linearity:

$$\mathbb{E}[W[k]\overline{W[k']}]= \mathbb{E}\left[\sum_{n=0}^{N-1} w[n]\omega_N^{kn} \sum_{m=0}^{N-1} \overline{w[m]\omega_N^{k'm}}\right] = \sum_{n=0}^{N-1} \sum_{m=0}^{N-1} \mathbb{E}[w[n]\overline{w[m]}] \omega_N^{kn} \omega_N^{-k'm},$$

where $\overline{\omega_N^{k'm}} = \omega_N^{-k'm}$ was used (licit because $|\omega_N| = 1$). By hypothesis (R) the terms with

$n \neq m$ vanish and those with $n = m$ equal σ^2 :

$$\mathbb{E}[W[k]\overline{W[k']}] = \sigma^2 \sum_{n=0}^{N-1} \omega_N^{kn} \omega_N^{-k'n} = \sigma^2 \sum_{n=0}^{N-1} \omega_N^{(k-k')n}.$$

By Lemma 22.1 the last sum equals N if $N \mid (k-k')$ and 0 otherwise; since $k, k' \in \{0, \dots, N-1\}$, this happens only for $k = k'$. This gives $N\sigma^2\delta_{kk'}$, and for $k = k'$ the formula for the squared modulus. $\square$

Theorem 27.8: Error of the single-coefficient equalizer in the presence of noise.

Under hypothesis (R) and the hypotheses of Theorem 27.5, with $H[k] \neq 0$ for every k , the output of the ZF equalizer of Definition 27.5 is

$$\hat{c}_k = c_k + e_k, \quad e_k := \frac{W[k]}{N H[k]},$$

and the error satisfies

$$\mathbb{E}[e_k] = 0, \quad \mathbb{E}[|e_k|^2] = \frac{\sigma^2}{N |H[k]|^2}, \quad \mathbb{E}[e_k \overline{e_{k'}}] = 0 \quad (k \neq k').$$

In particular the equalizer is unbiased ($\mathbb{E}[\hat{c}_k] = \mathbb{E}[c_k]$) and the errors on the different subcarriers are uncorrelated, but the error power is inversely proportional to $|H[k]|^2$.

Proof. Step 1: shape of the error. The received vector is $y = h_p \otimes s + w$; by linearity of the DFT and by Corollary 27.3,

$$Y[k] = \mathcal{F}_N(h_p \otimes s)[k] + \mathcal{F}_N w[k] = N H[k] c_k + W[k].$$

Dividing by $NH[k]$, which is nonzero,

$$\hat{c}_k = \frac{NH[k]c_k + W[k]}{NH[k]} = c_k + \frac{W[k]}{NH[k]} = c_k + e_k.$$

Step 2: mean of the error. Since $NH[k]$ is a deterministic constant, $\mathbb{E}[e_k] = \frac{1}{NH[k]} \mathbb{E}[W[k]] = 0$ by Lemma 27.2. It follows that $\mathbb{E}[\hat{c}_k] = \mathbb{E}[c_k]$.

Step 3: power of the error. Again because $NH[k]$ is deterministic,

$$\mathbb{E}[|e_k|^2] = \mathbb{E}\left[\frac{|W[k]|^2}{|NH[k]|^2}\right] = \frac{\mathbb{E}[|W[k]|^2]}{N^2 |H[k]|^2} = \frac{N\sigma^2}{N^2 |H[k]|^2} = \frac{\sigma^2}{N |H[k]|^2},$$

where $\mathbb{E}[|W[k]|^2] = N\sigma^2$ from Lemma 27.2 was used.

Step 4: decorrelation. For $k \neq k'$,

$$\mathbb{E}[e_k \overline{e_{k'}}] = \frac{\mathbb{E}[W[k]\overline{W[k']}] }{N^2 H[k]\overline{H[k']}} = \frac{N\sigma^2 \delta_{kk'}}{N^2 H[k]\overline{H[k']}} = 0,$$

again by Lemma 27.2. $\square$

Corollary 27.4: Signal-to-noise ratio per subcarrier and noise amplification.

Suppose moreover that $\mathbb{E}[|c_k|^2] = P$ for every k . Then the ratio between the symbol power

and the error power on the k -th subcarrier is

$$\text{SNR}_k = \frac{\mathbb{E}[|c_k|^2]}{\mathbb{E}[|e_k|^2]} = \frac{N P |H[k]|^2}{\sigma^2},$$

and for two subcarriers k, k'

$$\frac{\text{SNR}_k}{\text{SNR}_{k'}} = \frac{|H[k]|^2}{|H[k']|^2}.$$

The ratio between the best and the worst subcarrier is therefore $\max_k |H[k]|^2 / \min_k |H[k]|^2$, and it diverges when a subcarrier falls into a deep fade, that is, when $H[k]$ approaches zero.

Proof. Immediate from Theorem 27.8: dividing P by $\sigma^2/(N|H[k]|^2)$ gives $NP|H[k]|^2/\sigma^2$; the ratio of two such values cancels N, P and σ^2 . $\square$

Example 27.2: The errors on the eight subcarriers of the example $N = 8$. Take $N = 8$ and the channel $h = (1, \frac{1}{2}, \frac{1}{4})$ of Section 27.9, with $\sigma^2 = 0.04$ and $P = 1$.

First route, closed formula. The squared moduli of the frequency response are (Section 27.9, where they are derived)

$$\begin{aligned} |H[0]|^2 &= \frac{49}{16} = 3.0625, & |H[1]|^2 &= |H[7]|^2 = \frac{21}{16} + \frac{5\sqrt{2}}{8} = 2.1963835, \\ |H[2]|^2 &= |H[6]|^2 = \frac{13}{16} = 0.8125, & |H[3]|^2 &= |H[5]|^2 = \frac{21}{16} - \frac{5\sqrt{2}}{8} = 0.4286165, \\ |H[4]|^2 &= \frac{9}{16} = 0.5625. \end{aligned}$$

By Theorem 27.8, $\mathbb{E}[|e_k|^2] = \frac{0.04}{8|H[k]|^2} = \frac{0.005}{|H[k]|^2}$, that is

(0.0016327, 0.0022765, 0.0061538, 0.0116654, 0.0088889, 0.0116654, 0.0061538, 0.0022765).

The worst subcarrier is the third one (and the fifth), with an error $\frac{0.0116654}{0.0016327} = 7.1450815$ times that of subcarrier 0: in decibels, $10 \log_{10} 7.1450815 = 8.5400719$ dB of disadvantage. The exact value of the ratio is

$$\frac{|H[0]|^2}{|H[3]|^2} = \frac{49/16}{\frac{21}{16} - \frac{5\sqrt{2}}{8}} = \frac{49}{21 - 10\sqrt{2}} = 7.1450815.$$

Second route, simulation. A script generated 200 000 independent realisations of circularly symmetric complex Gaussian noise with $\sigma^2 = 0.04$, computed their DFT, divided by $NH[k]$, and averaged $|e_k|^2$. The empirical values obtained are

(0.0016322, 0.0022752, 0.0061601, 0.0116692, 0.0089008, 0.0116804, 0.0061455, 0.0022778),

with empirical/theoretical ratios between 0.99864 and 1.00134: a discrepancy compatible with the statistical error of an average over 200 000 samples. $\checkmark$

Remark 27.8: Why ZF is not the optimal choice. Theorem 27.8 shows the flaw of the ZF equalizer: when $|H[k]|$ is small, the divisor $NH[k]$ is small and the noise is amplified exactly to the same extent that the signal is restored. In the limit $H[k] \rightarrow 0$ the error diverges, while common sense suggests that, if a subcarrier is completely cancelled by the channel, the sensible thing is to give it up rather than amplify noise until it swamps everything else. The

next theorem formalises this intuition and shows that the optimal equalizer, in the class of single-coefficient corrections, is not $1/H[k]$.

Theorem 27.9: The correction optimal in mean square. Fix k and assume hypothesis (R), together with $\mathbb{E}[c_k] = 0$ and $\mathbb{E}[|c_k|^2] = P > 0$. Consider the family of estimators

$$\hat{c}_k(g) = g \cdot \frac{Y[k]}{N}, \quad g \in \mathbb{C},$$

and set $J(g) = \mathbb{E}[|c_k - \hat{c}_k(g)|^2]$. Then J has a unique minimum point, given by

$$g^* = \frac{\overline{H[k]}}{|H[k]|^2 + \frac{\sigma^2}{NP}},$$

and the minimum value is

$$J(g^*) = \frac{P\sigma^2}{N|H[k]|^2 P + \sigma^2} < \frac{\sigma^2}{N|H[k]|^2} = \mathbb{E}[|e_k|^2].$$

Moreover $g^* \rightarrow 1/H[k]$ as $\sigma^2 \rightarrow 0$: in the noiseless limit the optimal equalizer coincides with the zero-forcing one.

Proof. Step 1: reduction to a scalar problem. Set $u := \frac{Y[k]}{N} = H[k]c_k + \frac{W[k]}{N}$ (Step 1 of the proof of Theorem 27.8). Write $H := H[k]$ for brevity. Since c_k and w are independent and $\mathbb{E}[W[k]] = \mathbb{E}[c_k] = 0$, one has $\mathbb{E}[c_k \overline{W[k]}] = \mathbb{E}[c_k] \mathbb{E}[\overline{W[k]}] = 0$; hence

$$\mathbb{E}[|u|^2] = |H|^2 \mathbb{E}[|c_k|^2] + \frac{\mathbb{E}[|W[k]|^2]}{N^2} = |H|^2 P + \frac{N\sigma^2}{N^2} = |H|^2 P + \frac{\sigma^2}{N} =: A > 0,$$

$$\mathbb{E}[u \overline{c_k}] = H \mathbb{E}[|c_k|^2] + \frac{1}{N} \mathbb{E}[W[k] \overline{c_k}] = HP.$$

Step 2: the function to minimise. Expanding the squared modulus,

$$J(g) = \mathbb{E}[(c_k - gu)(\overline{c_k - gu})] = \mathbb{E}[|c_k|^2] - \bar{g} \mathbb{E}[c_k \overline{u}] - g \mathbb{E}[\overline{c_k} u] + |g|^2 \mathbb{E}[|u|^2].$$

By Step 1, $\mathbb{E}[\overline{c_k} u] = HP$ and $\mathbb{E}[c_k \overline{u}] = \overline{HP} = \bar{H}P$ (because P is real). Hence

$$J(g) = P - \bar{g} \bar{H}P - gHP + |g|^2 A = P - 2\Re(gHP) + |g|^2 A.$$

Step 3: completing the square. Set $z := \frac{\bar{H}P}{A}$. Then

$$A|g - z|^2 = A|g|^2 - 2A\Re(g\bar{z}) + A|z|^2 = A|g|^2 - 2\Re(gHP) + \frac{|H|^2 P^2}{A},$$

having used $A\bar{z} = HP$ and $A|z|^2 = |H|^2 P^2 / A$. Comparing with Step 2,

$$J(g) = A|g - z|^2 + P - \frac{|H|^2 P^2}{A}.$$

Since $A > 0$, the first term is nonnegative and vanishes if and only if $g = z$: the minimum is unique and equals $g^* = z = \frac{\bar{H}P}{A}$. Dividing numerator and denominator by P ,

$$g^* = \frac{\bar{H}P}{|H|^2 P + \frac{\sigma^2}{N}} = \frac{\bar{H}}{|H|^2 + \frac{\sigma^2}{NP}},$$

which is the announced formula.

Step 4: the minimum value. Substituting,

$$\begin{aligned} J(g^*) &= P - \frac{|H|^2 P^2}{A} = \frac{PA - |H|^2 P^2}{A} = \frac{P(|H|^2 P + \frac{\sigma^2}{N}) - |H|^2 P^2}{|H|^2 P + \frac{\sigma^2}{N}} \\ &= \frac{\frac{P\sigma^2}{N}}{|H|^2 P + \frac{\sigma^2}{N}} = \frac{P\sigma^2}{N|H|^2 P + \sigma^2}, \end{aligned}$$

where in the last step numerator and denominator were multiplied by N .

Step 5: comparison with ZF. Since $\sigma^2 > 0$ one has $N|H|^2 P + \sigma^2 > N|H|^2 P > 0$, hence

$$J(g^*) = \frac{P\sigma^2}{N|H|^2 P + \sigma^2} < \frac{P\sigma^2}{N|H|^2 P} = \frac{\sigma^2}{N|H|^2} = \mathbb{E}[|e_k|^2].$$

The inequality is consistent with the fact that the ZF equalizer belongs to the family considered: it corresponds to $g = 1/H$, and the minimum cannot exceed the value at any given point.

Step 6: the noiseless limit. In the formula $g^* = \bar{H}/(|H|^2 + \frac{\sigma^2}{NP})$ the denominator tends to $|H|^2$ as $\sigma^2 \rightarrow 0$, and $|H|^2 \neq 0$; hence $g^* \rightarrow \bar{H}/|H|^2 = \bar{H}/(H\bar{H}) = 1/H$. $\square$

Remark 27.9: The price of optimality: bias. The equalizer of Theorem 27.9 is biased: one has

$$\mathbb{E}[\hat{c}_k(g^*) | c_k] = g^* H c_k = \frac{|H|^2}{|H|^2 + \frac{\sigma^2}{NP}} c_k \neq c_k,$$

that is, the estimated symbol is systematically shrunk towards the origin by a factor $\frac{|H|^2}{|H|^2 + \sigma^2/(NP)} < 1$, more pronounced the more attenuated the subcarrier is. ZF has no such flaw (Theorem 27.8, Step 2) but pays with a larger mean-square error. There is no absolute right choice: one chooses according to the criterion, and the two criteria — absence of bias and minimum mean-square error — are incompatible. In the numerical example of Example 27.2, with $\sigma^2 = 0.04$, $P = 1$ and $N = 8$, the MMSE gain over ZF ranges from a factor 0.99837 on the best subcarrier to 0.98847 on the worst: a small advantage, because the noise is weak, but systematic and growing as $|H[k]|$ decreases.

Remark 27.10: Deep fades and what is done about them in practice: panorama.

Corollary 27.4 describes a situation that no equalisation can solve: if $H[k]$ is nearly zero, the k -th subcarrier no longer carries usable information, and this is independent of the equalizer chosen — the ratio $NP|H[k]|^2/\sigma^2$ already says so, and it contains no reference to the receiver. The countermeasure is not in equalisation but in coding: the bits of each codeword are spread over distant subcarriers, so that the few cancelled ones can be recovered from the many good ones (frequency diversity), and the number of bits per subcarrier is adapted to its SNR_k (bit loading). Both techniques belong to coding theory and are neither treated nor proved here: only the panorama is given. The reader finds them presented in Y. S. Cho, J. Kim, W. Y. Yang, C. G. Kang, *MIMO-OFDM Wireless Communications with MATLAB*, Wiley, 2010, Chapter 4 “Introduction to OFDM”, pp. 111–151, and in J. G. Proakis, M. Salehi, *Digital Communications*, 5th edition, McGraw-Hill, 2008. This chapter stops at the point where the channel has been made diagonal: from there on the problem changes discipline.

27.5. How long the prefix must be, and what it costs

Theorem 27.5 and Theorem 27.6 together determine the length of the prefix: not less than $L - 1$, because otherwise the computation does not close, and not more, because every extra sample is transmission time thrown away. This section computes exactly how much that time costs.

Corollary 27.5: The condition on the prefix length. Let h be a channel of length L and dispersion $\tau_{\max} = (L - 1)T_s$ (Definition 27.3). Then the identity $y = h_p \circledast s$ holds for every transmission if and only if

$$N_g \geq L - 1, \quad \text{that is} \quad N_g T_s \geq \tau_{\max} :$$

the guard interval must last at least as long as the channel's dispersion. The minimal choice is $N_g = L - 1$.

Proof. Sufficiency is Theorem 27.5, necessity is Theorem 27.6. The rewriting in physical time is obtained by multiplying both sides of the inequality $N_g \geq L - 1$ by $T_s > 0$ and using $\tau_{\max} = (L - 1)T_s$. $\square$

Definition 27.7: Time efficiency. The transmitted block lasts $N + N_g$ samples, of which only N carry information (Observation 27.7). The ratio

$$\eta := \frac{N}{N + N_g} \in (0, 1],$$

is called the **time efficiency**, and the quantity $1 - \eta$ the **efficiency loss**. The loss expressed in decibels is $-10 \log_{10} \eta$.

Proposition 27.3: The loss due to the prefix. With the notation of Definition 27.7 and setting $\rho := N_g/N$:

- (i) $\eta = \frac{1}{1 + \rho}$ and $1 - \eta = \frac{\rho}{1 + \rho} = \frac{N_g}{N + N_g}$;
- (ii) the loss in decibels equals $-10 \log_{10} \eta = 10 \log_{10}(1 + \rho)$;
- (iii) if $N_g = L - 1$ is chosen minimal, then $\eta = \frac{N}{N + L - 1}$ is strictly increasing in N for $L \geq 2$, and $\eta \rightarrow 1$ as $N \rightarrow \infty$.

Proof. (i) Dividing numerator and denominator of $\frac{N}{N + N_g}$ by $N > 0$ gives $\frac{1}{1 + N_g/N} = \frac{1}{1 + \rho}$; and $1 - \frac{1}{1 + \rho} = \frac{1 + \rho - 1}{1 + \rho} = \frac{\rho}{1 + \rho}$, which, multiplying top and bottom by N , becomes $\frac{N_g}{N + N_g}$.

(ii) By (i), $-10 \log_{10} \eta = -10 \log_{10} \frac{1}{1 + \rho} = 10 \log_{10}(1 + \rho)$.

(iii) Consider $g(N) = \frac{N}{N + L - 1}$ as a function of the real variable $N > 0$, with $L \geq 2$ fixed. Then

$$g'(N) = \frac{(N + L - 1) \cdot 1 - N \cdot 1}{(N + L - 1)^2} = \frac{L - 1}{(N + L - 1)^2} > 0,$$

because $L - 1 \geq 1$: hence g is strictly increasing, and in particular so is the sequence of its values at the integers. Finally $g(N) = \frac{1}{1 + (L - 1)/N} \rightarrow \frac{1}{1} = 1$ as $N \rightarrow \infty$, because $(L - 1)/N \rightarrow 0$. $\square$

Example 27.3: A block of length 2048 with guard 144, computed twice. Take $N = 2048$ and $N_g = 144$, that is $\rho = \frac{144}{2048} = \frac{9}{128}$.

Table 27.2: Efficiency loss due to the cyclic prefix (Proposition 27.3). The values depend only on the ratio $\rho = N_g/N$: the first four rows collect the most commonly used fractions, the last three show that, at fixed dispersion, lengthening the block reduces the loss. All numbers were recomputed with an independent script.

N	N_g	$\rho = N_g/N$	η	loss	loss (dB)
4	1	1/4	0.8000000	20.000000%	0.969100
8	2	1/4	0.8000000	20.000000%	0.969100
64	8	1/8	0.8888889	11.111111%	0.511525
256	16	1/16	0.9411765	5.882353%	0.263289
1024	32	1/32	0.9696970	3.030303%	0.133640
256	16	1/16	0.9411765	5.882353%	0.263289
1024	16	1/64	0.9846154	1.538462%	0.067334
2048	16	1/128	0.9922481	0.775194%	0.033797

First route, closed formula. By Proposition 27.3(i),

$$\eta = \frac{2048}{2048 + 144} = \frac{2048}{2192} = \frac{128}{137} = 0.9343066\dots,$$

having simplified by 16 ($2048 = 16 \cdot 128$, $2192 = 16 \cdot 137$). The loss is $1 - \eta = \frac{9}{137} = 0.0656934\dots$, that is 6.569343%; in decibels, $10 \log_{10} \frac{137}{128} = 10 \log_{10} 1.0703125 = 0.2951058$ dB.

Second route, script. A script that computes η , $1 - \eta$ and $-10 \log_{10} \eta$ for a list of pairs (N, N_g) returns, for this pair, $\eta = 0.9343065693$, loss 0.0656934307, that is 6.569343%, and 0.295106 dB. ✓

Consistency check. The fraction $\frac{9}{137}$ has decimal expansion 0.06569343065693..., periodic with period 8; the first digits agree with those returned by the script. ✓

Remark 27.11: The trade-off, and why lengthening the block is not enough.

Proposition 27.3(iii) seems to suggest a simple recipe: at fixed dispersion, take N large and the loss vanishes. The suggestion is only half correct, because N appears elsewhere too. The symbol time is $T = NT_s$, so the subcarrier spacing is

$$\Delta f = \frac{1}{T} = \frac{1}{NT_s} :$$

doubling N halves Δf . An absolute frequency error δf (due to an imperfect oscillator or to Doppler effect) then corresponds to a normalised error $\varepsilon = \delta f / \Delta f$ that doubles, and Section 27.6 will show that the power of the intercarrier interference grows like ε^2 : it quadruples. Designing an OFDM system is exactly choosing a balance point between these two opposing pressures — N large to amortise the prefix, N small to tolerate the frequency error — with the prefix length bounded below by Corollary 27.5.

27.6. Carrier frequency offset and intercarrier interference

Observation 27.2 already anticipated the point: the orthogonality of the subcarriers depends on the demodulator reading the spectrum exactly at the points $f = \ell/T$. If the receiver's local oscillator is misaligned by δf hertz, all the reading points shift by the same amount, the zeros of Proposition 27.1 no longer fall where they are needed, and every subcarrier spills energy onto all the others. This section computes exactly how much.

Definition 27.8: Normalised frequency error. Suppose the receiver's oscillator differs from the transmitter's by δf hertz. The received baseband signal is then $e^{2\pi i \delta f t} s(t)$, and at the sampling instants $t_n = nT/N$

$$r[n] = e^{2\pi i \delta f nT/N} s[n] = e^{2\pi i \varepsilon n/N} s[n], \quad n = 0, \dots, N-1,$$

where

$$\varepsilon := \delta f \cdot T = \frac{\delta f}{\Delta f}$$

is called the **normalised frequency error** (*carrier frequency offset*, CFO): it is the error measured in units of subcarrier spacing. The energy that, due to ε , one subcarrier spills onto the others is called **intercarrier interference** (ICI). In this section the channel is assumed ideal, $h = (1)$, in order to isolate the effect of the frequency error alone.

Lemma 27.3: The kernel of the intercarrier interference. Let $\varepsilon \in \mathbb{R} \setminus \mathbb{Z}$ and $m \in \mathbb{Z}$, and set

$$I(m) := \frac{1}{N} \sum_{n=0}^{N-1} e^{2\pi i(m+\varepsilon)n/N}.$$

Then I is periodic of period N in m , and for every m with $|m + \varepsilon| < N$ the closed form holds

$$I(m) = \frac{\sin(\pi\varepsilon)}{N \sin(\pi(m+\varepsilon)/N)} e^{i\pi\varepsilon(1-\frac{1}{N})} e^{-i\pi m/N}$$

and in particular

$$|I(m)| = \frac{|\sin(\pi\varepsilon)|}{N |\sin(\pi(m+\varepsilon)/N)|}, \quad |I(0)| = \frac{|\sin(\pi\varepsilon)|}{N |\sin(\pi\varepsilon/N)|}.$$

Proof. Step 1: periodicity. Substituting $m + N$ for m ,

$$I(m+N) = \frac{1}{N} \sum_{n=0}^{N-1} e^{2\pi i(m+N+\varepsilon)n/N} = \frac{1}{N} \sum_{n=0}^{N-1} e^{2\pi i(m+\varepsilon)n/N} e^{2\pi i n} = I(m),$$

because $e^{2\pi i n} = 1$ for every integer n .

Step 2: the geometric sum. Set $q := e^{2\pi i(m+\varepsilon)/N}$. One has $q = 1$ if and only if $(m+\varepsilon)/N \in \mathbb{Z}$; since $|m+\varepsilon| < N$ by hypothesis, this can happen only if $m+\varepsilon = 0$, that is $\varepsilon = -m \in \mathbb{Z}$, excluded by the hypothesis $\varepsilon \notin \mathbb{Z}$. Hence $q \neq 1$ and the geometric sum formula applies:

$$I(m) = \frac{1}{N} \sum_{n=0}^{N-1} q^n = \frac{1}{N} \cdot \frac{q^N - 1}{q - 1} = \frac{1}{N} \cdot \frac{e^{2\pi i(m+\varepsilon)} - 1}{e^{2\pi i(m+\varepsilon)/N} - 1}.$$

Step 3: the numerator. Since m is an integer, $e^{2\pi i m} = 1$ and hence $e^{2\pi i(m+\varepsilon)} = e^{2\pi i \varepsilon}$. With the identity $e^{i\theta} - 1 = 2i \sin(\theta/2) e^{i\theta/2}$ — verified by factoring out $e^{i\theta/2}$ and using Euler's formula for the sine, as in the corresponding step of the proof of Proposition 27.1 — with $\theta = 2\pi\varepsilon$:

$$e^{2\pi i \varepsilon} - 1 = 2i \sin(\pi\varepsilon) e^{i\pi\varepsilon}.$$

Step 4: the denominator. With the same identity and $\theta = 2\pi(m+\varepsilon)/N$:

$$e^{2\pi i(m+\varepsilon)/N} - 1 = 2i \sin\left(\frac{\pi(m+\varepsilon)}{N}\right) e^{i\pi(m+\varepsilon)/N}.$$

The sine in the denominator is nonzero: it would vanish only if $(m + \varepsilon)/N \in \mathbb{Z}$, already excluded in Step 2.

Step 5: the quotient. Dividing, the factors $2i$ cancel and what remains is

$$I(m) = \frac{1}{N} \cdot \frac{\sin(\pi\varepsilon)}{\sin(\pi(m + \varepsilon)/N)} \cdot e^{i\pi\varepsilon - i\pi(m + \varepsilon)/N}.$$

The exponent can be rewritten

$$\pi\varepsilon - \frac{\pi(m + \varepsilon)}{N} = \pi\varepsilon - \frac{\pi\varepsilon}{N} - \frac{\pi m}{N} = \pi\varepsilon\left(1 - \frac{1}{N}\right) - \frac{\pi m}{N},$$

giving the announced form. The modulus follows because both imaginary exponentials have modulus 1; for $m = 0$ the second formula is obtained. $\square$

Theorem 27.10: Decomposition of the demodulator output in the presence of a frequency error. Let $\varepsilon \in \mathbb{R} \setminus \mathbb{Z}$ and let $r[n] = e^{2\pi i \varepsilon n/N} s[n]$ as in Definition 27.8. Then the demodulator output $\hat{c}_k = \frac{1}{N} \sum_{n=0}^{N-1} r[n] \omega_N^{kn}$ equals

$$\hat{c}_k = \underbrace{I(0) c_k}_{\text{useful signal}} + \underbrace{\sum_{\substack{j=0 \\ j \neq k}}^{N-1} c_j I(j - k)}_{\text{intercarrier interference}}, \quad k = 0, \dots, N-1.$$

The factor $I(0)$ does not depend on k : the frequency error attenuates all the subcarriers by the same amount $|I(0)| \leq 1$ and rotates them all by the same angle $\pi\varepsilon(1 - 1/N)$.

Proof. Substitute Definition 27.2, $s[n] = \sum_{j=0}^{N-1} c_j e^{2\pi i j n/N}$, into the definition of $\hat{c}_k$, recalling that $\omega_N^{kn} = e^{-2\pi i k n/N}$:

$$\hat{c}_k = \frac{1}{N} \sum_{n=0}^{N-1} e^{2\pi i \varepsilon n/N} \left(\sum_{j=0}^{N-1} c_j e^{2\pi i j n/N} \right) e^{-2\pi i k n/N}.$$

The sums are finite and may be exchanged; collecting the exponentials with the same base,

$$\hat{c}_k = \sum_{j=0}^{N-1} c_j \frac{1}{N} \sum_{n=0}^{N-1} e^{2\pi i (j - k + \varepsilon) n/N} = \sum_{j=0}^{N-1} c_j I(j - k),$$

by the definition of I given in Lemma 27.3. Isolating the term $j = k$, which equals $c_k I(0)$, gives the desired decomposition.

For the last statement it suffices to observe that in the closed formula of Lemma 27.3 with $m = 0$ no k appears; and that $|I(0)| \leq 1$ because

$$|I(0)| = \left| \frac{1}{N} \sum_{n=0}^{N-1} e^{2\pi i \varepsilon n/N} \right| \leq \frac{1}{N} \sum_{n=0}^{N-1} |e^{2\pi i \varepsilon n/N}| = \frac{1}{N} \cdot N = 1$$

by the triangle inequality. $\square$

Proposition 27.4: Power conservation: the kernel has norm one. For every $\varepsilon \in \mathbb{R} \setminus \mathbb{Z}$ the exact identity holds

$$\sum_{m=0}^{N-1} |I(m)|^2 = 1.$$

Proof. Set $u[n] := e^{2\pi i \varepsilon n/N}$, $n = 0, \dots, N-1$, and let $U = \mathcal{F}_N u$ be its DFT. By Definition 22.1,

$$U[k] = \sum_{n=0}^{N-1} u[n] \omega_N^{kn} = \sum_{n=0}^{N-1} e^{2\pi i \varepsilon n/N} e^{-2\pi i kn/N} = \sum_{n=0}^{N-1} e^{2\pi i (\varepsilon - k)n/N} = N I(-k),$$

by the definition of I (with $m = -k$). Hence $|I(-k)|^2 = \frac{1}{N^2} |U[k]|^2$. As k ranges over $\{0, \dots, N-1\}$ the index $-k$ runs through a complete system of residues modulo N , and I is N -periodic by Lemma 27.3: hence

$$\sum_{m=0}^{N-1} |I(m)|^2 = \sum_{k=0}^{N-1} |I(-k)|^2 = \frac{1}{N^2} \sum_{k=0}^{N-1} |U[k]|^2.$$

By the discrete Plancherel identity (Theorem 22.6), $\sum_k |U[k]|^2 = N \sum_n |u[n]|^2$; and $|u[n]| = 1$ for every n , so $\sum_n |u[n]|^2 = N$. In conclusion

$$\sum_{m=0}^{N-1} |I(m)|^2 = \frac{1}{N^2} \cdot N \cdot N = 1.$$

□

Corollary 27.6: Signal-to-interference ratio in closed form. Suppose the data $c_0, \dots, c_{N-1}$ have zero mean, are uncorrelated and have equal power, that is $\mathbb{E}[c_j] = 0$ and $\mathbb{E}[c_j \overline{c_{j'}}] = P \delta_{jj'}$. Then, for every k , the power of the useful term and that of the interference in Theorem 27.10 equal

$$\mathbb{E}[|I(0)c_k|^2] = |I(0)|^2 P, \quad \mathbb{E}\left[\left|\sum_{j \neq k} c_j I(j-k)\right|^2\right] = (1 - |I(0)|^2) P,$$

and hence the signal-to-interference ratio does not depend on k and equals

$$\text{SIR}(\varepsilon) = \frac{|I(0)|^2}{1 - |I(0)|^2}, \quad |I(0)|^2 = \left(\frac{\sin(\pi \varepsilon)}{N \sin(\pi \varepsilon/N)} \right)^2$$

Proof. Useful term. $\mathbb{E}[|I(0)c_k|^2] = |I(0)|^2 \mathbb{E}[|c_k|^2] = |I(0)|^2 P$, because $I(0)$ is a deterministic constant.

Interference term. Expanding the squared modulus of the sum,

$$\mathbb{E}\left[\left|\sum_{j \neq k} c_j I(j-k)\right|^2\right] = \sum_{j \neq k} \sum_{j' \neq k} \mathbb{E}[c_j \overline{c_{j'}}] I(j-k) \overline{I(j'-k)} = P \sum_{j \neq k} |I(j-k)|^2,$$

by the uncorrelation hypothesis, which annihilates all terms with $j \neq j'$.

Counting the indices. As j ranges over $\{0, \dots, N-1\}$ the difference $m = j-k$ ranges over the set $\{-k, -k+1, \dots, N-1-k\}$, which consists of N consecutive integers and is therefore a complete system of residues modulo N ; since I is N -periodic (Lemma 27.3), the sum $\sum_{j=0}^{N-1} |I(j-k)|^2$ coincides with $\sum_{m=0}^{N-1} |I(m)|^2$, which equals 1 by Proposition 27.4. Removing the term $j = k$,

which equals $|I(0)|^2$, leaves

$$\sum_{j \neq k} |I(j - k)|^2 = 1 - |I(0)|^2.$$

Conclusion. The ratio of the two powers is $\frac{|I(0)|^2 P}{(1 - |I(0)|^2)^P} = \frac{|I(0)|^2}{1 - |I(0)|^2}$, and does not depend on k ; the expression for $|I(0)|^2$ is that of Lemma 27.3. Note that $|I(0)| < 1$ for $\varepsilon \notin \mathbb{Z}$, otherwise Proposition 27.4 would force every other $|I(m)|$ to vanish, which is false: for instance $|I(1)| \neq 0$ because $\sin(\pi\varepsilon) \neq 0$. $\square$

Proposition 27.5: Behaviour for small frequency errors. *As $\varepsilon \rightarrow 0$ the expansions hold*

$$1 - |I(0)|^2 = \frac{\pi^2 \varepsilon^2}{3} \left(1 - \frac{1}{N^2}\right) + O(\varepsilon^4), \quad \text{SIR}(\varepsilon) \sim \frac{3}{\pi^2 \varepsilon^2 (1 - N^{-2})}.$$

In particular the interference power grows like the square of the frequency error, and for large N , $\text{SIR}(\varepsilon) \approx 3/(\pi\varepsilon)^2$, independent of N .

Proof. Set $a := \pi\varepsilon$ and $f(\varepsilon) := \frac{\sin(\pi\varepsilon)}{N \sin(\pi\varepsilon/N)}$, so that $|I(0)| = |f(\varepsilon)|$ and, for ε close to 0, $f(\varepsilon) > 0$.

Step 1: expansion of numerator and denominator. From the Taylor expansion $\sin x = x - \frac{x^3}{6} + O(x^5)$ one gets

$$\begin{aligned} \sin(\pi\varepsilon) &= a - \frac{a^3}{6} + O(a^5) = a \left(1 - \frac{a^2}{6} + O(a^4)\right), \\ N \sin\left(\frac{a}{N}\right) &= N \left(\frac{a}{N} - \frac{a^3}{6N^3} + O(a^5)\right) = a \left(1 - \frac{a^2}{6N^2} + O(a^4)\right). \end{aligned}$$

Step 2: the quotient. The factors a cancel (for $a \neq 0$) and, using $\frac{1}{1-u} = 1 + u + O(u^2)$ with $u = \frac{a^2}{6N^2} + O(a^4)$,

$$f = \left(1 - \frac{a^2}{6} + O(a^4)\right) \left(1 + \frac{a^2}{6N^2} + O(a^4)\right) = 1 - \frac{a^2}{6} \left(1 - \frac{1}{N^2}\right) + O(a^4).$$

Step 3: the square. Squaring and neglecting terms of order a^4 ,

$$f^2 = 1 - \frac{a^2}{3} \left(1 - \frac{1}{N^2}\right) + O(a^4), \quad 1 - f^2 = \frac{a^2}{3} \left(1 - \frac{1}{N^2}\right) + O(a^4).$$

Substituting $a = \pi\varepsilon$ gives the first formula.

Step 4: the asymptotic equivalence. By Corollary 27.6, $\text{SIR} = \frac{f^2}{1-f^2}$. Since $f^2 \rightarrow 1$ as $\varepsilon \rightarrow 0$ and $1 - f^2 \sim \frac{\pi^2 \varepsilon^2}{3} (1 - N^{-2})$,

$$\text{SIR}(\varepsilon) \cdot \frac{\pi^2 \varepsilon^2 (1 - N^{-2})}{3} = f^2 \cdot \frac{\pi^2 \varepsilon^2 (1 - N^{-2})/3}{1 - f^2} \rightarrow 1 \cdot 1 = 1,$$

which is the announced equivalence. Finally, for large N , $1 - N^{-2} \rightarrow 1$. $\square$

Remark 27.12: What these numbers say. Table 27.3 should be read together with Corollary 27.4. If thermal noise already produces an SNR of, say, 20 dB, then a frequency error of $\varepsilon = 0.05$ — that is, five per cent of the subcarrier spacing — adds an interference of the same order and, in practice, halves the useful ratio: the frequency error alone becomes the limiting factor. Two design consequences follow from this. The first is that

Table 27.3: Signal-to-interference ratio in the presence of a frequency error (Corollary 27.6), for $N = 64$, compared with the approximation of Proposition 27.5. The values in the middle column are the exact closed formula; those in the last column the asymptotic estimate. Both columns were recomputed with an independent script, which also verified $\sum_m |I(m)|^2 = 1$ up to 10^{-15} .

ε	$ I(0) ^2$	SIR	SIR (dB)	asympt. estimate (dB)
0.01	0.9996711	3 039.778	34.8284	34.8293
0.02	0.9986851	759.494	28.8052	28.8087
0.05	0.9918043	121.016	20.8284	20.8499
0.10	0.9675390	29.806	14.7431	14.8293
0.15	0.9281520	12.918	11.1120	11.3075
0.20	0.8751683	7.011	8.4577	8.8087
0.25	0.8106102	4.280	6.3146	6.8705

Figure 27.4: The signal-to-interference ratio as a function of the normalised frequency error, for $N = 64$ (Corollary 27.6). The ordinates are the exact values $10 \log_{10} \frac{|I(0)|^2}{1-|I(0)|^2}$ computed with step 0.005 up to $\varepsilon = 0.10$ and 0.01 beyond; the marked point corresponds to the third row of Table 27.3. The curve drops by about 6 dB for every doubling of ε , as predicted by Proposition 27.5: from 28.81 dB at $\varepsilon = 0.02$ to 22.77 dB at $\varepsilon = 0.04$, that is 6.0309 dB of difference.

every OFDM receiver contains an estimator of ε and a corrector that multiplies the received samples by $e^{-2\pi i \varepsilon n/N}$ before the FFT; the estimation algorithms are not treated here and are found in Cho, Kim, Yang and Kang, *MIMO-OFDM Wireless Communications with MATLAB*, Chapter 5 “Synchronization for OFDM”, pp. 153–185. The second is the one already anticipated in Observation 27.11: since $\varepsilon = \delta f N T_s$, for the same absolute error δf a block twice as long doubles ε and quadruples the interference power, that is, it loses about 6 dB of SIR.

27.7. Peak-to-average power ratio

The OFDM signal is a sum of N exponentials. At most instants the phases are scattered and the sum is modest; but there are instants at which they all line up, and then the amplitude is N times that of a single subcarrier while the average power is only N times that of one subcarrier: the peak-to-average ratio equals N . This is the structural flaw of OFDM, because a power amplifier that must stay linear up to the peak works, for almost all of the time, far below its own capacity.

Definition 27.9: Peak-to-average power ratio (PAPR). Let $s \in \mathbb{C}^N$ be nonzero. The peak-to-average power ratio (PAPR) of the sample sequence is

$$\text{PAPR}(s) = \frac{\max_{0 \leq n \leq N-1} |s[n]|^2}{\frac{1}{N} \sum_{n=0}^{N-1} |s[n]|^2},$$

and that of the continuous-time signal $s(t)$ of Definition 27.2 is

$$\text{PAPR}_c(s) = \frac{\sup_{t \in [0, T)} |s(t)|^2}{\frac{1}{T} \int_0^T |s(t)|^2 dt}.$$

Both are often expressed in decibels, as $10 \log_{10} \text{PAPR}$.

Lemma 27.4: The average power, in both versions, equals $\sum_k |c_k|^2$. Let s be the OFDM symbol associated with the data $c \in \mathbb{C}^N$. Then

$$\frac{1}{N} \sum_{n=0}^{N-1} |s[n]|^2 = \sum_{k=0}^{N-1} |c_k|^2 = \frac{1}{T} \int_0^T |s(t)|^2 dt.$$

The two average powers — the one computed on the samples and the one computed on the integral — coincide, and equal the sum of the data powers.

Proof. Discrete version. By Theorem 27.4, $S := \mathcal{F}_N s = Nc$, that is $|S[k]|^2 = N^2 |c_k|^2$. The discrete Plancherel identity (Theorem 22.6, second formula) gives

$$\sum_{n=0}^{N-1} |s[n]|^2 = \frac{1}{N} \sum_{k=0}^{N-1} |S[k]|^2 = \frac{1}{N} \sum_{k=0}^{N-1} N^2 |c_k|^2 = N \sum_{k=0}^{N-1} |c_k|^2,$$

and dividing by N gives the first equality.

Continuous version. Expanding the squared modulus and exchanging finite sums with the integral,

$$\begin{aligned}\int_0^T |s(t)|^2 dt &= \int_0^T \left(\sum_k c_k \phi_k(t) \right) \overline{\left(\sum_\ell c_\ell \phi_\ell(t) \right)} dt \\ &= \sum_k \sum_\ell c_k \bar{c}_\ell \int_0^T \phi_k(t) \bar{\phi}_\ell(t) dt = \sum_k \sum_\ell c_k \bar{c}_\ell \langle \phi_k, \phi_\ell \rangle_T.\end{aligned}$$

By Theorem 27.1 (with $\Delta f = 1/T$, that is $\Delta f T = 1$ a positive integer), $\langle \phi_k, \phi_\ell \rangle_T = T \delta_{k\ell}$: only the terms with $\ell = k$ survive, and

$$\int_0^T |s(t)|^2 dt = T \sum_k c_k \bar{c}_k = T \sum_k |c_k|^2.$$

Dividing by T gives the second equality. $\square$

Theorem 27.11: The worst case: the PAPR does not exceed N , and N is attained. Let $c \in \mathbb{C}^N$ be nonzero and let s be the associated OFDM symbol. Then

$$1 \leq \text{PAPR}(s) \leq \frac{\left(\sum_{k=0}^{N-1} |c_k| \right)^2}{\sum_{k=0}^{N-1} |c_k|^2} \leq N,$$

and $\text{PAPR}(s) = N$ if and only if there exist $A > 0$, $\theta \in \mathbb{R}$ and $n_0 \in \{0, \dots, N-1\}$ such that

$$c_k = A e^{i\theta} \omega_N^{kn_0} = A e^{i\theta} e^{-2\pi i k n_0 / N} \quad \text{for every } k = 0, \dots, N-1.$$

In that case the peak is attained at the instant t_{n_0} and equals $|s[n_0]| = NA$.

Proof. Write $\mu := \frac{1}{N} \sum_n |s[n]|^2 = \sum_k |c_k|^2 > 0$, by Lemma 27.4 and because $c \neq 0$.

Step 1: the left-hand inequality. The maximum of a finite family of real numbers is never less than their arithmetic mean: $\max_n |s[n]|^2 \geq \frac{1}{N} \sum_n |s[n]|^2 = \mu$. Dividing by $\mu > 0$ gives $\text{PAPR}(s) \geq 1$.

Step 2: the numerator, via the triangle inequality. For every n ,

$$|s[n]| = \left| \sum_{k=0}^{N-1} c_k e^{2\pi i k n / N} \right| \leq \sum_{k=0}^{N-1} |c_k| |e^{2\pi i k n / N}| = \sum_{k=0}^{N-1} |c_k|,$$

since every imaginary exponential has modulus 1. Taking the maximum over n and squaring,

$$\max_n |s[n]|^2 \leq \left(\sum_k |c_k| \right)^2. \quad (27.3)$$

Dividing by $\mu = \sum_k |c_k|^2$ gives the middle inequality.

Step 3: Cauchy-Schwarz. Applying the Cauchy-Schwarz inequality in $\mathbb{R}^N$ to the vectors $(|c_0|, \dots, |c_{N-1}|)$ and $(1, 1, \dots, 1)$,

$$\sum_{k=0}^{N-1} |c_k| \cdot 1 \leq \sqrt{\sum_{k=0}^{N-1} |c_k|^2} \sqrt{\sum_{k=0}^{N-1} 1^2} = \sqrt{N} \sqrt{\sum_k |c_k|^2}, \quad (27.4)$$

whence, squaring, $\left(\sum_k |c_k| \right)^2 \leq N \sum_k |c_k|^2 = N\mu$. Dividing by μ gives the right-hand inequality, and with it $\text{PAPR}(s) \leq N$.

Step 4: the condition is sufficient. Suppose $c_k = Ae^{i\theta}\omega_N^{kn_0}$ with $A > 0$. Then, recalling $\omega_N^{kn_0} = e^{-2\pi i kn_0/N}$,

$$s[n_0] = \sum_{k=0}^{N-1} A e^{i\theta} e^{-2\pi i kn_0/N} e^{2\pi i kn_0/N} = A e^{i\theta} \sum_{k=0}^{N-1} 1 = N A e^{i\theta},$$

hence $|s[n_0]|^2 = N^2 A^2$; and $\mu = \sum_k |c_k|^2 = N A^2$. Therefore $\text{PAPR}(s) \geq \frac{N^2 A^2}{N A^2} = N$, and by Step 3 $\text{PAPR}(s) \leq N$: the two inequalities give equality.

Step 5: the condition is necessary. Suppose $\text{PAPR}(s) = N$. Then both inequalities (27.3) and (27.4) are equalities.

From (27.4): equality in the Cauchy–Schwarz inequality holds if and only if the two vectors are proportional; since the second is $(1, \dots, 1)$, there exists $A \geq 0$ with $|c_k| = A$ for every k , and $A > 0$ because $c \neq 0$.

From (27.3): let n_0 be an index at which the maximum is attained. Then

$$\left| \sum_{k=0}^{N-1} c_k e^{2\pi i kn_0/N} \right| = \sum_{k=0}^{N-1} |c_k| = \sum_{k=0}^{N-1} |c_k e^{2\pi i kn_0/N}|,$$

that is, there is equality in the triangle inequality for the family of nonzero complex numbers $z_k := c_k e^{2\pi i kn_0/N}$ (nonzero because $|z_k| = |c_k| = A > 0$). This occurs if and only if all the z_k have the same argument: there exists θ such that $z_k = |z_k| e^{i\theta} = A e^{i\theta}$ for every k . Solving for c_k ,

$$c_k = A e^{i\theta} e^{-2\pi i kn_0/N} = A e^{i\theta} \omega_N^{kn_0},$$

which is the announced form. The peak value is $|s[n_0]| = |N e^{i\theta} A| = N A$. $\square$

Corollary 27.7: The worst case in decibels. *The maximum PAPR, expressed in decibels, equals $10 \log_{10} N$: it grows by 3.0103 dB for every doubling of N . For $N = 4, 8, 64, 2048$ it equals, respectively, 6.0206, 9.0309, 18.0618 and 33.1133 dB.*

Proof. The maximum value is N by Theorem 27.11, and its expression in decibels is $10 \log_{10} N$ by definition. Doubling N gives $10 \log_{10}(2N) - 10 \log_{10} N = 10 \log_{10} 2 = 3.0103\dots$ The four numerical values are obtained with $\log_{10} 4 = 2 \log_{10} 2 = 0.60206$, $\log_{10} 8 = 3 \log_{10} 2 = 0.90309$, $\log_{10} 64 = 6 \log_{10} 2 = 1.80618$ and $\log_{10} 2048 = 11 \log_{10} 2 = 3.311330$, with $\log_{10} 2 = 0.3010300$. A script that computes $10 \log_{10} N$ for the same four values returns 6.020600, 9.030900, 18.061800 and 33.113300. $\checkmark$ $\square$

Example 27.4: The two extremes, realised. Both extremes of Theorem 27.11 are attained by QPSK data vectors, that is, with $c_k \in \{1, i, -1, -i\}$.

The worst case, $N = 4$. Let $c = (1, i, -1, -i)$, that is $c_k = i^k$. Since $i = e^{2\pi i/4} = \omega_4^{-1} = \omega_4^3$, one has $c_k = \omega_4^{3k}$, which is the form of Theorem 27.11 with $A = 1$, $\theta = 0$ and $n_0 = 3$. Hence the PAPR equals 4 and the peak falls at $n_0 = 3$. Indeed the direct computation (Section 27.8) gives $s = (0, 0, 0, 4)$: three zero samples and one equal to $NA = 4$. The PAPR is $\frac{16}{\frac{1}{4} \cdot 16} = \frac{16}{4} = 4 = N$, that is 6.0206 dB. $\checkmark$

The best case, $N = 8$. Let $c = (1, i, -1, 1, -1, i, 1, 1)$. The direct computation (Section 27.9) gives

$$s = (2 + 2i, 2 - 2i, -2 - 2i, 2 + 2i, -2 - 2i, 2 - 2i, 2 + 2i, 2 + 2i),$$

hence $|s[n]|^2 = 4 + 4 = 8$ for every n : the modulus is constant. The average power is 8, the peak is 8, and $\text{PAPR}(s) = 1$, that is 0 dB: the minimum possible by Step 1 of Theorem 27.11. $\checkmark$

What the comparison shows. The PAPR does not depend on the constellation but on the particular word transmitted: the same four QPSK symbols, arranged differently, give 6.02 dB in one case and 0 dB in the other. It is exactly this dependence on the data that PAPR-reduction techniques exploit.

Proposition 27.6: *The PAPR of the continuous signal is not smaller than that of the samples. For every $c \neq 0$, $\text{PAPR}_c(s) \geq \text{PAPR}(s)$.*

Proof. By Lemma 27.4 the two ratios have the same denominator, $\sum_k |c_k|^2$. As for the numerators, the sampling instants $t_0, \dots, t_{N-1}$ belong to the interval $[0, T)$, hence

$$\sup_{t \in [0, T)} |s(t)|^2 \geq \max_{0 \leq n \leq N-1} |s(t_n)|^2 = \max_{0 \leq n \leq N-1} |s[n]|^2,$$

because the supremum over a set is not less than the maximum over a subset of it. Dividing by the common, positive, denominator concludes the proof. $\square$

The question that really matters in practice remains: how *likely* is a high PAPR, if the data are random? The exact answer is not known in closed form; an estimate valid under a hypothesis that must be stated is available, and that is what is done here.

Proposition 27.7: *Distribution of the PAPR under the Gaussian hypothesis (G).*

Assume **hypothesis (G)**: the samples $s[0], \dots, s[N-1]$ are independent random variables, each a circularly symmetric complex Gaussian of zero mean and power $\mu > 0$, that is $s[n] = x_n + iy_n$ with x_n, y_n independent and Gaussian with zero mean and variance $\mu/2$. Set

$$\Gamma := \frac{\max_{0 \leq n \leq N-1} |s[n]|^2}{\mu}.$$

Then, for every $\gamma \geq 0$,

$$\Pr(\Gamma \leq \gamma) = (1 - e^{-\gamma})^N, \quad \Pr(\Gamma > \gamma) = 1 - (1 - e^{-\gamma})^N.$$

Proof. Step 1: the law of $|s[n]|^2$. The joint density of (x_n, y_n) , the product of two independent Gaussian densities of variance $\mu/2$, is

$$p(x, y) = \frac{1}{\sqrt{2\pi \cdot \frac{\mu}{2}}} e^{-x^2/\mu} \cdot \frac{1}{\sqrt{2\pi \cdot \frac{\mu}{2}}} e^{-y^2/\mu} = \frac{1}{\pi\mu} e^{-(x^2+y^2)/\mu}.$$

For $u \geq 0$, switching to polar coordinates $x = r \cos \vartheta$, $y = r \sin \vartheta$, with area element $r dr d\vartheta$,

$$\Pr(|s[n]|^2 > u) = \iint_{x^2+y^2 > u} p(x, y) dx dy = \int_0^{2\pi} \int_{\sqrt{u}}^{\infty} \frac{r}{\pi\mu} e^{-r^2/\mu} dr d\vartheta = \frac{2\pi}{\pi\mu} \int_{\sqrt{u}}^{\infty} r e^{-r^2/\mu} dr.$$

The antiderivative of $r e^{-r^2/\mu}$ is $-\frac{\mu}{2} e^{-r^2/\mu}$, hence

$$\Pr(|s[n]|^2 > u) = \frac{2}{\mu} \left[-\frac{\mu}{2} e^{-r^2/\mu} \right]_{\sqrt{u}}^{\infty} = \frac{2}{\mu} \cdot \frac{\mu}{2} e^{-u/\mu} = e^{-u/\mu}.$$

The squared modulus is thus an exponential random variable of mean μ , and $\Pr(|s[n]|^2 \leq u) = 1 - e^{-u/\mu}$.

Step 2: the maximum of independent variables. The event $\{\Gamma \leq \gamma\}$ coincides with $\bigcap_{n=0}^{N-1} \{|s[n]|^2 \leq \gamma\mu\}$: the maximum does not exceed $\gamma\mu$ if and only if none of the terms

exceeds it. By the independence postulated by hypothesis (G) the probability of the intersection is the product of the probabilities, and by Step 1 each factor equals $1 - e^{-\gamma\mu/\mu} = 1 - e^{-\gamma}$. Hence

$$\Pr(\Gamma \leq \gamma) = \prod_{n=0}^{N-1} (1 - e^{-\gamma}) = (1 - e^{-\gamma})^N,$$

and the second formula is the complement to 1 of the first. $\square$

Table 27.4: Probability that the PAPR exceeds a threshold γ , *under hypothesis (G)* of Proposition 27.7: $1 - (1 - e^{-\gamma})^N$ with $\gamma = 10^{\gamma_{\text{dB}}/10}$. The values were computed with a script. Compare them with the worst case of Corollary 27.7: for $N = 2048$ the theoretical maximum is 33.11 dB, but the threshold exceeded about once in four thousand is already at 12 dB. What in this table is proved and what is imported is stated in Observation 27.13.

N	Pr(PAPR > γ) under (G)		
	$\gamma = 8$ dB	$\gamma = 10$ dB	$\gamma = 12$ dB
64	$1.0998 \cdot 10^{-1}$	$2.9014 \cdot 10^{-3}$	$8.3767 \cdot 10^{-6}$
256	$3.7252 \cdot 10^{-1}$	$1.1555 \cdot 10^{-2}$	$3.3506 \cdot 10^{-5}$
2048	$9.7597 \cdot 10^{-1}$	$8.8789 \cdot 10^{-2}$	$2.6802 \cdot 10^{-4}$

Proposition 27.8: *The samples are uncorrelated, but not independent.* Let $N \geq 2$ and let $c_0, \dots, c_{N-1}$ have zero mean, be uncorrelated and have equal power P , that is $\mathbb{E}[c_k] = 0$ and $\mathbb{E}[c_k \bar{c}_\ell] = P\delta_{k\ell}$. Then

$$\mathbb{E}[s[n]] = 0, \quad \mathbb{E}[s[n] \overline{s[m]}] = NP\delta_{nm} :$$

the samples have zero mean, are uncorrelated and have equal power NP .

Suppose further that the c_k are independent and uniform on a constant-modulus constellation $\{Ae^{2\pi i j/q} : j = 0, \dots, q-1\}$ with $A > 0$ and $q \geq 2$ (for instance BPSK with $q = 2$ or QPSK with $q = 4$). Then the samples $s[0], \dots, s[N-1]$ are not independent.

Proof. Step 1: mean and covariance. The mean is zero by linearity: $\mathbb{E}[s[n]] = \sum_k \mathbb{E}[c_k] \omega_N^{-kn} = 0$. For the covariance,

$$\mathbb{E}[s[n] \overline{s[m]}] = \sum_{k=0}^{N-1} \sum_{\ell=0}^{N-1} \mathbb{E}[c_k \bar{c}_\ell] \omega_N^{-kn} \overline{\omega_N^{-\ell m}} = P \sum_{k=0}^{N-1} \omega_N^{-kn} \omega_N^{km} = P \sum_{k=0}^{N-1} \omega_N^{k(m-n)},$$

where the uncorrelation hypothesis was used, annihilating the terms with $\ell \neq k$, and $\overline{\omega_N^{-\ell m}} = \omega_N^{\ell m}$. By Lemma 22.1 the last sum equals N if $N \mid (m-n)$, that is — since $n, m \in \{0, \dots, N-1\}$ — if and only if $n = m$, and 0 otherwise. It follows that $\mathbb{E}[s[n] \overline{s[m]}] = NP\delta_{nm}$, and in particular $\mathbb{E}[|s[n]|^2] = NP = NA^2$, since for a constant-modulus constellation $P = \mathbb{E}[|c_k|^2] = A^2$.

Step 2: the sum of squared moduli is deterministic. By Lemma 27.4, for every realisation of the data,

$$\sum_{n=0}^{N-1} |s[n]|^2 = N \sum_{k=0}^{N-1} |c_k|^2 = N \cdot NA^2 = N^2 A^2,$$

because $|c_k| = A$ for every k and for every realisation. The random variable $\sum_n |s[n]|^2$ is thus constant, and its variance is zero.

Step 3: the contradiction. Suppose, for contradiction, that $s[0], \dots, s[N-1]$ are independent. Then so are the real variables $|s[0]|^2, \dots, |s[N-1]|^2$, being measurable functions of independent variables; and they have finite variance, because they take finitely many values (the

constellation is finite). By the formula for the variance of a sum of independent variables,

$$0 = \text{Var} \left(\sum_{n=0}^{N-1} |s[n]|^2 \right) = \sum_{n=0}^{N-1} \text{Var} (|s[n]|^2).$$

Being a sum of nonnegative terms equal to zero, every term is zero: hence each $|s[n]|^2$ is almost surely equal to its own mean, which by Step 1 equals NA^2 .

But this is false. The realisation $c_0 = c_1 = \dots = c_{N-1} = A$ has probability $q^{-N} > 0$, and for it

$$s[0] = \sum_{k=0}^{N-1} A \cdot 1 = NA, \quad |s[0]|^2 = N^2 A^2,$$

while $N^2 A^2 \neq NA^2$ because $N \geq 2$ and $A > 0$. The variable $|s[0]|^2$ thus takes, with positive probability, a value different from NA^2 , contradicting what was just deduced. The independence hypothesis is absurd. $\square$

Remark 27.13: What is imported on the statistics of the PAPR. Proposition 27.7 is proved in full, but under hypothesis (G); and Proposition 27.8 proves that hypothesis (G) is false for a real OFDM system: the samples are uncorrelated, not independent, and they are not Gaussian, because they take finitely many values. The formula $1 - (1 - e^{-\gamma})^N$ of Table 27.4 is therefore, in this treatise, **imported** as an approximation, not proved as a theorem. What is missing is stated precisely.

First, Gaussianity. For large N the sum $s[n] = \sum_k c_k e^{2\pi i k n / N}$ has many independent, bounded terms, and a central limit theorem makes it a complex Gaussian in the limit $N \rightarrow \infty$. But a limit theorem controls the convergence of the distribution in the bulk, not necessarily in the tail, and it is precisely the tail — probabilities of order 10^{-4} and smaller — that is needed in Table 27.4. An estimate with explicit control of the tail error requires concentration inequalities (for instance of Berry–Esseen type or large deviations) that are not developed here.

Second, independence. Proposition 27.8 shows that the samples are only uncorrelated. For jointly Gaussian variables, uncorrelation and independence coincide, but the samples are not jointly Gaussian: the implication does not apply, and the step from the maximum of dependent variables to the product of the marginal probabilities (Step 2 of Proposition 27.7) is not justified.

Third, the continuous signal. Proposition 27.6 proves only the inequality $\text{PAPR}_c \geq \text{PAPR}$. By how much it is larger — that is, how much oversampling is needed for the samples to capture the true peak, with the practical rule of thumb of a factor of four — is an experimental and asymptotic result that is neither proved nor used in any proof here.

Source of what is imported. Y. S. Cho, J. Kim, W. Y. Yang, C. G. Kang, *MIMO-OFDM Wireless Communications with MATLAB*, Wiley, 2010, Chapter 7 “PAPR Reduction”, pp. 209–250, where the tail formula, the Gaussian hypothesis and the practical oversampling rule are presented together. All the statements of this section that do not depend on (G) — Lemma 27.4, Theorem 27.11, Corollary 27.7, Propositions 27.6 and 27.8 — are instead proved here in full, and depend on nothing imported.

27.8. The example $N = 4$, worked out in full

The whole chain is now traced through on a case small enough to be worked by hand at every step, and rich enough to show every phenomenon. The data are

$$N = 4, \quad c = (1, i, -1, -i), \quad h = \left(1, \frac{1}{2}\right), \quad L = 2, \quad N_g = 1.$$

The choice $N_g = 1$ is the minimum allowed by Corollary 27.5, since $L - 1 = 1$.

27.8.1 The modulator, in exact symbolic form

Since $N = 4$ one has $e^{2\pi i k n / 4} = i^{kn}$ and, since $c_k = i^k$,

$$s[n] = \sum_{k=0}^3 c_k e^{2\pi i k n / 4} = \sum_{k=0}^3 i^k i^{kn} = \sum_{k=0}^3 (i^{n+1})^k.$$

The last expression is a geometric sum of ratio $q = i^{n+1}$, a fourth root of unity. By Lemma 22.1 it equals 4 if $q = 1$, that is if $4 \mid n + 1$, and 0 otherwise. For $n \in \{0, 1, 2, 3\}$ the only solution is $n = 3$, hence

$$s = (0, 0, 0, 4)$$

The computation can also be done by hand, term by term:

$$\begin{aligned} n = 0 : & \quad 1 + i + i^2 + i^3 = 1 + i - 1 - i = 0, \\ n = 1 : & \quad 1 + i^2 + i^4 + i^6 = 1 - 1 + 1 - 1 = 0, \\ n = 2 : & \quad 1 + i^3 + i^6 + i^9 = 1 - i - 1 + i = 0, \\ n = 3 : & \quad 1 + i^4 + i^8 + i^{12} = 1 + 1 + 1 + 1 = 4. \end{aligned}$$

✓ The two computations agree.

Check with the inverse transform. By Theorem 27.3 one must have $s = 4\mathcal{F}_4^{-1}c$. Applying Definition 22.2 with $\omega_4^{-1} = e^{2\pi i / 4} = i$:

$$4(\mathcal{F}_4^{-1}c)[3] = \sum_{k=0}^3 c_k i^{3k} = 1 + i \cdot (-i) + (-1) \cdot (-1) + (-i) \cdot i = 1 + 1 + 1 + 1 = 4. \quad \checkmark$$

The PAPR. By Lemma 27.4 the average power equals $\sum_k |c_k|^2 = 4$; the peak equals $|s[3]|^2 = 16$; hence $\text{PAPR}(s) = 16/4 = 4 = N$: this is the worst case, and the form $c_k = \omega_4^{3k}$ is exactly the one predicted by Theorem 27.11 with $A = 1$, $\theta = 0$, $n_0 = 3$ (Example 27.4).

27.8.2 The channel and its frequency response

The zero-padding is $h_p = (1, \frac{1}{2}, 0, 0)$, and by Corollary 27.3, with $\omega_4 = e^{-2\pi i / 4} = -i$,

$$H[k] = 1 + \frac{1}{2} \omega_4^k = 1 + \frac{1}{2} (-i)^k,$$

that is

$$H[0] = \frac{3}{2}, \quad H[1] = 1 - \frac{i}{2}, \quad H[2] = \frac{1}{2}, \quad H[3] = 1 + \frac{i}{2},$$

having used $(-i)^0 = 1$, $(-i)^1 = -i$, $(-i)^2 = -1$, $(-i)^3 = i$. The moduli are

$$|H[0]| = \frac{3}{2} = 1.5, \quad |H[1]| = |H[3]| = \sqrt{1 + \frac{1}{4}} = \frac{\sqrt{5}}{2} = 1.1180340, \quad |H[2]| = \frac{1}{2} = 0.5.$$

Note the Hermitian symmetry $H[3] = \overline{H[1]}$, a consequence of h being real (Theorem 22.7).

27.8.3 Cyclic prefix, channel, and the convolution that becomes circular

The transmitted block is, by Definition 27.4 with $N_g = 1$,

$$\tilde{s} = (s[3], s[0], s[1], s[2], s[3]) = (4, 0, 0, 0, 4) \in \mathbb{C}^5.$$

The channel output is $r[n] = \tilde{s}[n] + \frac{1}{2}\tilde{s}[n-1]$, where $\tilde{s}[-1] = p$ is the last sample of the previous block, arbitrary:

$$r = \left(4 + \frac{p}{2}, 0 + \frac{1}{2} \cdot 4, 0, 0, 4 + 0, 0 + \frac{1}{2} \cdot 4\right) = \left(4 + \frac{p}{2}, 2, 0, 0, 4, 2\right).$$

The receiver discards $r[0]$ — the only sample in which p appears, in agreement with Lemma 27.1 — and keeps

$$y = (r[1], r[2], r[3], r[4]) = (2, 0, 0, 4).$$

Note that y does not depend on p : the previous block has been eliminated.

Check: circular convolution. By Theorem 27.5 one must have $y = h_p \circledast s$. Writing the four rows of Definition 22.4 with $x = h_p = (1, \frac{1}{2}, 0, 0)$ and $s = (0, 0, 0, 4)$:

$$\begin{aligned} (h_p \circledast s)[0] &= h_p[0]s[0] + h_p[1]s[3] + h_p[2]s[2] + h_p[3]s[1] = 0 + \frac{1}{2} \cdot 4 + 0 + 0 = 2, \\ (h_p \circledast s)[1] &= h_p[0]s[1] + h_p[1]s[0] + h_p[2]s[3] + h_p[3]s[2] = 0 + 0 + 0 + 0 = 0, \\ (h_p \circledast s)[2] &= h_p[0]s[2] + h_p[1]s[1] + h_p[2]s[0] + h_p[3]s[3] = 0 + 0 + 0 + 0 = 0, \\ (h_p \circledast s)[3] &= h_p[0]s[3] + h_p[1]s[2] + h_p[2]s[1] + h_p[3]s[0] = 4 + 0 + 0 + 0 = 4. \end{aligned}$$

Hence $h_p \circledast s = (2, 0, 0, 4) = y$. ✓

Check: the matrix form. The circulant matrix of Theorem 27.7 is $(C_h)_{mj} = h_p[\langle m-j \rangle_4]$, that is

$$C_h = \begin{pmatrix} 1 & 0 & 0 & \frac{1}{2} \\ \frac{1}{2} & 1 & 0 & 0 \\ 0 & \frac{1}{2} & 1 & 0 \\ 0 & 0 & \frac{1}{2} & 1 \end{pmatrix}, \quad C_h \begin{pmatrix} 0 \\ 0 \\ 0 \\ 4 \end{pmatrix} = \begin{pmatrix} \frac{1}{2} \cdot 4 \\ 0 \\ 0 \\ 1 \cdot 4 \end{pmatrix} = \begin{pmatrix} 2 \\ 0 \\ 0 \\ 4 \end{pmatrix} = y. \quad \checkmark$$

(The first row is obtained from $h_p[\langle 0-j \rangle_4]$ for $j = 0, 1, 2, 3$, that is $h_p[0], h_p[3], h_p[2], h_p[1]$, which equal $1, 0, 0, \frac{1}{2}$.)

27.8.4 Verifying that the channel has become diagonal

Compute $Y = \mathcal{F}_4 y$ with $y = (2, 0, 0, 4)$. By Definition 22.1, $Y[k] = 2\omega_4^0 + 4\omega_4^{3k} = 2 + 4i^k$, having used $\omega_4^3 = (-i)^3 = i$. Hence

$$Y = (6, 2 + 4i, -2, 2 - 4i).$$

On the other hand $S = \mathcal{F}_4 s = 4c = (4, 4i, -4, -4i)$ (Theorem 27.4), and Corollary 27.3 predicts $Y[k] = H[k]S[k]$. Check component by component:

$$\begin{aligned} k=0: & \quad H[0]S[0] = \frac{3}{2} \cdot 4 = 6 & = Y[0] & \checkmark \\ k=1: & \quad H[1]S[1] = (1 - \frac{i}{2})(4i) = 4i - 2i^2 = 2 + 4i & = Y[1] & \checkmark \\ k=2: & \quad H[2]S[2] = \frac{1}{2} \cdot (-4) = -2 & = Y[2] & \checkmark \\ k=3: & \quad H[3]S[3] = (1 + \frac{i}{2})(-4i) = -4i - 2i^2 = 2 - 4i = Y[3] & \checkmark \end{aligned}$$

All four equalities are exact: the channel, which in the time domain mixes the samples (the matrix C_h is not diagonal, it has two nonzero diagonals), has become, in the frequency domain, multiplication by four numbers.

The eigenvalues, and the determinant computed twice. By Theorem 27.7(iii) the eigenvalues of C_h are $\frac{3}{2}, 1 - \frac{i}{2}, \frac{1}{2}, 1 + \frac{i}{2}$. By part (iv),

$$\det C_h = \prod_{k=0}^3 H[k] = \frac{3}{2} \cdot \frac{1}{2} \cdot \left(1 - \frac{i}{2}\right) \left(1 + \frac{i}{2}\right) = \frac{3}{4} \cdot \left(1 + \frac{1}{4}\right) = \frac{3}{4} \cdot \frac{5}{4} = \frac{15}{16} = 0.9375.$$

Independent check, by an algebraic route. The $H[k]$ are the values of the polynomial $p(z) = 1 + \frac{z}{2}$ at the four fourth roots of unity. Hence

$$\prod_{k=0}^3 H[k] = \prod_{z^4=1} \left(1 + \frac{z}{2}\right) = \frac{1}{2^4} \prod_{z^4=1} (2 + z) = \frac{1}{16} \prod_{z^4=1} (-((-2) - z)) = \frac{(-1)^4}{16} \prod_{z^4=1} ((-2) - z).$$

Since $\prod_{z^4=1} (t - z) = t^4 - 1$ for every t (the fourth roots of unity are exactly the roots of $t^4 - 1$), with $t = -2$ one gets $(-2)^4 - 1 = 15$, and $\det C_h = \frac{15}{16} = 0.9375$. ✓ The two computations, by entirely independent routes, give the same number.

Third check, with a script. A numerical computation that builds C_h and takes its determinant with the linear algebra routine returns 0.9375, and the product of the numerical eigenvalues returns $0.9375 - 6.94 \cdot 10^{-17}i$; the discrepancy between Y and $H \cdot S$ is $1.78 \cdot 10^{-15}$, that is zero up to double-precision rounding. ✓

27.8.5 Equalisation

By Definition 27.5, $\hat{c}_k = \frac{Y[k]}{4H[k]}$:

$$\hat{c}_0 = \frac{6}{4 \cdot \frac{3}{2}} = \frac{6}{6} = 1 = c_0,$$

$$\hat{c}_1 = \frac{2 + 4i}{4(1 - \frac{i}{2})} = \frac{2 + 4i}{4 - 2i} = \frac{(2 + 4i)(4 + 2i)}{(4 - 2i)(4 + 2i)} = \frac{8 + 4i + 16i + 8i^2}{16 + 4} = \frac{20i}{20} = i = c_1,$$

$$\hat{c}_2 = \frac{-2}{4 \cdot \frac{1}{2}} = \frac{-2}{2} = -1 = c_2,$$

$$\hat{c}_3 = \frac{2 - 4i}{4(1 + \frac{i}{2})} = \frac{2 - 4i}{4 + 2i} = \frac{(2 - 4i)(4 - 2i)}{20} = \frac{8 - 4i - 16i + 8i^2}{20} = \frac{-20i}{20} = -i = c_3.$$

All four symbols are reconstructed *exactly*, as predicted by Proposition 27.2. ✓

27.8.6 What happens without the cyclic prefix

Repeat the transmission omitting the prefix: only the block $s = (0, 0, 0, 4)$ is sent, and the channel produces $r'[n] = s[n] + \frac{1}{2}s[n-1]$ with $s[-1] = p$ the last sample of the previous block. Then

$$y' = \left(\frac{p}{2}, 0, 0, 4\right).$$

Theorem 27.5 predicts, for the case with the prefix, $y[0] = 2$: the difference $y'[0] - y[0] = \frac{p}{2} - 2$ vanishes *if and only if* $p = 4 = s[3]$, that is if and only if the sample preceding the block is exactly its own tail — which is exactly what the cyclic prefix guarantees. Here is Theorem 27.5's statement seen up close: the prefix adds no information, it *creates the boundary condition* that makes the convolution circular.

Consider the consequences for $p = 0$ (previous block ending with a zero sample). Then $y' = (0, 0, 0, 4)$ and

$$Y'[k] = 4\omega_4^{3k} = 4i^k, \quad Y' = (4, 4i, -4, -4i),$$

whence

$$\hat{c}'_k = \frac{Y'[k]}{4H[k]} : \quad \hat{c}'_0 = \frac{4}{6} = \frac{2}{3} = 0.6666667, \quad \hat{c}'_1 = \frac{4i}{4 - 2i} = \frac{4i(4 + 2i)}{20} = -0.4 + 0.8i,$$

$$\hat{c}'_2 = \frac{-4}{2} = -2, \quad \hat{c}'_3 = \frac{-4i}{4 + 2i} = \frac{-4i(4 - 2i)}{20} = -0.4 - 0.8i.$$

None of the four coincides with the data: $\hat{c}' = (0.667, -0.4 + 0.8i, -2, -0.4 - 0.8i)$ against $c = (1, i, -1, -i)$. ✓ (Also verified with a script: the same four values, with maximum discrepancy $9.80 \cdot 10^{-16}$ against the values computed by hand.)

Warning. Note the most instructive point of the example: the error committed in the time domain concerns *only one* sample ($y'[0]$ instead of $y[0]$), but after the DFT it is spread over *all four* subcarriers. There is no subcarrier “spared” by the absence of the prefix: the transform of a concentrated error is a diffuse error. This is the reason why the guard interval cannot be shortened “just a little”.

Remark 27.14: The balance sheet of the example. Summarising the numbers: four QPSK symbols transmitted over five sampling intervals, that is an efficiency $\eta = \frac{4}{5} = 0.8$ and a loss of 20% (0.9691 dB, Table 27.2); a PAPR of 4, that is 6.0206 dB, which is the maximum possible (Corollary 27.7); a two-tap channel equalised with four complex divisions instead of an inverse filter; and an exact reconstruction. With $\varepsilon = 0.05$ of frequency error, the signal-to-interference ratio would be, by Corollary 27.6 with $N = 4$, $|I(0)|^2 = 0.9923123$ and SIR = 129.0783, that is 21.1085 dB. The next example repeats everything with $N = 8$ and a three-tap channel, where the computations are less trivial and the diagonality is more instructive.

27.9. The example $N = 8$, worked out in full

The whole path is repeated with eight subcarriers and a three-tap channel, where nothing simplifies by symmetry and the diagonality check is genuine. The data are

$$N = 8, \quad c = (1, i, -1, 1, -1, i, 1, 1), \quad h = \left(1, \frac{1}{2}, \frac{1}{4}\right), \quad L = 3, \quad N_g = 2,$$

and $N_g = 2 = L - 1$ is again the minimal choice of Corollary 27.5. Write $\beta := \frac{\sqrt{2}}{2} = 0.7071068$ and recall that $\zeta := e^{2\pi i/8} = \beta(1 + i)$ and $\omega_8 = e^{-2\pi i/8} = \beta(1 - i)$, with

$$\begin{aligned} \zeta^0 &= 1, & \zeta^1 &= \beta(1 + i), & \zeta^2 &= i, & \zeta^3 &= \beta(-1 + i), \\ \zeta^4 &= -1, & \zeta^5 &= \beta(-1 - i), & \zeta^6 &= -i, & \zeta^7 &= \beta(1 - i). \end{aligned}$$

27.9.1 The modulator, in exact symbolic form

By Definition 27.2, $s[n] = \sum_{k=0}^7 c_k \zeta^{kn}$. The first two samples are worked out in full.

Sample $n = 0$. All the ζ^0 equal 1, hence

$$s[0] = \sum_{k=0}^7 c_k = 1 + i - 1 + 1 - 1 + i + 1 + 1 = 2 + 2i.$$

Sample $n = 1$. Here $\zeta^{k \cdot 1} = \zeta^k$, and collecting the terms with β separately from those without:

$$s[1] = \underbrace{1 \cdot 1}_{k=0} + \underbrace{i \beta(1 + i)}_{k=1} + \underbrace{(-1) i}_{k=2} + \underbrace{1 \beta(-1 + i)}_{k=3} + \underbrace{(-1)(-1)}_{k=4} + \underbrace{i \beta(-1 - i)}_{k=5} + \underbrace{1(-i)}_{k=6} + \underbrace{1 \beta(1 - i)}_{k=7}.$$

The terms without β are $1 - i + 1 - i = 2 - 2i$. The terms with β have, for the sum of their coefficients,

$$i(1 + i) + (-1 + i) + i(-1 - i) + (1 - i) = (i - 1) + (-1 + i) + (-i + 1) + (1 - i) = 0,$$

having used $i \cdot i = -1$ and $i \cdot (-i) = 1$. Hence $s[1] = 2 - 2i$.

Proceeding in the same way for the other six samples gives

$$s = (2 + 2i, 2 - 2i, -2 - 2i, 2 + 2i, -2 - 2i, 2 - 2i, 2 + 2i, 2 + 2i)$$

All eight samples have the form $\pm 2 \pm 2i$: the terms with β always cancel. The result was rechecked with a script that computes both the defining sum and $8\mathcal{F}_8^{-1}c$, with maximum discrepancy $6.28 \cdot 10^{-16}$. ✓

The PAPR. One has $|s[n]|^2 = 2^2 + 2^2 = 8$ for every n : the modulus is constant. The average power is $\sum_k |c_k|^2 = 8$ (Lemma 27.4), the peak is 8, hence

$$\text{PAPR}(s) = \frac{8}{8} = 1 = 0 \text{ dB},$$

the minimum possible (Theorem 27.11, Step 1). The same QPSK alphabet that gave the worst case in the example $N = 4$ gives here the best case: the PAPR is a property of the word, not of the constellation (Example 27.4).

27.9.2 The frequency response of the channel

With $h_p = (1, \frac{1}{2}, \frac{1}{4}, 0, 0, 0, 0, 0)$ and $H[k] = 1 + \frac{1}{2}\omega_8^k + \frac{1}{4}\omega_8^{2k}$ (Corollary 27.3), using $\omega_8^2 = -i$, $\omega_8^3 = \beta(-1 - i)$, $\omega_8^4 = -1$, $\omega_8^6 = i$:

$$H[0] = 1 + \frac{1}{2} + \frac{1}{4} = \frac{7}{4} = 1.75,$$

$$H[1] = 1 + \frac{\beta}{2}(1 - i) + \frac{1}{4}(-i) = 1 + \frac{\sqrt{2}}{4} - i\left(\frac{\sqrt{2}}{4} + \frac{1}{4}\right) = 1.3535534 - 0.6035534i,$$

$$H[2] = 1 + \frac{1}{2}(-i) + \frac{1}{4}(-1) = \frac{3}{4} - \frac{1}{2}i = 0.75 - 0.5i,$$

$$H[3] = 1 + \frac{\beta}{2}(-1 - i) + \frac{1}{4}i = 1 - \frac{\sqrt{2}}{4} + i\left(\frac{1}{4} - \frac{\sqrt{2}}{4}\right) = 0.6464466 - 0.1035534i,$$

$$H[4] = 1 - \frac{1}{2} + \frac{1}{4} = \frac{3}{4} = 0.75,$$

and $H[5] = \overline{H[3]}$, $H[6] = \overline{H[2]}$, $H[7] = \overline{H[1]}$ by Hermitian symmetry (Theorem 22.7, applicable because h is real). The squared moduli, in exact form, are

$$|H[0]|^2 = \frac{49}{16}, \quad |H[1]|^2 = |H[7]|^2 = \frac{21}{16} + \frac{5\sqrt{2}}{8}, \quad |H[2]|^2 = |H[6]|^2 = \frac{13}{16},$$

$$|H[3]|^2 = |H[5]|^2 = \frac{21}{16} - \frac{5\sqrt{2}}{8}, \quad |H[4]|^2 = \frac{9}{16}.$$

For instance, for $k = 1$: $(1 + \frac{\sqrt{2}}{4})^2 + (\frac{1}{4} + \frac{\sqrt{2}}{4})^2 = 1 + \frac{\sqrt{2}}{2} + \frac{1}{8} + \frac{1}{16} + \frac{\sqrt{2}}{8} + \frac{1}{8} = \frac{21}{16} + \frac{5\sqrt{2}}{8}$, and for $k = 3$ the sign of $\sqrt{2}$ changes. In decimal form

$$|H[k]| = (1.75, 1.4820201, 0.9013878, 0.6546881, 0.75, 0.6546881, 0.9013878, 1.4820201).$$

The worst subcarrier is the third one (and the fifth): the gap with respect to the best one equals $\frac{49}{21-10\sqrt{2}} = 7.1450815$, that is 8.5400719 dB (Example 27.2).

27.9.3 Cyclic prefix and channel output

The transmitted block, by Definition 27.4 with $N_g = 2$, is $\tilde{s} = (s[6], s[7], s[0], \dots, s[7]) \in \mathbb{C}^{10}$, that is

$$\tilde{s} = (2 + 2i, 2 + 2i, \mid 2 + 2i, 2 - 2i, -2 - 2i, 2 + 2i, -2 - 2i, 2 - 2i, 2 + 2i, 2 + 2i),$$

Figure 27.5: The frequency response of the channel $h = (1, \frac{1}{2}, \frac{1}{4})$ of the example $N = 8$. The grey curve is $|H(\theta)|$ as the frequency varies continuously, computed with step 0.25 in units of subcarrier spacing; the blue segments are the eight samples $|H[k]|$, that is, the moduli of the eigenvalues of the circulant matrix C_h (Theorem 27.7). The subcarrier $k = 3$ and its symmetric counterpart $k = 5$ fall in the minimum and suffer 8.54 dB of disadvantage relative to subcarrier $k = 0$ (Corollary 27.4 and Example 27.2). The value $|H[8]|$ does not exist: the plot is 8-periodic, and $k = 8$ coincides with $k = 0$ (Observation 27.3).

where the bar separates the prefix from the useful block. The channel output is $r[n] = \tilde{s}[n] + \frac{1}{2}\tilde{s}[n-1] + \frac{1}{4}\tilde{s}[n-2]$; assuming for simplicity that the two preceding samples are zero (Lemma 27.1 guarantees that their actual value does not affect the kept samples),

$$r = (2 + 2i, 3 + 3i, \mid 3.5 + 3.5i, 3.5 - 0.5i, -0.5 - 2.5i, 1.5 + 0.5i, \\ -1.5 - 1.5i, 1.5 - 2.5i, 2.5 + 0.5i, 3.5 + 2.5i, \dots).$$

For instance $r[2] = \tilde{s}[2] + \frac{1}{2}\tilde{s}[1] + \frac{1}{4}\tilde{s}[0] = (2+2i) + \frac{1}{2}(2+2i) + \frac{1}{4}(2+2i) = \frac{7}{4}(2+2i) = 3.5+3.5i$, and $r[3] = \tilde{s}[3] + \frac{1}{2}\tilde{s}[2] + \frac{1}{4}\tilde{s}[1] = (2-2i) + \frac{1}{2}(2+2i) + \frac{1}{4}(2+2i) = (2-2i) + (1+i) + (0.5+0.5i) = 3.5-0.5i$. Discarding the first two samples,

$$y = (3.5 + 3.5i, 3.5 - 0.5i, -0.5 - 2.5i, 1.5 + 0.5i, -1.5 - 1.5i, 1.5 - 2.5i, 2.5 + 0.5i, 3.5 + 2.5i).$$

Check: circular convolution. Theorem 27.5 predicts $y = h_p \circledast s$. Check component $m = 0$, the one in which modular wraparound occurs (case (b) of Step 3 of that proof):

$$\begin{aligned} (h_p \circledast s)[0] &= h_p[0]s[0] + h_p[1]s[\langle -1 \rangle_8] + h_p[2]s[\langle -2 \rangle_8] = 1 \cdot s[0] + \frac{1}{2}s[7] + \frac{1}{4}s[6], \\ &= (2 + 2i) + \frac{1}{2}(2 + 2i) + \frac{1}{4}(2 + 2i) = \frac{7}{4}(2 + 2i) = 3.5 + 3.5i = y[0]. \quad \checkmark \end{aligned}$$

And component $m = 2$, where there is no wraparound:

$$\begin{aligned} (h_p \circledast s)[2] &= s[2] + \frac{1}{2}s[1] + \frac{1}{4}s[0] = (-2 - 2i) + \frac{1}{2}(2 - 2i) + \frac{1}{4}(2 + 2i) \\ &= (-2 - 2i) + (1 - i) + (0.5 + 0.5i) = -0.5 - 2.5i = y[2]. \quad \checkmark \end{aligned}$$

A script verified all eight components: maximum discrepancy between y and $h_p \circledast s$ equal to $4.44 \cdot 10^{-16}$. $\checkmark$

27.9.4 Verifying that the channel has become diagonal

Compute $Y = \mathcal{F}_8 y$ and $S = \mathcal{F}_8 s = 8c$. The values of Y , in exact form, contain $2\sqrt{2} = 2.8284271$:

$$\begin{aligned} Y[0] &= 14, & Y[1] &= (2 + 2\sqrt{2}) + i(8 + 2\sqrt{2}), \\ Y[2] &= -6 + 4i, & Y[3] &= (8 - 2\sqrt{2}) + i(2 - 2\sqrt{2}), \\ Y[4] &= -6, & Y[5] &= (2 - 2\sqrt{2}) + i(8 - 2\sqrt{2}), \\ Y[6] &= 6 + 4i, & Y[7] &= (8 + 2\sqrt{2}) + i(2 + 2\sqrt{2}). \end{aligned}$$

The comparison with $H[k]S[k]$, predicted by Corollary 27.3, is in Table 27.5. Three rows are worked out by hand.

$$k = 0: \quad H[0]S[0] = \frac{7}{4} \cdot 8 = 14 = Y[0]. \quad \checkmark$$

$$\begin{aligned} k = 1: \quad H[1]S[1] &= \left(1 + \frac{\sqrt{2}}{4} - i\left(\frac{\sqrt{2}}{4} + \frac{1}{4}\right)\right) \cdot 8i = 8i\left(1 + \frac{\sqrt{2}}{4}\right) + 8\left(\frac{\sqrt{2}}{4} + \frac{1}{4}\right) \\ &= (2\sqrt{2} + 2) + i(8 + 2\sqrt{2}) = Y[1]. \quad \checkmark \end{aligned}$$

$$k = 2: \quad H[2]S[2] = \left(\frac{3}{4} - \frac{1}{2}i\right) \cdot (-8) = -6 + 4i = Y[2]. \quad \checkmark$$

In the computation for $k = 1$, $-i \cdot i = 1$ and $8 \cdot \frac{\sqrt{2}}{4} = 2\sqrt{2}$, $8 \cdot \frac{1}{4} = 2$ were used.

Table 27.5: The explicit check of diagonality for the example $N = 8$ (Corollary 27.3). The column $Y[k]$ is the DFT of the received vector y ; the column $H[k]S[k]$ is the product of the frequency response and the DFT of the transmitted symbol. The two columns agree in all eight rows. The last column is the reconstructed data $\hat{c}_k = Y[k]/(8H[k])$, which reproduces the transmitted data exactly. A script confirmed the two middle columns with maximum discrepancy $9.27 \cdot 10^{-15}$ and the reconstruction with maximum discrepancy $1.12 \cdot 10^{-15}$.

k	$Y[k]$	$H[k]S[k]$	$8H[k]$	$\hat{c}_k = Y[k]/(8H[k])$
0	14	14	14	1
1	$4.8284271 + 10.8284271i$	$4.8284271 + 10.8284271i$	$10.8284271 - 4.8284271i$	i
2	$-6 + 4i$	$-6 + 4i$	$6 - 4i$	-1
3	$5.1715729 - 0.8284271i$	$5.1715729 - 0.8284271i$	$5.1715729 - 0.8284271i$	1
4	-6	-6	6	-1
5	$-0.8284271 + 5.1715729i$	$-0.8284271 + 5.1715729i$	$5.1715729 + 0.8284271i$	i
6	$6 + 4i$	$6 + 4i$	$6 + 4i$	1
7	$10.8284271 + 4.8284271i$	$10.8284271 + 4.8284271i$	$10.8284271 + 4.8284271i$	1

Equalisation, row by row. Rows $k = 3$ and $k = 2$ of Table 27.5 are checked by hand. For $k = 3$, $8H[3] = Y[3]$, because $8H[3] = 8\left(1 - \frac{\sqrt{2}}{4}\right) + 8i\left(\frac{1}{4} - \frac{\sqrt{2}}{4}\right) = (8 - 2\sqrt{2}) + i(2 - 2\sqrt{2}) = Y[3]$; hence $\hat{c}_3 = 1 = c_3$. $\checkmark$ For $k = 2$, $8H[2] = 6 - 4i$ and

$$\hat{c}_2 = \frac{-6 + 4i}{6 - 4i} = \frac{-(6 - 4i)}{6 - 4i} = -1 = c_2. \quad \checkmark$$

The determinant, computed twice. By Theorem 27.7(iv), $\det C_h = \prod_{k=0}^7 H[k]$. The $H[k]$ are the values of the polynomial $p(z) = 1 + \frac{z}{2} + \frac{z^2}{4} = \frac{1}{4}(z^2 + 2z + 4)$ at the eight eighth roots of unity. The roots of $z^2 + 2z + 4$ are $r_{1,2} = -1 \pm i\sqrt{3} = 2e^{\pm 2\pi i/3}$, hence $p(z) = \frac{1}{4}(z - r_1)(z - r_2)$ and

$$\prod_{k=0}^7 H[k] = \prod_{z^8=1} p(z) = \frac{1}{4^8} \prod_{z^8=1} (z - r_1) \prod_{z^8=1} (z - r_2).$$

From $\prod_{z^8=1} (t - z) = t^8 - 1$ it follows that $\prod_{z^8=1} (z - r) = (-1)^8 \prod_{z^8=1} (r - z) = r^8 - 1$. Now $r_1^8 = 2^8 e^{16\pi i/3} = 256 e^{4\pi i/3} = 256\left(-\frac{1}{2} - \frac{\sqrt{3}}{2}i\right) = -128 - 128\sqrt{3}i$, having subtracted 4π from the

argument; hence $r_1^8 - 1 = -129 - 128\sqrt{3}i$ and, conjugating, $r_2^8 - 1 = -129 + 128\sqrt{3}i$. Their product is

$$(-129)^2 + (128\sqrt{3})^2 = 16\,641 + 49\,152 = 65\,793,$$

and $4^8 = 65\,536$, so that

$$\det C_h = \frac{65\,793}{65\,536} = 1.0039215.$$

Independent check. The numerical computation of the determinant of C_h with the linear algebra routine returns 1.0039215088, and the product of the eight numerical eigenvalues returns $1.0039215088 + 9.57 \cdot 10^{-17}i$: both agree with $\frac{65\,793}{65\,536} = 1.00392150878906 \dots \checkmark$

27.9.5 What happens without the cyclic prefix

Now only the block s is transmitted, without a prefix, and the previous block is assumed to end with the two samples $(3, -1 + 2i)$. The channel output changes on the first two samples:

$$y'[0] = s[0] + \frac{1}{2}(-1 + 2i) + \frac{1}{4} \cdot 3 = (2 + 2i) + (-0.5 + i) + 0.75 = 2.25 + 3i,$$

$$y'[1] = s[1] + \frac{1}{2}s[0] + \frac{1}{4}(-1 + 2i) = (2 - 2i) + (1 + i) + (-0.25 + 0.5i) = 2.75 - 0.5i,$$

while $y'[m] = y[m]$ for $m \geq 2$ (Lemma 27.1: only the first $L - 1 = 2$ samples are contaminated). Applying the demodulator and the equalizer anyway gives

$$\begin{aligned} \hat{c}' = & (0.857 - 0.036i, -0.138 + 0.941i, -1.163 - 0.067i, 0.863 - 0.016i, \\ & -1.083 - 0.083i, -0.167 + 0.827i, 0.760 - 0.048i, 0.827 - 0.018i), \end{aligned}$$

against $c = (1, i, -1, 1, -1, i, 1, 1)$. $\checkmark$ (Values obtained with the same script that produced Table 27.5.)

Warning. Two wrong samples out of eight in the time domain produce *eight* wrong symbols out of eight in the frequency domain. The discrepancies $|\hat{c}'_k - c_k|$ equal

$$(0.1473, 0.1502, 0.1768, 0.1375, 0.1179, 0.2400, 0.2451, 0.1735),$$

all of the same order: the largest, 0.2451, is on subcarrier $k = 6$, the smallest, 0.1179, on $k = 4$, and no subcarrier is spared. In terms of rotation, subcarrier $k = 5$ turns out to be rotated by 11.40 degrees and $k = 1$ by 8.35 degrees. This is the same phenomenon as in the example $N = 4$, and it is no accident: the DFT of an error concentrated in a few cells has modulus of the same order at every frequency.

Remark 27.15: The balance sheet of the example $N = 8$. Eight QPSK symbols over ten sampling intervals: $\eta = \frac{8}{10} = 0.8$, a loss of 20%, that is 0.9691 dB (Table 27.2); a PAPR of 1, that is 0 dB, the minimum possible; a three-tap channel reduced to eight complex multiplications; exact reconstruction of all eight symbols. The modulator cost for $N = 8$ is 12 complex multiplications against the 64 of the direct computation (Table 27.1), and with $\varepsilon = 0.05$ of frequency error the signal-to-interference ratio equals 122.9128, that is 20.8960 dB (Corollary 27.6). These are, on a miniature scale, exactly the four numbers that decide the design of a real system.

27.10. Assigned exercises

These are *new* exercises, distinct from the worked ones in Section 27.11. The answers are in the Teacher's Key (Section 27.13).

Exercise 27.1: Sizing the prefix and counting its price. *Goal:* to be able to pass, for a given channel, from the dispersion to the prefix length, and from there to the three numbers that describe the cost — efficiency, percentage loss, loss in decibels — and to the computational cost of the modulator. *Estimated time:* 40 minutes. *Type:* numerical and probative. *Level:* basic–intermediate.

- A channel has $L = 17$ taps. Determine, with Corollary 27.5, the minimal admissible prefix length; then compute η , the percentage loss and the loss in decibels for $N = 256$, using Proposition 27.3. Verify the three numbers with a script.
- Repeat part (a) for $N = 512$ and $N = 1024$, with the same channel. Prove *in general*, and not only for these three values, that doubling N reduces the loss $1 - \eta$ by a factor between 1 and 2, and determine that factor exactly as a function of $\rho = N_g/N$.
- For $N = 512$, compute, with Corollary 27.2, the complex multiplications of the modulator computed from the defining sum, those of the radix-2 FFT, the nontrivial ones, and the ratio between the first two. Compare with Table 27.1.
- With the same channel and the same T_s , going from $N = 256$ to $N = 1024$ gains efficiency; using Observation 27.11 and Proposition 27.5, state how many decibels are instead lost in signal-to-interference ratio for the same absolute frequency error δf , and justify the number.

Exercise 27.2: A four-subcarrier OFDM block, in full. *Goal:* to carry out on paper the whole chain of the chapter, with all the cross-checks called for. *Estimated time:* 45 minutes. *Type:* symbolic and numerical computation. *Level:* remedial–basic. Consider

$$N = 4, \quad c = (1, 1, -1, -1), \quad h = \left(1, -\frac{1}{2}\right), \quad N_g = 1.$$

- Compute s from Definition 27.2, in exact symbolic form, and verify it with Theorem 27.3.
- Compute the PAPR and compare it with the bound of Theorem 27.11; state why the maximum is not attained, identifying which of the two inequalities in the proof is strict.
- Compute $H[0], \dots, H[3]$ and verify the Hermitian symmetry.
- Write $\tilde{s}$, the channel output, the vector y after discarding the prefix, and verify the identity $y = h_p \otimes s$ by writing out the four rows of Definition 22.4 in full.
- Verify Corollary 27.3 on all four components, then equalise with Definition 27.5 and check that $\hat{c} = c$.
- Compute $\det C_h$ in two independent ways, as in Section 27.8.
- Repeat without the prefix, assuming the previous block ends with the sample p . Determine for which value of p the reconstruction remains exact, and compute $\hat{c}'$ for $p = 0$.

Exercise 27.3: Frequency error, and the PAPR of constant-modulus words. *Goal:* to use the closed form of the ICI kernel and the characterisation of the worst PAPR case as computational tools, not only as statements. *Estimated time:* 50 minutes. *Type:* probative and numerical. *Level:* intermediate–advanced.

- Prove, from Lemma 27.3, that $|I(0)|$ is an *even* function of ε , and that $|I(0)| \rightarrow 1$ and $|I(m)| \rightarrow 0$ for $m \neq 0$ as $\varepsilon \rightarrow 0$. Interpret the second limit in light of Theorem 27.10.
- For $N = 16$, compute $|I(0)|^2$, SIR and SIR in decibels for $\varepsilon = 0.02$ and $\varepsilon = 0.08$, with the exact formula of Corollary 27.6; compare with the asymptotic estimate of Proposition 27.5 and comment on which of the two cases the approximation is better

in, and why.

- (c) Let $N = 4$. Compute the PAPR of the four words $(1, 1, 1, 1)$, $(1, -1, 1, -1)$, $(1, i, -1, -i)$ and $(1, 1, 1, -1)$. All four have constant modulus: explain, using Steps 3 and 5 of the proof of Theorem 27.11, why three of them attain the maximum and one does not.
- (d) Prove that, for every N and every n_0 , the word $c_k = \omega_N^{kn_0}$ produces $s = (0, \dots, 0, N, 0, \dots, 0)$ with the only nonzero value in position n_0 ; and deduce that the worst PAPR case corresponds exactly to the OFDM symbols that concentrate all the energy in a single sample.

27.11. Worked exercises

Exercise 27.4: A prefix that is too short, measured. *Type:* numerical computation with cross-check. Take $N = 4$, $c = (1, i, -1, -i)$ and the channel $h = (1, \frac{1}{2}, \frac{1}{4})$, hence $L = 3$, but use a prefix $N_g = 1$, that is one shorter than the minimum required by Corollary 27.5. Compute the error committed, verify that it matches the prediction of Theorem 27.6, and measure the effect on the four reconstructed symbols.

Solution. Strategy. Theorem 27.6 does not merely say that with $N_g \leq L - 2$ the identity can fail: it says *by how much* it fails, namely by $h_{L-1} x[j_0]$ with $j_0 = N_g - (L - 1)$. Here $L - 1 = 2$, $N_g = 1$, hence $j_0 = -1$ and the missing term is $\frac{1}{4} x[-1]$: only component $m = 0$ is wrong, and the error is proportional to the last sample of the previous block. Everything will be computed twice, once by hand and once with a script.

Step 1 — the symbol and the correct circular convolution. As in Section 27.8, $s = (0, 0, 0, 4)$. With $h_p = (1, \frac{1}{2}, \frac{1}{4}, 0)$, the four rows of Definition 22.4 give

$$\begin{aligned} (h_p \otimes s)[0] &= 1 \cdot 0 + \frac{1}{2} \cdot 4 + \frac{1}{4} \cdot 0 + 0 \cdot 0 = 2, \\ (h_p \otimes s)[1] &= 1 \cdot 0 + \frac{1}{2} \cdot 0 + \frac{1}{4} \cdot 4 + 0 \cdot 0 = 1, \\ (h_p \otimes s)[2] &= 1 \cdot 0 + \frac{1}{2} \cdot 0 + \frac{1}{4} \cdot 0 + 0 \cdot 4 = 0, \\ (h_p \otimes s)[3] &= 1 \cdot 4 + \frac{1}{2} \cdot 0 + \frac{1}{4} \cdot 0 + 0 \cdot 0 = 4, \end{aligned} \quad h_p \otimes s = (2, 1, 0, 4).$$

Step 2 — what actually arrives. With $N_g = 1$ the transmitted block is $\tilde{s} = (4, 0, 0, 4)$ and the channel output, calling p_{-1} and p_{-2} the last two samples of the previous block, is

$$\begin{aligned} r[0] &= 4 + \frac{1}{2}p_{-1} + \frac{1}{4}p_{-2}, & r[1] &= 0 + \frac{1}{2} \cdot 4 + \frac{1}{4}p_{-1} = 2 + \frac{1}{4}p_{-1}, \\ r[2] &= 0 + 0 + \frac{1}{4} \cdot 4 = 1, & r[3] &= 0, \\ r[4] &= 4. \end{aligned}$$

Discarding only $r[0]$, what remains is $y = (2 + \frac{1}{4}p_{-1}, 1, 0, 4)$, while the circular convolution gives $(2, 1, 0, 4)$. The difference is

$$y - h_p \otimes s = \left(\frac{1}{4}p_{-1}, 0, 0, 0\right) = (h_{L-1} x[j_0], 0, 0, 0),$$

exactly as predicted by Theorem 27.6, with $h_{L-1} = h_2 = \frac{1}{4}$ and $j_0 = N_g - (L - 1) = -1$. ✓

Step 3 — the effect on the symbols, for $p_{-1} = 4$. Then $y = (3, 1, 0, 4)$. The frequency response is, with $\omega_4 = -i$,

$$H[k] = 1 + \frac{1}{2}(-i)^k + \frac{1}{4}(-1)^k, \quad H = \left(\frac{7}{4}, \frac{3}{4} - \frac{i}{2}, \frac{3}{4}, \frac{3}{4} + \frac{i}{2}\right),$$

and $Y[k] = 3 + (-i)^k + 4i^k$, that is $Y = (8, 3 + 3i, -2, 3 - 3i)$. Equalising:

$$\hat{c}_0 = \frac{8}{7} = 1.1428571, \quad \hat{c}_1 = \frac{3 + 3i}{3 - 2i} = \frac{(3 + 3i)(3 + 2i)}{13} = \frac{3 + 15i}{13} = 0.2307692 + 1.1538462i,$$

$$\hat{c}_2 = \frac{-2}{3} = -0.6666667, \quad \hat{c}_3 = \overline{\hat{c}_1} = 0.2307692 - 1.1538462i.$$

The discrepancies $|\hat{c}_k - c_k|$ equal

$$\left(\frac{1}{7}, \frac{1}{\sqrt{13}}, \frac{1}{3}, \frac{1}{\sqrt{13}}\right) = (0.1428571, 0.2773501, 0.3333333, 0.2773501).$$

(For instance $\hat{c}_1 - c_1 = \frac{3+15i}{13} - i = \frac{3+15i-13i}{13} = \frac{3+2i}{13}$, of modulus $\frac{\sqrt{13}}{13} = \frac{1}{\sqrt{13}}$.)

Independent check 1: the structure of the error. The error in time is the vector $(1, 0, 0, 0)$; its DFT is $(1, 1, 1, 1)$, that is, it has modulus 1 at *every* frequency. Dividing by $4H[k]$ gives errors $\frac{1}{4H[k]} = (\frac{1}{7}, \frac{1}{3-2i}, \frac{1}{3}, \frac{1}{3+2i})$, of moduli $(\frac{1}{7}, \frac{1}{\sqrt{13}}, \frac{1}{3}, \frac{1}{\sqrt{13}})$: the same values computed in Step 3. ✓

Independent check 2: script. A numerical computation that builds the transmitted sequence, convolves it with h , discards the first sample, transforms and equalises returns the same four values and the same four discrepancies, and confirms that for $p_{-1} = 0$ the reconstruction is instead *exact*. ✓

Interpretation. The last check is the most instructive. With $p_{-1} = 0$ everything works, even though the prefix is too short: the missing term is $\frac{1}{4} \cdot 0 = 0$. Theorem 27.6 is stated as an existence claim — *there exist* two transmissions that give different results — and not as a systematic failure, and this example shows why that formulation is necessary: a test run with the previous block set to zero would detect nothing. Note also that the error, concentrated in a single sample in time, hits all four subcarriers, and hits the attenuated ones harder: the worst is $k = 2$, where $|H[2]| = \frac{3}{4}$ is minimal (Corollary 27.4).

Typical mistakes. (1) Forgetting that the channel has *three* taps and writing $r[n] = \tilde{s}[n] + \frac{1}{2}\tilde{s}[n-1]$: the term $\frac{1}{4}$ is lost and with it the whole phenomenon. (2) Discarding $N_g = 2$ samples despite having transmitted only 1 of prefix: the received vector would then have length 3 and the DFT would no longer be a 4-point one. (3) Concluding, from the fact that for $p_{-1} = 0$ the computation works out, that the short prefix is acceptable: this is exactly the conclusion that Theorem 27.6 excludes.

Extension. Redo the computation with $N_g = 0$ (no prefix): the error becomes $(\frac{1}{2}p_{-1} + \frac{1}{4}p_{-2} - 2, \frac{1}{4}p_{-1} - 1, 0, 0)$, that is, two wrong components instead of one, in agreement with Lemma 27.1, which predicts $L - 1 - N_g = 2$.

Exercise 27.5: How much frequency error can be tolerated. *Type:* inverse problem, with a comparison between the exact formula and the asymptotic estimate. A system with $N = 1024$ subcarriers must guarantee a signal-to-interference ratio of at least 25 dB. Determine the maximum admissible normalised frequency error ε , first with the estimate of Proposition 27.5 and then with the exact formula of Corollary 27.6, and assess how conservative the estimate is.

Solution. Strategy. The exact formula $\text{SIR} = \frac{|I(0)|^2}{1 - |I(0)|^2}$ does not invert in closed form, because $|I(0)|$ contains two sines with different arguments. The asymptotic estimate, instead, inverts immediately, and provides a first-attempt value to be refined numerically.

Step 1 — the threshold. 25 dB corresponds to $\text{SIR} = 10^{25/10} = 10^{2.5} = 316.2277660$.

Step 2 — inverting the asymptotic estimate. From Proposition 27.5, $\text{SIR} \approx \frac{3}{\pi^2 \varepsilon^2 (1 - N^{-2})}$; equating with the threshold and solving for ε ,

$$\varepsilon \approx \sqrt{\frac{3}{\pi^2 \cdot 316.2277660 \cdot (1 - 1024^{-2})}}.$$

With $\pi^2 = 9.8696044$ and $1 - 1024^{-2} = 0.99999905$, the denominator equals $9.8696044 \cdot 316.2277660 \cdot 0.99999905 = 3121.0400$, hence

$$\varepsilon^2 \approx \frac{3}{3121.0400} = 9.6122 \cdot 10^{-4}, \quad \varepsilon \approx 0.0310035.$$

Step 3 — the exact formula. Compute the exact SIR at $\varepsilon = 0.0310035$:

$$|I(0)|^2 = \left(\frac{\sin(\pi \cdot 0.0310035)}{1024 \sin(\pi \cdot 0.0310035/1024)} \right)^2 = 0.9968417, \quad \text{SIR} = \frac{0.9968417}{0.0031583} = 315.6280,$$

that is 24.9918 dB: just *below* the threshold. The asymptotic estimate is thus slightly optimistic, as it must be: from the expansion in Step 3 of Proposition 27.5, the neglected term is of order ε^4 and has a sign that makes $1 - |I(0)|^2$ grow beyond the approximated value, hence makes the SIR drop.

Step 4 — the exact value. Solving numerically by bisection the equation $\text{SIR}(\varepsilon) = 316.2277660$ gives

$$\varepsilon_{\max} = 0.0309742,$$

with $\text{SIR}(\varepsilon_{\max}) = 316.2277660$, that is exactly 25.0000 dB. ✓

Independent check 1: consistency between the two values. The relative discrepancy between the estimate and the exact value is $\frac{0.0310035 - 0.0309742}{0.0309742} = 9.5 \cdot 10^{-4}$, that is less than one part per thousand: the asymptotic estimate is usable in design, provided one knows it is optimistic and leaves a margin. ✓

Independent check 2: Table 27.3. For $N = 64$ and $\varepsilon = 0.02$ that table gives 28.8052 dB exact against 28.8087 dB asymptotic: a discrepancy of 0.0035 dB in the same direction (optimistic estimate), consistent with what was found here. ✓

Interpretation. The number $\varepsilon_{\max} = 0.031$ should be read together with Observation 27.11: since $\varepsilon = \delta f N T_s$, with $N = 1024$ one is asking of the oscillator a precision relative to the subcarrier spacing of three per cent. If N were doubled to 2048 to halve the prefix loss, the same δf would double ε and the SIR would drop by about 6 dB, below 19 dB: the gain in efficiency would come at a high price.

Typical mistakes. (1) Inverting the exact formula as if it were $\text{SIR} = 3/(\pi\varepsilon)^2$, forgetting the factor $(1 - N^{-2})$: for $N = 1024$ the effect is negligible, but for $N = 4$ or $N = 8$ it is not at all. (2) Using $\text{SIR} = 10^{25}$ instead of $10^{2.5}$: confusing decibels and powers. (3) Forgetting that the estimate is optimistic and sizing the system exactly at $\varepsilon = 0.0310035$, obtaining 24.99 dB instead of the required 25.

Extension. Redo the computation for a threshold of 30 dB: the asymptotic estimate gives $\varepsilon \approx 0.0174346$, and verify that the exact value is again slightly lower, $\varepsilon_{\max} = 0.0174293$.

Exercise 27.6: Three words, the same alphabet, three different PAPRs. *Type:* exact symbolic computation with verification. For $N = 8$, compute the PAPR of the three words

$$\begin{aligned} c^{(1)} &= (1, 1, 1, 1, 1, 1, 1, 1), & c^{(2)} &= (1, i, -1, 1, -1, i, 1, 1), \\ c^{(3)} &= (1, 1, 1, 1, -1, -1, -1, -1), \end{aligned}$$

all of constant modulus $A = 1$, and explain the result in light of Theorem 27.11.

Solution. Strategy. The average power is the same for the three words, and equals $\sum_k |c_k|^2 = 8$ (Lemma 27.4); only the peak changes. For $c^{(1)}$ and $c^{(3)}$ it is convenient to sum the geometric series; for $c^{(2)}$ the computation has already been done in Section 27.9.

Step 1 — the constant word. With $c_k^{(1)} = 1$ for every k ,

$$s[n] = \sum_{k=0}^7 e^{2\pi i k n / 8} = \sum_{k=0}^7 (\zeta^n)^k,$$

a geometric sum of ratio ζ^n , an eighth root of unity. By Lemma 22.1 it equals 8 if $8 \mid n$ and 0 otherwise, hence $s = (8, 0, 0, 0, 0, 0, 0, 0)$. The peak is 64, the average 8, and $\text{PAPR} = \frac{64}{8} = 8 = N$: the worst case. Check consistency with Theorem 27.11: here $c_k = \omega_8^{k \cdot 0} = 1$, that is $A = 1$, $\theta = 0$, $n_0 = 0$, and indeed the peak falls at $n_0 = 0$. ✓

Step 2 — the word from the example. In Section 27.9, $|s[n]|^2 = 8$ was obtained for every n , hence peak 8, average 8 and $\text{PAPR} = 1$: the best case.

Step 3 — the “half and half” word. Here $c_k^{(3)} = 1$ for $k \leq 3$ and -1 for $k \geq 4$, hence

$$s[n] = \sum_{k=0}^3 \zeta^{kn} - \sum_{k=4}^7 \zeta^{kn} = \sum_{k=0}^3 \zeta^{kn} (1 - \zeta^{4n}) = (1 - (-1)^n) \sum_{k=0}^3 \zeta^{kn},$$

having factored out $\zeta^{4n} = (\zeta^4)^n = (-1)^n$ from the second sum (setting $k = k' + 4$). Hence $s[n] = 0$ for n even. For n odd the factor equals 2 and the geometric sum of ratio $\zeta^n \neq 1$ equals $\frac{\zeta^{4n}-1}{\zeta^n-1} = \frac{-2}{\zeta^n-1}$, so that

$$s[n] = \frac{-4}{\zeta^n - 1}, \quad n \text{ odd}.$$

With $\beta = \frac{\sqrt{2}}{2}$: for $n = 1$, $\zeta - 1 = (\beta - 1) + \beta i$ and

$$|\zeta - 1|^2 = (\beta - 1)^2 + \beta^2 = \beta^2 - 2\beta + 1 + \beta^2 = 2 - \sqrt{2} = 0.5857864,$$

having used $2\beta^2 = 1$ and $2\beta = \sqrt{2}$; hence $|s[1]|^2 = \frac{16}{2-\sqrt{2}}$. Rationalising,

$$|s[1]|^2 = \frac{16(2 + \sqrt{2})}{(2 - \sqrt{2})(2 + \sqrt{2})} = \frac{16(2 + \sqrt{2})}{2} = 8(2 + \sqrt{2}) = 16 + 8\sqrt{2} = 27.3137085.$$

For $n = 3$, $\zeta^3 - 1 = (-\beta - 1) + \beta i$ and $|\zeta^3 - 1|^2 = 2 + \sqrt{2}$, whence $|s[3]|^2 = \frac{16}{2+\sqrt{2}} = 8(2 - \sqrt{2}) = 4.6862915$. By symmetry $|s[7]| = |s[1]|$ and $|s[5]| = |s[3]|$.

The peak is thus $16 + 8\sqrt{2}$ and

$$\text{PAPR}(s^{(3)}) = \frac{16 + 8\sqrt{2}}{8} = 2 + \sqrt{2} = 3.4142136,$$

that is $10 \log_{10}(2 + \sqrt{2}) = 5.3329068$ dB.

Independent check 1: the total power. It must equal $\sum_n |s[n]|^2 = N \sum_k |c_k|^2 = 8 \cdot 8 = 64$ (Lemma 27.4). Indeed

$$2(16 + 8\sqrt{2}) + 2(16 - 8\sqrt{2}) = 32 + 32 = 64. \quad \checkmark$$

The terms in $\sqrt{2}$ cancel: this check immediately exposes a sign error in the rationalisation.

Independent check 2: script. The numerical computation of $8\mathcal{F}_8^{-1}c^{(3)}$ returns $s^{(3)} = (0, 2 + 4.8284271i, 0, 2 + 0.8284271i, 0, 2 - 0.8284271i, 0, 2 - 4.8284271i)$, with $|s[1]|^2 = 4 + 23.3137085 = 27.3137085$ and PAPR 3.4142136, that is 5.3329068 dB: the same values. ✓ (Note $4.8284271 = 2 + 2\sqrt{2}$.)

Interpretation. Three words with the same alphabet and the same power give 9.0309 dB, 0 dB and 5.3329 dB. Theorem 27.11 explains the first case (the word $c^{(1)}$ has the form $Ae^{i\theta}\omega_N^{kn_0}$ with $n_0 = 0$) and the third (neither inequality is saturated: the phases never align perfectly); the second is the opposite case, in which the energy is uniformly spread over all samples. It is on this dependence on the word that PAPR-reduction techniques are based, choosing among equivalent representations of the same data the one with the smaller peak (Observation 27.13 for the source).

Typical mistakes. (1) Computing the average power as $\frac{1}{N}\sum_k |c_k|^2$ instead of $\sum_k |c_k|^2$: the PAPR is wrong by a factor of N . (2) In Step 3, forgetting the factor $(1 - (-1)^n)$ and concluding that s has eight nonzero components. (3) Rationalising $\frac{16}{2-\sqrt{2}}$ by multiplying by $2 - \sqrt{2}$ instead of $2 + \sqrt{2}$.

Extension. Show that for $N = 8$ and BPSK words ($c_k \in \{\pm 1\}$) the maximum PAPR 8 is attained only by $c = (1, 1, \dots, 1)$ and by $c = (1, -1, 1, -1, 1, -1, 1, -1)$, and by their opposites. (Hint: Theorem 27.11 forces $c_k = e^{i\theta}\omega_8^{kn_0}$; for all the c_k to be real, $\omega_8^{n_0}$ must be real, that is $n_0 \in \{0, 4\}$, and $e^{i\theta} \in \{1, -1\}$.)

27.12. Self-assessment quiz

- (Definition) The *cyclic prefix* of length N_g is
 - an interval of N_g zero samples prepended to the block
 - a copy of the last N_g samples of the block, prepended to the block itself
 - a copy of the first N_g samples of the block, appended after the block
 - a known sequence of N_g samples used to estimate the channel
- (Hypothesis) In Theorem 27.5 the hypothesis $N_g \geq L - 1$ serves to
 - guarantee that h_p has length N
 - guarantee that all the indices $m + N_g - l$ are nonnegative, that is, that no sample of the previous block enters the kept samples
 - make the matrix C_h invertible
 - ensure that $H[k] \neq 0$ for every k
- (Symbolic computation) The modulus of the common attenuation factor produced by a normalised frequency error ε equals
 - $\frac{|\sin(\pi\varepsilon)|}{\pi\varepsilon}$
 - $\frac{|\sin(\pi\varepsilon)|}{N|\sin(\pi\varepsilon/N)|}$
 - $\frac{|\sin(\pi\varepsilon/N)|}{N|\sin(\pi\varepsilon)|}$
 - $\frac{1}{N}\left|\frac{\sin(\pi\varepsilon)}{\sin(\pi\varepsilon/N)}\right|$
- (Numerical computation) With $N = 2048$ and $N_g = 144$ the efficiency loss due to the cyclic prefix equals
 - 7.031250%
 - 6.569343%
 - 0.295106%
 - 20.000000%
- (Proof step) In Step 3 of Theorem 27.5, case (b) with $l > m$, the equality $\tilde{s}[N_g - d] = s[N - d]$ holds because
 - the index $N_g - d$ falls in the prefix, which by Definition 27.4 is a copy of the tail of s
 - circular convolution is commutative
 - h has finite length
 - $\langle m - l \rangle_N = m - l$ even when $m < l$
- (Error diagnosis) A designer shortens the prefix from $N_g = L - 1$ to $N_g = L - 2$ to gain efficiency, and tests the system on an ideal single-tap channel ($L = 1$, $h = (1)$). The test

passes. Why does it not detect the error?

- A) because with $L = 1$ the condition $N_g \geq L - 1$ is satisfied by any $N_g \geq 0$, and the critical case is never exercised
 - B) because the DFT is unitary and conserves energy
 - C) because the ZF equalizer automatically corrects interblock interference
 - D) because the PAPR does not depend on the prefix length
7. (Transfer) N is doubled while keeping fixed the sampling step T_s , the channel and the absolute frequency error δf . Then
- A) both the prefix loss and the intercarrier interference power decrease
 - B) the prefix loss roughly halves and the intercarrier interference power roughly quadruples
 - C) the prefix loss doubles and the interference halves
 - D) neither changes, because both depend only on the ratio N_g/N
8. (Source and metacognition) The paper that in 1971 replaced the bank of oscillators with the discrete Fourier transform, making OFDM realisable, is
- A) R. W. Chang, *Synthesis of band-limited orthogonal signals for multichannel data transmission*, *Bell System Technical Journal* **45** (1966), pp. 1775–1796
 - B) S. B. Weinstein, P. M. Ebert, *Data transmission by frequency-division multiplexing using the discrete Fourier transform*, *IEEE Transactions on Communication Technology* **19** (1971), pp. 628–634
 - C) A. Peled, A. Ruiz, *Frequency domain data transmission using reduced computational complexity algorithms*, ICASSP 1980, pp. 964–967

27.13. Teacher’s key

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 1–4).

- 1) **B.** *Rationale:* this is literally Definition 27.4, $\tilde{s}[n] = s[\langle n - N_g \rangle_N]$, which for $n < N_g$ gives $s[N - N_g + n]$, that is, the last N_g samples. *Distractors:* A describes the empty guard interval, which eliminates interblock interference but does not produce circular convolution — this is exactly the difference between the pre-1980 solution and that of Peled and Ruiz; C reverses the order (the cyclic suffix exists, but it is a different technique and is not the one used here); D confuses the prefix with a pilot sequence. *Diagnosed error:* believing the prefix only serves to “leave room” for the echo. *Source:* Peled and Ruiz, ICASSP 1980, pp. 964–967. *Prerequisite:* Definition 22.4. *Remedy:* redo Section 27.8, the “without prefix” part, with $p = 0$ and with $p = 4$, and observe that only the second gives the circular result.
- 2) **B.** *Rationale:* Step 2 of that proof checks $n_l = m + N_g - l \geq N_g - (L - 1) \geq 0$; it is the only point where the hypothesis is used, and it serves to exclude negative indices, that is, samples of the previous block (Lemma 27.1). *Distractors:* A confuses the hypothesis $N_g \geq L - 1$ with the hypothesis $L \leq N$, used in Step 4 for the zero-padding; C and D are independent consequences or conditions (the invertibility of C_h and the non-vanishing of the $H[k]$ are the same thing by Theorem 27.7(iv), and have nothing to do with N_g). *Diagnosed error:* not being able to identify at which step a given hypothesis is used. *Source:* here, Theorem 27.5, Step 2. *Prerequisite:* Lemma 27.1. *Remedy:* redo Step 2 with $N_g = L - 2$ and identify for which pair (m, l) the index becomes negative.
- 3) **B.** *Rationale:* this is $|I(0)|$ of Lemma 27.3, with $m = 0$. *Distractors:* A is the limit as $N \rightarrow \infty$ of the correct answer, that is, the sinc function: it is the formula for the continuous-time case, not the sampled one, and it is already wrong for $N = 4$; C swaps numerator and

denominator, and would give an *amplification* greater than 1; D is identically $1/N$ and does not depend on ε , so it cannot describe an attenuation that grows with the error. *Diagnosed error*: substituting the discrete Dirichlet kernel with the continuous sinc function. *Source*: here, Lemma 27.3; cf. Lemma 22.3 for the same structure in Chapter 22. *Prerequisite*: geometric sum, Lemma 22.1. *Remedy*: compute $|I(0)|$ for $N = 4$ and $\varepsilon = 0.25$ with both formulas: the correct answer gives $\frac{\sin(\pi/4)}{4\sin(\pi/16)} = \frac{0.7071068}{0.7803612} = 0.9061274$, distractor A gives $\text{sinc}(0.25) = \frac{0.7071068}{0.7853982} = 0.9003163$; the difference, 0.0057962, is small but nonzero, and grows as N decreases.

4) **B. Rationale**: by Proposition 27.3(i) the loss is $\frac{N_g}{N+N_g} = \frac{144}{2192} = \frac{9}{137} = 0.0656934\dots$, that is 6.569343% (Example 27.3). *Distractors*: A is $\rho = \frac{144}{2048} = \frac{9}{128} = 7.03125\%$, that is the ratio N_g/N and not $N_g/(N+N_g)$: this is the most frequent mistake; C is the value of the loss *in decibels* (0.295106), read as a percentage; D is the loss for $\rho = \frac{1}{4}$, that is, another row of Table 27.2. *Diagnosed error*: confusing ρ with $1-\eta$, and decibels with percentages. *Source*: Proposition 27.3 and verification with a script. *Prerequisite*: $\frac{1}{1+\rho}$ against $\frac{\rho}{1+\rho}$. *Remedy*: redo the computation for $\rho = \frac{1}{8}$ (answer: 11.11111% and 0.511525 dB) and for $\rho = \frac{1}{16}$ (5.882353% and 0.263289 dB), checking against Table 27.2.

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 5–8).

5) **A. Rationale**: in case (b), $n_l = N_g - d$ with $1 \leq d \leq N_g$, hence $0 \leq n_l \leq N_g - 1$: the index falls in the first row of Definition 27.4, where $\tilde{s}[n] = s[N - N_g + n]$, and substituting $n = N_g - d$ gives $s[N - d]$. *Distractors*: B is true but unused (commutativity of circular convolution does not appear in that proof); C is used elsewhere, to guarantee that the sum over l is finite; D is *false*: when $m < l$ the representative is $m - l + N$, and this is exactly the point of the proof. *Diagnosed error*: skipping the computation of the modular representative and relying on intuition. *Source*: here, Theorem 27.5, Step 3. *Prerequisite*: Observation 27.5. *Remedy*: rewrite the table of $\tilde{s}[n]$ for $N = 8$, $N_g = 2$ and check the equality by hand for all pairs (m, l) with $l > m$.

6) **A. Rationale**: the condition of Corollary 27.5 is $N_g \geq L - 1$; with $L = 1$ it becomes $N_g \geq 0$, satisfied by any prefix, even an empty one. The test never exercises the critical case, which requires $L \geq 2$ and $h_{L-1} \neq 0$: these are exactly the hypotheses of Theorem 27.6. *Distractors*: B is true but irrelevant — and worse, it is a check that does *not* detect the error, as seen in Worked Exercise 27.4; C is false: the ZF equalizer assumes diagonality, it does not restore it; D is true but beside the point. *Diagnosed error*: testing outside the regime in which the hypothesis is binding. *Source*: here, Theorem 27.6 and Worked Exercise 27.4. *Prerequisite*: Corollary 27.5. *Remedy*: redo Worked Exercise 27.4 first with $p_{-1} = 0$ (the test passes) and then with $p_{-1} = 4$ (the test fails).

7) **B. Rationale**: at fixed N_g , $1 - \eta = \frac{N_g}{N+N_g}$ roughly halves when N doubles (Proposition 27.3(iii)); and since $\varepsilon = \delta f N T_s$, doubling N doubles ε , and by Proposition 27.5 the interference power grows like ε^2 , hence quadruples (−6.03 dB of SIR; Figure 27.4). *Distractors*: A and C reverse one of the two effects; D forgets that ε depends on N and not only on ρ . *Diagnosed error*: optimising a parameter while looking at only one constraint. *Source*: here, Observation 27.11. *Prerequisite*: Definition 27.8. *Remedy*: work through Worked Exercise 27.5 and then redo it with $N = 2048$.

8) **B. Rationale**: this is the paper by Weinstein and Ebert, which introduced the DFT-based realisation (here, Theorems 27.3 and 27.4). *Distractors*: A is Chang, 1966, who introduced the orthogonality of the subcarriers but not the transform-based realisation; C is Peled and Ruiz, 1980, to whom the cyclic prefix is due; D is Cooley and Tukey, 1965, who provide the *algorithm* used to compute the transform but which has nothing to do

with telecommunications and is the source of Chapter 23. *Diagnosed error*: attributing a composite idea to a single paper, or confusing the algorithm with the application. *Source*: the four citations are verified and reported in the sources environment of this chapter and of Chapter 23. *Prerequisite*: Observation 27.4. *Remedy*: reread Observation 27.4 and match each of the three ideas to its own paper and to its own section of the chapter.

BEST PRACTICE

Assigned exercises — answers.

Exercise 27.1. (a) $N_g = L - 1 = 16$; for $N = 256$, $\eta = \frac{256}{272} = \frac{16}{17} = 0.9411765$, loss $\frac{1}{17} = 5.882353\%$, that is 0.263289 dB. (b) $N = 512$: $\eta = \frac{32}{33} = 0.9696970$, loss 3.030303%, 0.133640 dB. $N = 1024$: $\eta = \frac{64}{65} = 0.9846154$, loss 1.538462%, 0.067334 dB. In general, going from N to $2N$ at fixed N_g , the loss goes from $\frac{\rho}{1+\rho}$ to $\frac{\rho/2}{1+\rho/2} = \frac{\rho}{2+\rho}$, hence it is reduced by the factor $\frac{2+\rho}{1+\rho}$, which for $\rho > 0$ is strictly between 1 and 2 and tends to 2 as $\rho \rightarrow 0$. (For $\rho = \frac{1}{16}$ the factor equals $\frac{33}{17} = 1.9412$.) (c) $N = 512 = 2^9$: direct sum $512^2 = 262\,144$ multiplications; FFT $\frac{512}{2} \cdot 9 = 2\,304$; nontrivial $2\,304 - 768 + 2 = 1\,538$; ratio $\frac{262\,144}{2\,304} = 113.777778$. (d) ε quadruples (from N to $4N$), the ICI power grows like ε^2 hence by a factor of 16: $10 \log_{10} 16 = 12.0412$ dB of signal-to-interference ratio are lost.

Exercise 27.2. (a) $s[n] = 1 + i^n - i^{2n} - i^{3n}$, hence $s = (0, 2 + 2i, 0, 2 - 2i)$. (b) Average power $\sum_k |c_k|^2 = 4$; peak $|s[1]|^2 = 8$; PAPR = 2, that is 3.0103 dB, against the maximum 4. The Cauchy–Schwarz inequality is saturated (all $|c_k|$ equal 1), the triangle one is not: at no instant do the four phases align. (c) $H[k] = 1 - \frac{1}{2}(-i)^k$, that is $H = (\frac{1}{2}, 1 + \frac{i}{2}, \frac{3}{2}, 1 - \frac{i}{2})$; $H[3] = \overline{H[1]}$. (d) $\tilde{s} = (2 - 2i, 0, 2 + 2i, 0, 2 - 2i)$; $r = (2 - 2i, -1 + i, 2 + 2i, -1 - i, 2 - 2i, -1 + i)$; $y = (-1 + i, 2 + 2i, -1 - i, 2 - 2i) = h_p \circledast s$. (e) $S = 4c = (4, 4, -4, -4)$, $Y = (2, 4 + 2i, -6, -4 + 2i)$, and $Y[k] = H[k]S[k]$ for all four; $\hat{c} = (1, 1, -1, -1) = c$. (f) $\det C_h = \frac{1}{2} \cdot \frac{3}{2} \cdot |1 + \frac{i}{2}|^2 = \frac{3}{4} \cdot \frac{5}{4} = \frac{15}{16} = 0.9375$; by an algebraic route $\prod_{z^4=1} (1 - \frac{z}{2}) = \frac{1}{16} \prod_{z^4=1} (2 - z) = \frac{2^4 - 1}{16} = \frac{15}{16}$. (g) The reconstruction remains exact if and only if $p = s[3] = 2 - 2i$. For $p = 0$ one gets $y' = (0, 2 + 2i, -1 - i, 2 - 2i)$ and $\hat{c}' = (1.5 - 0.5i, 1.1 - 0.3i, -0.8333333 - 0.1666667i, -0.7 - 0.1i)$: all four symbols are wrong.

Exercise 27.3. (a) In the formula of Lemma 27.3 with $m = 0$, substituting $-\varepsilon$ for ε changes the sign of both $\sin(\pi\varepsilon)$ and $\sin(\pi\varepsilon/N)$, and the quotient is unchanged: $|I(0)|$ is even. As $\varepsilon \rightarrow 0$, $|I(0)| \rightarrow 1$ by Proposition 27.5; and for $m \not\equiv 0 \pmod{N}$ the numerator $\sin(\pi\varepsilon) \rightarrow 0$ while the denominator $N \sin(\pi m/N) \neq 0$ stays bounded away from zero, hence $|I(m)| \rightarrow 0$. In Theorem 27.10 this means that without a frequency error only the term $j = k$ remains: orthogonality is recovered. (b) $N = 16$, $\varepsilon = 0.02$: $|I(0)|^2 = 0.9986899$, SIR = 762.2882, that is 28.8212 dB, against the asymptotic estimate 762.8889, that is 28.8246 dB. $\varepsilon = 0.08$: $|I(0)|^2 = 0.9792019$, SIR = 47.0813, that is 16.7285 dB, against 47.6806, that is 16.7834 dB. The approximation is better for small ε , because the neglected term is of order ε^4 : the discrepancy goes from 0.0034 dB to 0.0549 dB, that is, it grows by a factor of 16 when ε quadruples, as predicted. (c) $(1, 1, 1, 1)$, $(1, -1, 1, -1)$ and $(1, i, -1, -i)$ have PAPR 4, that is 6.0206 dB: they are of the form $\omega_4^{kn_0}$ with $n_0 = 0$, $n_0 = 2$ and $n_0 = 3$ respectively, and give $s = (4, 0, 0, 0)$, $s = (0, 0, 4, 0)$, $s = (0, 0, 0, 4)$. The word $(1, 1, 1, -1)$, instead, has $s = (2, 2i, 2, -2i)$, all of modulus 2, hence PAPR 1: the Cauchy–Schwarz inequality is saturated (all moduli equal) but the triangle one never is, because $(1, 1, 1, -1)$ is not of the form $Ae^{i\theta}\omega_4^{kn_0}$ for any n_0 . (d) With $c_k = \omega_N^{kn_0}$ one has $s[n] = \sum_k \omega_N^{kn_0} \omega_N^{-kn} = \sum_k \omega_N^{k(n_0-n)}$, which by Lemma 22.1 equals N if $n = n_0$ and 0 otherwise. The average power is $\sum_k |c_k|^2 = N$ and the peak N^2 : PAPR = N . Conversely Step 5 of Theorem 27.11 shows that these are the only words with maximum PAPR, up to the factor $Ae^{i\theta}$.

27.14. Chapter formulary

Subcarriers and orthogonality. $\Delta f = 1/T$, $T_s = T/N$, $t_n = nT/N$.

$$\begin{aligned}\phi_k(t) &= e^{2\pi i k \Delta f t}, & \langle \phi_k, \phi_\ell \rangle_T &= T \delta_{k\ell} \iff \Delta f T \in \{1, 2, 3, \dots\}, \\ \Psi_k(f) &= T e^{-i\pi(fT-k)} \text{sinc}(fT-k), & \Psi_k(\ell/T) &= T \delta_{k\ell}, & \phi_k(t_n) &= \omega_N^{-kn}.\end{aligned}$$

Modulator and demodulator. With $\omega_N = e^{-2\pi i/N}$:

$$s[n] = \sum_{k=0}^{N-1} c_k \omega_N^{-kn} = N(\mathcal{F}_N^{-1}c)[n] = (\overline{\mathcal{F}_N c})[n], \quad c_k = \frac{1}{N}(\mathcal{F}_N s)[k].$$

Cost: N^2 multiplications from the definition; $\frac{N}{2} \log_2 N$ with radix-2 FFT, of which $\frac{N}{2} \log_2 N - \frac{3N}{2} + 2$ nontrivial. For $N = 2048$: 4 194 304 against 11 264 (ratio $\frac{4096}{11} = 372.363636$).

Cyclic prefix and diagonalisation. Channel $h \in \mathbb{C}^L$, h_p its zero-padding to length N .

$$\tilde{s}[n] = s[\langle n - N_g \rangle_N], \quad n = 0, \dots, N + N_g - 1; \quad y[m] = r[m + N_g].$$

If $N_g \geq L - 1$ (necessary and sufficient condition) then

$$\begin{aligned}y &= h_p \otimes s = C_h s, & C_h &= \text{circ}(h_p), & F_N C_h F_N^* &= \text{diag}(H), \\ H[k] &= \sum_{l=0}^{L-1} h_l \omega_N^{kl}, & Y[k] &= H[k] S[k] = N H[k] c_k, & \det C_h &= \prod_{k=0}^{N-1} H[k].\end{aligned}$$

In physical time: $N_g T_s \geq \tau_{\max} = (L - 1) T_s$.

Single-coefficient equalisation. With noise under hypothesis (R), $\mathbb{E}|W[k]|^2 = N\sigma^2$:

$$\begin{aligned}\text{ZF: } \hat{c}_k &= \frac{Y[k]}{N H[k]} = c_k + \frac{W[k]}{N H[k]}, & \mathbb{E}[|e_k|^2] &= \frac{\sigma^2}{N |H[k]|^2}, & \text{SNR}_k &= \frac{NP |H[k]|^2}{\sigma^2}. \\ \text{MMSE: } g^* &= \frac{\overline{H[k]}}{|H[k]|^2 + \frac{\sigma^2}{NP}}, & J(g^*) &= \frac{P\sigma^2}{N |H[k]|^2 P + \sigma^2} < \frac{\sigma^2}{N |H[k]|^2}.\end{aligned}$$

Efficiency. With $\rho = N_g/N$:

$$\eta = \frac{N}{N + N_g} = \frac{1}{1 + \rho}, \quad 1 - \eta = \frac{\rho}{1 + \rho}, \quad \text{loss in dB} = 10 \log_{10}(1 + \rho).$$

Values: $\rho = \frac{1}{4} \Rightarrow 20\%$ and 0.969100 dB; $\rho = \frac{1}{8} \Rightarrow 11.111111\%$ and 0.511525 dB; $\rho = \frac{1}{16} \Rightarrow 5.882353\%$ and 0.263289 dB; $\rho = \frac{9}{128} \Rightarrow 6.569343\%$ and 0.295106 dB.

Frequency error. $\varepsilon = \delta f / \Delta f = \delta f N T_s$, $r[n] = e^{2\pi i \varepsilon n / N} s[n]$.

$$I(m) = \frac{\sin(\pi \varepsilon)}{N \sin(\pi(m + \varepsilon)/N)} e^{i\pi \varepsilon(1 - \frac{1}{N})} e^{-i\pi m / N}, \quad I(m + N) = I(m), \quad \sum_{m=0}^{N-1} |I(m)|^2 = 1.$$

$$\hat{c}_k = I(0)c_k + \sum_{j \neq k} c_j I(j-k), \quad \text{SIR}(\varepsilon) = \frac{|I(0)|^2}{1 - |I(0)|^2} \sim \frac{3}{\pi^2 \varepsilon^2 (1 - N^{-2})}.$$

For $N = 64$: $\varepsilon = 0.05 \Rightarrow 20.8284$ dB; $\varepsilon = 0.10 \Rightarrow 14.7431$ dB.

PAPR.

$$\text{PAPR}(s) = \frac{\max_n |s[n]|^2}{\frac{1}{N} \sum_n |s[n]|^2}, \quad \frac{1}{N} \sum_n |s[n]|^2 = \sum_k |c_k|^2 = \frac{1}{T} \int_0^T |s(t)|^2 dt.$$

$$1 \leq \text{PAPR}(s) \leq \frac{(\sum_k |c_k|)^2}{\sum_k |c_k|^2} \leq N, \quad \text{PAPR} = N \iff c_k = A e^{i\theta} \omega_N^{kn_0}.$$

In decibels the maximum is $10 \log_{10} N$: 6.0206 dB for $N = 4$, 9.0309 dB for $N = 8$, 33.1133 dB for $N = 2048$. Under the Gaussian hypothesis (G), *imported*: $\Pr(\text{PAPR} > \gamma) = 1 - (1 - e^{-\gamma})^N$.

The numbers of the examples. $N = 4$, $c = (1, i, -1, -i)$, $h = (1, \frac{1}{2})$, $N_g = 1$:

$$s = (0, 0, 0, 4), \quad H = \left(\frac{3}{2}, 1 - \frac{i}{2}, \frac{1}{2}, 1 + \frac{i}{2}\right), \quad y = (2, 0, 0, 4), \quad Y = (6, 2 + 4i, -2, 2 - 4i),$$

$\det C_h = \frac{15}{16}$, $\text{PAPR} = 4$. $N = 8$, $c = (1, i, -1, 1, -1, i, 1, 1)$, $h = (1, \frac{1}{2}, \frac{1}{4})$, $N_g = 2$:

$$s = (2 + 2i, 2 - 2i, -2 - 2i, 2 + 2i, -2 - 2i, 2 - 2i, 2 + 2i, 2 + 2i), \quad \text{PAPR} = 1,$$

$$H[0] = \frac{7}{4}, \quad H[2] = \frac{3}{4} - \frac{i}{2}, \quad H[4] = \frac{3}{4}, \quad |H[1]|^2 = \frac{21}{16} + \frac{5\sqrt{2}}{8}, \quad |H[3]|^2 = \frac{21}{16} - \frac{5\sqrt{2}}{8},$$

$$y = (3.5 + 3.5i, 3.5 - 0.5i, -0.5 - 2.5i, 1.5 + 0.5i, -1.5 - 1.5i, 1.5 - 2.5i, 2.5 + 0.5i, 3.5 + 2.5i),$$

$$\det C_h = \frac{65793}{65536} = 1.0039215.$$

Part E

Applications to automation

Rotations of space, SO(3) and quaternions

Chapter 11 established *what* the rotations of space are: by Euler's theorem (Theorem 11.8) each has an axis and an angle; by Theorem 11.10 the unit quaternions realise all of them, each twice. This chapter takes up the next question, the engineer's rather than the geometer's: *how one writes* a rotation, how its representations are converted into one another, and what breaks when the conversion passes near a singularity.

Three representations are in use. The **rotation matrix** is the most direct but uses nine numbers for three degrees of freedom, and keeping it orthogonal in finite-precision arithmetic costs effort. **Euler angles** (in the *roll-pitch-yaw* variant used by robots) use three parameters, the minimum possible, and precisely for that reason carry an unavoidable singularity: *gimbal lock*. The **unit quaternion** uses four parameters tied by a single quadratic constraint, has no singularity, composes with sixteen multiplications instead of twenty-seven, and renormalises by dividing by a norm. Between matrix and axis-angle the bridge is Rodrigues' formula, from 1840; between quaternion and matrix the bridge is Hamilton's calculus, from 1843. The two bridges are the same formula written twice, and this coincidence — proved in full in Section 28.5 — is the technical heart of the chapter.

The thread that runs through it all is still the circle. Every rotation of space is a plane rotation in the plane orthogonal to its own axis: Rodrigues' formula does nothing more than write $\cos \theta$ and $\sin \theta$ in that plane and leave the axis fixed. And the unit quaternions are the sphere S^3 , which covers $SO(3)$ twice exactly as, one dimension down, S^1 covers $SO(2)$ once (Theorem 11.7).

INFO

Level and prerequisites. Level C (undergraduate), with Section 28.6 at level C–D.

Internal prerequisites. The orthogonal group and the rotation group (Definition 11.2); Euler's theorem on the axis of rotation (Theorem 11.8); the Cartan–Dieudonné theorem (Theorem 11.9); the algebra of quaternions (Definition 11.3) and the action $\Phi_q(v) = qv\bar{q}$ together with its character as a double covering (Theorem 11.10); the Hopf fibration (Theorem 11.11); $SO(2) \cong S^1$ (Theorem 11.7); Lagrange's identity $\|\mathbf{a} \times \mathbf{b}\|^2 = \|\mathbf{a}\|^2\|\mathbf{b}\|^2 - \langle \mathbf{a}, \mathbf{b} \rangle^2$ (Lemma 10.1) and the invariance of the cross product under $SO(3)$ (Proposition 3.4, Step 1); trigonometric functions and the addition and duplication formulas (Volume II, Chapter 1).

External prerequisites, assumed and not reproved (a first course in linear algebra and analysis):

- the matrix exponential series $e^M = \sum_{n \geq 0} M^n/n!$ converges in norm for every real 3×3 matrix M , because $\|M^n\| \leq \|M\|^n$ by submultiplicativity of the operator norm and $\sum \|M\|^n/n!$ converges;
- an absolutely convergent series may be reordered and regrouped;
- the rank of a matrix is the maximum number of independent columns, and a square matrix is invertible if and only if its determinant is nonzero;
- the inverse function theorem in $\mathbb{R}^3$.

Everything else is proved here.

What is learned. Proving Rodrigues' formula in matrix form and recognising it as the exponential of a skew-symmetric matrix; multiplying quaternions in scalar-vector form and proving that the norm is multiplicative; converting in both directions among matrix, quaternion and axis-angle, treating $\theta = 0$ and $\theta = \pi$ explicitly; proving *gimbal lock* as a rank drop of the Jacobian; choosing the sign of the quaternion before interpolating, and knowing why.

Warning. Conventions of the chapter.

- Vectors of $\mathbb{R}^3$ are columns; $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$ is the canonical basis; $\langle \cdot, \cdot \rangle$ is the Euclidean scalar product and $\times$ the cross product.
- I is the 3×3 identity matrix and $M^\top$ the transpose. Matrices act on the left: $R\mathbf{v}$.
- An **active** rotation moves the vector while leaving the axes fixed. All formulas of the chapter are active; for the passive reading (axes rotating, vector fixed) one substitutes $R^\top$ for R .
- The orientation is right-handed: $\mathbf{e}_1 \times \mathbf{e}_2 = \mathbf{e}_3$, and a rotation through a positive angle about $\mathbf{u}$ is counterclockwise as seen from the tip of $\mathbf{u}$.
- A quaternion is written $q = (w, \mathbf{v})$ with $w \in \mathbb{R}$ and $\mathbf{v} \in \mathbb{R}^3$, that is $q = w + v_1i + v_2j + v_3k$: this is Definition 11.3 with the real part placed first. The conjugate is $\bar{q} = (w, -\mathbf{v})$ and the norm $\|q\|^2 = w^2 + \|\mathbf{v}\|^2$.
- θ is the angle of rotation; the half-angle $\theta/2$ appears throughout. Angles are written in degrees in numerical calculations and in radians in formulas.

28.1. The rotation group and the elementary rotations

Recall Definition 11.2: the *rotation group* of space is

$$SO(3) = \{R \in \mathbb{R}^{3 \times 3} : R^\top R = I, \det R = +1\},$$

a group under matrix multiplication. Its three *elementary rotations* are the rotations about the coordinate axes.

Definition 28.1: Elementary rotations. For $\alpha \in \mathbb{R}$ one sets

$$R_x(\alpha) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \alpha & -\sin \alpha \\ 0 & \sin \alpha & \cos \alpha \end{pmatrix}, \quad R_y(\alpha) = \begin{pmatrix} \cos \alpha & 0 & \sin \alpha \\ 0 & 1 & 0 \\ -\sin \alpha & 0 & \cos \alpha \end{pmatrix},$$

$$R_z(\alpha) = \begin{pmatrix} \cos \alpha & -\sin \alpha & 0 \\ \sin \alpha & \cos \alpha & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

The sign of R_y is opposite to the other two because the cyclic triple is (x, y, z) : in the rotation about y the rotated plane is (z, x) and not (x, z) .

Proposition 28.1: The elementary rotations are rotations. For every α one has $R_x(\alpha), R_y(\alpha), R_z(\alpha) \in SO(3)$, and the one-parameter group identities hold

$$R_*(\alpha)R_*(\beta) = R_*(\alpha + \beta), \quad R_*(\alpha)^{-1} = R_*(-\alpha) = R_*(\alpha)^\top, \quad * \in \{x, y, z\}.$$

Proof. Step 1 — orthogonality. The computation is carried out for R_z ; the other two cases are identical after permuting the indices. The columns of $R_z(\alpha)$ are $c_1 = (\cos \alpha, \sin \alpha, 0)^\top$, $c_2 = (-\sin \alpha, \cos \alpha, 0)^\top$, $c_3 = (0, 0, 1)^\top$. Then $\langle c_1, c_1 \rangle = \cos^2 \alpha + \sin^2 \alpha = 1$, $\langle c_2, c_2 \rangle = \sin^2 \alpha + \cos^2 \alpha = 1$, and $\langle c_1, c_2 \rangle = 0$. Similarly, $\langle c_1, c_3 \rangle = \langle c_2, c_3 \rangle = 0$.

$\cos^2 \alpha = 1$, $\langle c_3, c_3 \rangle = 1$, $\langle c_1, c_2 \rangle = -\cos \alpha \sin \alpha + \sin \alpha \cos \alpha = 0$ and $\langle c_1, c_3 \rangle = \langle c_2, c_3 \rangle = 0$. The columns therefore form an orthonormal basis, that is $R_z^\top R_z = I$.

Step 2 — determinant. Expanding along the third row, $\det R_z(\alpha) = 1 \cdot (\cos^2 \alpha + \sin^2 \alpha) = 1$. Likewise $\det R_x(\alpha) = \cos^2 \alpha + \sin^2 \alpha = 1$ expanding along the first row, and $\det R_y(\alpha) = \cos^2 \alpha - (\sin \alpha)(-\sin \alpha) = 1$ expanding along the second row. Hence all three belong to $SO(3)$.

Step 3 — one-parameter group. Again for R_z :

$$R_z(\alpha)R_z(\beta) = \begin{pmatrix} \cos \alpha \cos \beta - \sin \alpha \sin \beta & -\cos \alpha \sin \beta - \sin \alpha \cos \beta & 0 \\ \sin \alpha \cos \beta + \cos \alpha \sin \beta & -\sin \alpha \sin \beta + \cos \alpha \cos \beta & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

and the addition formulas (Volume II, Chapter 1) recognise in this matrix $R_z(\alpha + \beta)$. Setting $\beta = -\alpha$ gives $R_z(\alpha)R_z(-\alpha) = R_z(0) = I$, that is $R_z(\alpha)^{-1} = R_z(-\alpha)$; and $R_z(-\alpha) = R_z(\alpha)^\top$ by direct inspection, since $\cos$ is even and $\sin$ is odd. The other two cases are identical. $\square$

The first structural fact is that, unlike $SO(2)$, the group $SO(3)$ is not commutative. Theorem 11.7 had already announced this; here an explicit counterexample is given, which will be used repeatedly in what follows.

Theorem 28.1: *$SO(3)$ is not commutative. Set $A = R_z(90^\circ)R_x(90^\circ)$ and $B = R_x(90^\circ)R_z(90^\circ)$. Then*

$$A = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}, \quad B = \begin{pmatrix} 0 & -1 & 0 \\ 0 & 0 & -1 \\ 1 & 0 & 0 \end{pmatrix},$$

and in particular $Ae_1 = e_2$ while $Be_1 = e_3$. Hence $A \neq B$ and $SO(3)$ is not abelian.

Proof. Step 1 — the two elementary matrices. By Definition 28.1, with $\cos 90^\circ = 0$ and $\sin 90^\circ = 1$,

$$R_z(90^\circ) = \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad R_x(90^\circ) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}.$$

Step 2 — the product $A = R_z(90^\circ)R_x(90^\circ)$. This is computed row by row. The first row of $R_z(90^\circ)$ is $(0, -1, 0)$; multiplied by the columns $(1, 0, 0)^\top$, $(0, 0, 1)^\top$, $(0, -1, 0)^\top$ of $R_x(90^\circ)$ this gives $0 \cdot 1 + (-1) \cdot 0 + 0 \cdot 0 = 0$, then $0 \cdot 0 + (-1) \cdot 0 + 0 \cdot 1 = 0$, then $0 \cdot 0 + (-1) \cdot (-1) + 0 \cdot 0 = 1$: the first row of A is $(0, 0, 1)$. The second row of $R_z(90^\circ)$ is $(1, 0, 0)$ and reproduces the first row of $R_x(90^\circ)$, namely $(1, 0, 0)$. The third row of $R_z(90^\circ)$ is $(0, 0, 1)$ and reproduces the third row of $R_x(90^\circ)$, namely $(0, 1, 0)$. Hence A is the matrix of the statement.

Step 3 — the product $B = R_x(90^\circ)R_z(90^\circ)$. The rows of $R_x(90^\circ)$ are $(1, 0, 0)$, $(0, 0, -1)$, $(0, 1, 0)$: the first reproduces the first row of $R_z(90^\circ)$, namely $(0, -1, 0)$; the second gives the opposite of the third row of $R_z(90^\circ)$, namely $(0, 0, -1)$; the third gives the second row of $R_z(90^\circ)$, namely $(1, 0, 0)$. Hence B is the matrix of the statement.

Step 4 — comparison. The first column of A is $(0, 1, 0)^\top = e_2$, that of B is $(0, 0, 1)^\top = e_3$. Since $e_2 \neq e_3$, the two matrices already differ in the first column: $A \neq B$. Both belong to $SO(3)$ because they are products of elements of $SO(3)$ (Proposition 28.1 and closure of the group). Hence there exist in $SO(3)$ two elements that do not commute.

Step 5 — geometric reading. The computation says something that can be checked by hand with a book: rotating it a quarter turn about the vertical axis and then a quarter turn about the front axis does not take it where the reversed sequence does. The difference is measurable: it will be seen in Example 28.2 that A and B have the *same* angle, 120° , but

different axes.

Step 6 — independent check. The symbolic computation was repeated in `numpy` by building $R_z(\pi/2)$ and $R_x(\pi/2)$ from the trigonometric functions and multiplying them in the two orders: one obtains exactly the two matrices of the statement, with $A\mathbf{e}_1 = (0, 1, 0)^\top$ and $B\mathbf{e}_1 = (0, 0, 1)^\top$. ✓ $\square$

***Remark 28.1: What is lost and what is gained.** Non-commutativity has two immediate practical consequences. First: the order in which a controller applies rotations is part of the specification, not a detail; the ZYX , ZYZ , XYZ conventions of manufacturers describe different orders and produce different matrices from the same three numbers. Second: there is no “sum of orientations”. Interpolating two triples of Euler angles component by component does not in general produce the shortest path between the two orientations — see Proposition 28.6. In $SO(2)$, where the group is commutative, the average of two angles is still a sensible angle: this is why the plane case does not prepare one for the pitfalls of the spatial case.*

A fact already proved elsewhere in the treatise and used constantly in what follows is that rotations “commute with the cross product”: for $A \in SO(3)$ and $\mathbf{u}, \mathbf{v} \in \mathbb{R}^3$ one has

$$A(\mathbf{u} \times \mathbf{v}) = (A\mathbf{u}) \times (A\mathbf{v}), \quad (28.1)$$

while for A orthogonal with $\det A = -1$ the right-hand side changes sign. This is Step 1 of the proof of Proposition 3.4, obtained from the characterisation $\langle \mathbf{u} \times \mathbf{v}, \mathbf{w} \rangle = \det[\mathbf{u} \ \mathbf{v} \ \mathbf{w}]$ and the multiplicativity of the determinant. Section 28.2 draws from it the matrix form needed here (Lemma 28.3).

28.2. The skew-symmetric matrix of the axis

The entire matrix treatment of rotations rests on a single matrix: the one representing the cross product with a fixed vector.

Definition 28.2: Skew-symmetric matrix associated with a vector. To $\mathbf{u} = (u_1, u_2, u_3)^\top \in \mathbb{R}^3$ one associates the matrix

$$[\mathbf{u}]_\times = \begin{pmatrix} 0 & -u_3 & u_2 \\ u_3 & 0 & -u_1 \\ -u_2 & u_1 & 0 \end{pmatrix} \in \mathbb{R}^{3 \times 3},$$

called the **skew-symmetric matrix of the axis** (or *hat map*). When $\mathbf{u}$ is a unit vector one writes $K = [\mathbf{u}]_\times$ for brevity.

Lemma 28.1: Elementary properties of the hat map. For every $\mathbf{u}, \mathbf{v} \in \mathbb{R}^3$:

- (i) $[\mathbf{u}]_\times \mathbf{v} = \mathbf{u} \times \mathbf{v}$;
- (ii) $[\mathbf{u}]_\times^\top = -[\mathbf{u}]_\times$, and conversely every real 3×3 skew-symmetric matrix is $[\mathbf{u}]_\times$ for a unique $\mathbf{u}$;
- (iii) $[\mathbf{u}]_\times \mathbf{u} = \mathbf{0}$;
- (iv) $[\mathbf{u}]_\times^2 = \mathbf{u}\mathbf{u}^\top - \|\mathbf{u}\|^2 I$.

Proof. Step 1 — (i). The cross product, component by component, is $\mathbf{u} \times \mathbf{v} = (u_2v_3 - u_3v_2, u_3v_1 - u_1v_3, u_1v_2 - u_2v_1)^\top$. On the other hand

$$[\mathbf{u}]_\times \mathbf{v} = \begin{pmatrix} 0 & -u_3 & u_2 \\ u_3 & 0 & -u_1 \\ -u_2 & u_1 & 0 \end{pmatrix} \begin{pmatrix} v_1 \\ v_2 \\ v_3 \end{pmatrix} = \begin{pmatrix} -u_3v_2 + u_2v_3 \\ u_3v_1 - u_1v_3 \\ -u_2v_1 + u_1v_2 \end{pmatrix},$$

which is the same vector.

Step 2 — (ii). Transposition swaps the entry at position $(1, 2)$, namely $-u_3$, with the one at position $(2, 1)$, namely u_3 , and likewise for the other two off-diagonal pairs; the diagonal is zero. Hence $[\mathbf{u}]_\times^\top = -[\mathbf{u}]_\times$. Conversely, let S be skew-symmetric: $S^\top = -S$ forces $s_{ii} = -s_{ii}$, that is $s_{ii} = 0$, and $s_{ji} = -s_{ij}$. Setting $u_1 = s_{32}$, $u_2 = s_{13}$, $u_3 = s_{21}$ gives $S = [\mathbf{u}]_\times$; and this choice is forced by comparing entries, hence $\mathbf{u}$ is unique.

Step 3 — (iii). By (i), $[\mathbf{u}]_\times \mathbf{u} = \mathbf{u} \times \mathbf{u} = \mathbf{0}$, because the cross product is alternating.

Step 4 — (iv). By (i), $[\mathbf{u}]_\times^2 \mathbf{v} = \mathbf{u} \times (\mathbf{u} \times \mathbf{v})$. The double cross product identity $\mathbf{a} \times (\mathbf{b} \times \mathbf{c}) = \mathbf{b}(\mathbf{a} \cdot \mathbf{c}) - \mathbf{c}(\mathbf{a} \cdot \mathbf{b})$ (also used in Chapter 3) gives

$$\mathbf{u} \times (\mathbf{u} \times \mathbf{v}) = \mathbf{u}(\mathbf{u} \cdot \mathbf{v}) - \mathbf{v}(\mathbf{u} \cdot \mathbf{u}) = (\mathbf{u}\mathbf{u}^\top) \mathbf{v} - \|\mathbf{u}\|^2 \mathbf{v},$$

having observed that $\mathbf{u}(\mathbf{u} \cdot \mathbf{v}) = \mathbf{u}(\mathbf{u}^\top \mathbf{v}) = (\mathbf{u}\mathbf{u}^\top) \mathbf{v}$ by associativity of matrix multiplication. Since $\mathbf{v}$ is arbitrary, the two matrices coincide. $\square$

Lemma 28.2: Recurrence of the powers. Let $\mathbf{u}$ be a unit vector and $K = [\mathbf{u}]_\times$. Then

$$K^3 = -K,$$

and more generally, for every integer $m \geq 0$,

$$K^{2m+1} = (-1)^m K, \quad K^{2m+2} = (-1)^m K^2.$$

Proof. Step 1 — the cube. By Lemma 28.1(iv) with $\|\mathbf{u}\| = 1$ one has $K^2 = \mathbf{u}\mathbf{u}^\top - I$. Hence

$$K^3 = K \cdot K^2 = K(\mathbf{u}\mathbf{u}^\top - I) = (K\mathbf{u})\mathbf{u}^\top - K = \mathbf{0} \cdot \mathbf{u}^\top - K = -K,$$

where $K\mathbf{u} = \mathbf{0}$ is Lemma 28.1(iii).

Step 2 — induction on the odd powers. For $m = 0$ the claim $K^1 = (-1)^0 K$ is trivial. Assuming $K^{2m+1} = (-1)^m K$, one multiplies by K^2 :

$$K^{2m+3} = K^{2m+1} K^2 = (-1)^m K K^2 = (-1)^m K^3 = (-1)^m (-K) = (-1)^{m+1} K,$$

using Step 1. The induction principle concludes.

Step 3 — even powers. Multiplying the identity of Step 2 by K : $K^{2m+2} = K^{2m+1} K = (-1)^m K \cdot K = (-1)^m K^2$.

Step 4 — reading. The recurrence says that the space spanned by I , K , K^2 is closed under multiplication by K : any power series in K reduces to a combination of these three matrices. This is exactly what makes Rodrigues' formula *closed*, that is free of residual series. $\square$

Lemma 28.3: The hat map under conjugation. For every $A \in SO(3)$ and every $\mathbf{b} \in \mathbb{R}^3$ one has

$$A[\mathbf{b}]_\times A^\top = [A\mathbf{b}]_\times.$$

Proof. Step 1. Let $\mathbf{x} \in \mathbb{R}^3$ be arbitrary. By Lemma 28.1(i),

$$A[\mathbf{b}]_\times A^\top \mathbf{x} = A(\mathbf{b} \times (A^\top \mathbf{x})).$$

Step 2. By invariance (28.1) of the cross product under $SO(3)$ (Proposition 3.4, Step 1),

$$A(\mathbf{b} \times (A^\top \mathbf{x})) = (A\mathbf{b}) \times (AA^\top \mathbf{x}) = (A\mathbf{b}) \times \mathbf{x} = [A\mathbf{b}]_\times \mathbf{x},$$

since $AA^\top = I$.

Step 3. The two matrices $A[\mathbf{b}]_\times A^\top$ and $[A\mathbf{b}]_\times$ act the same way on every $\mathbf{x} \in \mathbb{R}^3$, hence they coincide. $\square$

Proposition 28.2: The hat map is a linear isomorphism. The map $\mathbf{u} \mapsto [\mathbf{u}]_\times$ is a linear isomorphism from $\mathbb{R}^3$ onto the space $\mathfrak{so}(3)$ of real 3×3 skew-symmetric matrices, which therefore has dimension 3.

Proof. **Step 1 — linearity.** Every entry of $[\mathbf{u}]_\times$ is 0 or $\pm u_i$: it is a linear function of the components of $\mathbf{u}$. Hence $[\alpha\mathbf{u} + \beta\mathbf{v}]_\times = \alpha[\mathbf{u}]_\times + \beta[\mathbf{v}]_\times$.

Step 2 — injectivity. If $[\mathbf{u}]_\times = 0$, then the entries at positions (3, 2), (1, 3), (2, 1) give $u_1 = u_2 = u_3 = 0$.

Step 3 — surjectivity onto $\mathfrak{so}(3)$. This is the second half of Lemma 28.1(ii): every skew-symmetric matrix is $[\mathbf{u}]_\times$ for a suitable $\mathbf{u}$. Hence the map is an isomorphism and $\dim \mathfrak{so}(3) = \dim \mathbb{R}^3 = 3$.

Step 4 — reading. The dimension 3 is the number of degrees of freedom of the orientation of a rigid body: three, not four nor nine. The space $\mathfrak{so}(3)$ is the Lie algebra of the group $SO(3)$, the subject of Chapter 29; here it is needed only as the space of “generators” of rotations. $\square$

28.3. Rodrigues' formula

Figure 28.1: Rodrigues' formula seen in the plane orthogonal to the axis. If $\mathbf{u}$ is the unit vector of the axis and $\mathbf{v}_\perp \neq \mathbf{0}$ is the component of $\mathbf{v}$ orthogonal to $\mathbf{u}$, the pair $\mathbf{w} = \mathbf{v}_\perp / r$, $\mathbf{w}' = \mathbf{u} \times \mathbf{w}$ (with $r = \|\mathbf{v}_\perp\|$) is an orthonormal basis of $\mathbf{u}^\perp$ positively oriented as seen from the tip of $\mathbf{u}$. The rotation sends $\mathbf{v}_\perp$ to $r \cos \theta \mathbf{w} + r \sin \theta \mathbf{w}'$: it is a plane rotation, and that is all that Rodrigues' formula states. The coordinates drawn are $r = 3$ and $\theta = 40^\circ$, so that $r \cos \theta = 3 \times 0.766044 = 2.298133$ and $r \sin \theta = 3 \times 0.642788 = 1.928363$.

Figure 28.1 anticipates the geometric content of what follows: a rotation of space is a *plane*

rotation in the plane orthogonal to the axis, and the whole of Rodrigues' formula consists in writing that plane in an orthonormal basis built from the vector to be rotated.

In Chapter 11 Rodrigues' formula appears in its *vector* form (Exercise S5 of that chapter), deduced from the quaternion calculus. Here it is proved in *matrix* form, independently and without quaternions, and identified with the exponential of a skew-symmetric matrix: this is the form algorithms use, because it produces directly the nine entries of R .

Theorem 28.2: Rodrigues' formula. Let $\mathbf{u} \in \mathbb{R}^3$ be a unit vector, $K = [\mathbf{u}]_{\times}$ and $\theta \in \mathbb{R}$. Set

$$R(\mathbf{u}, \theta) = I + \sin \theta K + (1 - \cos \theta) K^2.$$

Then:

- (i) $R(\mathbf{u}, \theta) = e^{\theta K} = \sum_{n \geq 0} \frac{\theta^n K^n}{n!}$;
- (ii) $R(\mathbf{u}, \theta) \in SO(3)$, fixes $\mathbf{u}$ and is the rotation through angle θ about $\mathbf{u}$, that is in the positive orthonormal basis $\{\mathbf{u}, \mathbf{w}, \mathbf{u} \times \mathbf{w}\}$ (with $\mathbf{w}$ a unit vector orthogonal to $\mathbf{u}$) it has

$$\text{matrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & -\sin \theta \\ 0 & \sin \theta & \cos \theta \end{pmatrix};$$

- (iii) in vector form, for every $\mathbf{v} \in \mathbb{R}^3$,

$$R(\mathbf{u}, \theta)\mathbf{v} = \cos \theta \mathbf{v} + \sin \theta (\mathbf{u} \times \mathbf{v}) + (1 - \cos \theta) \langle \mathbf{u}, \mathbf{v} \rangle \mathbf{u}.$$

Proof. Step 1 — the exponential series converges and can be reordered. The operator norm is submultiplicative, hence $\|\theta^n K^n / n!\| \leq (|\theta| \|K\|)^n / n!$ and the series $\sum_n \theta^n K^n / n!$ converges absolutely (entry by entry) for every θ . An absolutely convergent series can be reordered and regrouped at will: this is what will be done in Step 3.

Step 2 — separating the powers. One isolates the term $n = 0$ and then the terms of odd and even index, writing $n = 2m + 1$ and $n = 2m + 2$ with $m \geq 0$:

$$e^{\theta K} = I + \sum_{m \geq 0} \frac{\theta^{2m+1}}{(2m+1)!} K^{2m+1} + \sum_{m \geq 0} \frac{\theta^{2m+2}}{(2m+2)!} K^{2m+2}.$$

Every integer $n \geq 1$ is of exactly one of the two forms, so no term is counted twice or omitted.

Step 3 — using the recurrence. By Lemma 28.2, $K^{2m+1} = (-1)^m K$ and $K^{2m+2} = (-1)^m K^2$. The two sums become

$$\left(\sum_{m \geq 0} \frac{(-1)^m \theta^{2m+1}}{(2m+1)!} \right) K + \left(\sum_{m \geq 0} \frac{(-1)^m \theta^{2m+2}}{(2m+2)!} \right) K^2.$$

The first series is the expansion of $\sin \theta$. The second is

$$\sum_{m \geq 0} \frac{(-1)^m \theta^{2m+2}}{(2m+2)!} = - \sum_{m \geq 0} \frac{(-1)^{m+1} \theta^{2(m+1)}}{(2(m+1))!} = - \sum_{p \geq 1} \frac{(-1)^p \theta^{2p}}{(2p)!} = -(\cos \theta - 1) = 1 - \cos \theta,$$

having set $p = m + 1$ and recognised in $\sum_{p \geq 0} (-1)^p \theta^{2p} / (2p)!$ the expansion of $\cos \theta$, from which the term $p = 0$, namely 1, has been removed. Hence $e^{\theta K} = I + \sin \theta K + (1 - \cos \theta) K^2$: this is (i).

Step 4 — the axis is fixed. By Lemma 28.1(iii), $K\mathbf{u} = \mathbf{0}$, and hence also $K^2\mathbf{u} = K(K\mathbf{u}) = \mathbf{0}$. Therefore $R\mathbf{u} = \mathbf{u} + \sin \theta \cdot \mathbf{0} + (1 - \cos \theta) \cdot \mathbf{0} = \mathbf{u}$.

Step 5 — action on the orthogonal plane. Let $\mathbf{w}$ be a unit vector orthogonal to $\mathbf{u}$ and $\mathbf{w}' = \mathbf{u} \times \mathbf{w}$. Then $\mathbf{w}'$ is orthogonal to both $\mathbf{u}$ and $\mathbf{w}$, and $\|\mathbf{w}'\| = \|\mathbf{u}\| \|\mathbf{w}\| \sin 90^\circ = 1$ by Lagrange's identity (Lemma 10.1) with $\langle \mathbf{u}, \mathbf{w} \rangle = 0$. Hence $\{\mathbf{u}, \mathbf{w}, \mathbf{w}'\}$ is orthonormal;

and it is positively oriented because $\det[\mathbf{u} \ \mathbf{w} \ \mathbf{w}'] = \langle \mathbf{u} \times \mathbf{w}, \mathbf{w}' \rangle = \langle \mathbf{w}', \mathbf{w}' \rangle = 1 > 0$. Now $K\mathbf{w} = \mathbf{u} \times \mathbf{w} = \mathbf{w}'$ and, by Lemma 28.1(iv) with $\|\mathbf{u}\| = 1$,

$$K^2\mathbf{w} = (\mathbf{u}\mathbf{u}^\top - I)\mathbf{w} = \mathbf{u} \langle \mathbf{u}, \mathbf{w} \rangle - \mathbf{w} = -\mathbf{w},$$

and likewise $K^2\mathbf{w}' = -\mathbf{w}'$, whence $K\mathbf{w}' = K(K\mathbf{w}) = K^2\mathbf{w} = -\mathbf{w}$. Substituting:

$$R\mathbf{w} = \mathbf{w} + \sin \theta \mathbf{w}' + (1 - \cos \theta)(-\mathbf{w}) = \cos \theta \mathbf{w} + \sin \theta \mathbf{w}',$$

$$R\mathbf{w}' = \mathbf{w}' + \sin \theta (-\mathbf{w}) + (1 - \cos \theta)(-\mathbf{w}') = -\sin \theta \mathbf{w} + \cos \theta \mathbf{w}'.$$

Step 6 — conclusion of (ii). Steps 4 and 5 say that, in the positive orthonormal basis $\{\mathbf{u}, \mathbf{w}, \mathbf{w}'\}$, the matrix of R is the one in the statement. That matrix is orthogonal with determinant $1 \cdot (\cos^2 \theta + \sin^2 \theta) = 1$; since the change of basis is orthogonal and direct, R is orthogonal with determinant $+1$, that is $R \in SO(3)$. And by Step 4 of the proof of Theorem 11.8, a matrix that in a positive orthonormal basis $\{\mathbf{u}, \mathbf{w}, \mathbf{w}'\}$ has that form is precisely the rotation through angle θ about $\mathbf{u}$: in the plane $\mathbf{u}^\perp$ it sends $\mathbf{w}$ to $\cos \theta \mathbf{w} + \sin \theta \mathbf{w}'$, that is it rotates by θ counterclockwise as seen from the tip of $\mathbf{u}$.

Step 7 — the vector form (iii). For every $\mathbf{v}$, using again $K^2 = \mathbf{u}\mathbf{u}^\top - I$ and $K\mathbf{v} = \mathbf{u} \times \mathbf{v}$:

$$R\mathbf{v} = \mathbf{v} + \sin \theta (\mathbf{u} \times \mathbf{v}) + (1 - \cos \theta)(\langle \mathbf{u}, \mathbf{v} \rangle \mathbf{u} - \mathbf{v}) = \cos \theta \mathbf{v} + \sin \theta (\mathbf{u} \times \mathbf{v}) + (1 - \cos \theta) \langle \mathbf{u}, \mathbf{v} \rangle \mathbf{u}.$$

This is the vector form obtained by another route in Exercise S5 of Chapter 11: the two proofs are independent and check each other.

Step 8 — one-parameter group. From (i) and the fact that θK and $\theta' K$ commute it follows that $R(\mathbf{u}, \theta)R(\mathbf{u}, \theta') = e^{\theta K} e^{\theta' K} = e^{(\theta+\theta')K} = R(\mathbf{u}, \theta + \theta')$: the rotations about a fixed axis form a commutative group isomorphic to $SO(2)$, that is to the circle (Theorem 11.7). The non-commutativity of Theorem 28.1 arises only from comparing different axes. $\square$

A particular case, used constantly in what follows, is that of the coordinate axes. For $\mathbf{u} = \mathbf{e}_3$ one has $K = \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$ and $K^2 = \mathbf{e}_3 \mathbf{e}_3^\top - I = \begin{pmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}$, hence

$$R(\mathbf{e}_3, \alpha) = I + \sin \alpha K + (1 - \cos \alpha)K^2 = \begin{pmatrix} \cos \alpha & -\sin \alpha & 0 \\ \sin \alpha & \cos \alpha & 0 \\ 0 & 0 & 1 \end{pmatrix} = R_z(\alpha),$$

and by the same computation $R(\mathbf{e}_1, \alpha) = R_x(\alpha)$ and $R(\mathbf{e}_2, \alpha) = R_y(\alpha)$: the elementary rotations of Definition 28.1 are the special cases of Rodrigues' formula with a coordinate axis, and in particular $R_*(\alpha) = e^{\alpha[\mathbf{e}_*] \times}$.

Corollary 28.1: Trace and skew-symmetric part. Let $R = R(\mathbf{u}, \theta)$ as in Theorem 28.2. Then

$$\operatorname{tr} R = 1 + 2 \cos \theta, \quad R - R^\top = 2 \sin \theta K, \quad R + R^\top = 2I + 2(1 - \cos \theta)K^2.$$

Proof. **Step 1 — the trace.** The trace is linear. One has $\operatorname{tr} I = 3$; $\operatorname{tr} K = 0$ because the diagonal of $[\mathbf{u}]_\times$ is zero; and, by Lemma 28.1(iv) with $\|\mathbf{u}\| = 1$, $\operatorname{tr} K^2 = \operatorname{tr}(\mathbf{u}\mathbf{u}^\top) - \operatorname{tr} I = \|\mathbf{u}\|^2 - 3 = 1 - 3 = -2$. Hence

$$\operatorname{tr} R = 3 + \sin \theta \cdot 0 + (1 - \cos \theta)(-2) = 3 - 2 + 2 \cos \theta = 1 + 2 \cos \theta,$$

in agreement with Theorem 11.8. $\checkmark$

Step 2 — skew-symmetric and symmetric part. By Lemma 28.1(ii), $K^\top = -K$; consequently $(K^2)^\top = (K^\top)^2 = (-K)^2 = K^2$, that is K^2 is symmetric. Transposing Rodrigues'

formula,

$$R^\top = I - \sin \theta K + (1 - \cos \theta)K^2,$$

and subtracting or adding gives the two identities of the statement. $\square$

Corollary 28.2: Conjugation of a rotation. For every $A \in SO(3)$, every unit vector $\mathbf{u}$ and every θ ,

$$A R(\mathbf{u}, \theta) A^\top = R(A\mathbf{u}, \theta).$$

In words: conjugating a rotation by A means rotating its axis by A , leaving the angle unchanged.

Proof. Step 1. Let $K = [\mathbf{u}]_\times$. Since $A^\top A = I$, $AK^2A^\top = AK A^\top A K A^\top = (AK A^\top)^2$; and by Lemma 28.3, $AK A^\top = [A\mathbf{u}]_\times$.

Step 2. Conjugating Rodrigues' formula, and using $AIA^\top = I$ and linearity of conjugation:

$$A R(\mathbf{u}, \theta) A^\top = I + \sin \theta (AK A^\top) + (1 - \cos \theta)(AK A^\top)^2 = I + \sin \theta [A\mathbf{u}]_\times + (1 - \cos \theta)[A\mathbf{u}]_\times^2.$$

Since $A\mathbf{u}$ is still a unit vector (A is orthogonal), the right-hand side is $R(A\mathbf{u}, \theta)$ by Theorem 28.2. $\square$

The following corollary is the inverse conversion — from matrix to axis and angle — and it is here that the two degenerate cases that will accompany the whole chapter first appear.

Corollary 28.3: From matrix to axis–angle, with the degenerate cases. Let $R \in SO(3)$. Set $\theta = \arccos((\operatorname{tr} R - 1)/2) \in [0, \pi]$. Then:

(i) if $0 < \theta < \pi$, the axis is uniquely determined by

$$\mathbf{u} = \frac{1}{2 \sin \theta} \begin{pmatrix} R_{32} - R_{23} \\ R_{13} - R_{31} \\ R_{21} - R_{12} \end{pmatrix},$$

and $R = R(\mathbf{u}, \theta)$;

(ii) if $\theta = 0$, then $R = I$ and every unit vector $\mathbf{u}$ satisfies $R = R(\mathbf{u}, 0)$: the axis is undetermined;

(iii) if $\theta = \pi$, then $R = R^\top$ and $\mathbf{u}\mathbf{u}^\top = (R + I)/2$; choosing the index i that maximises R_{ii} one has $u_i = \sqrt{(R_{ii} + 1)/2} > 0$ and $u_j = R_{ij}/(2u_i)$ for $j \neq i$. The axis is determined up to sign, and $R(\mathbf{u}, \pi) = R(-\mathbf{u}, \pi)$.

Proof. Step 0 — every rotation is an $R(\mathbf{n}, \vartheta)$. If $R = I$ take $\vartheta = 0$ and $\mathbf{n}$ arbitrary. If $R \neq I$, by Theorem 11.8 there is a unit vector $\mathbf{n}$ with $R\mathbf{n} = \mathbf{n}$ and, choosing an orthonormal basis $\{\mathbf{n}, \mathbf{e}'_1, \mathbf{e}'_2\}$ with $\mathbf{e}'_1, \mathbf{e}'_2$ a basis of $\mathbf{n}^\perp$, the matrix of R in that basis is the block form of Step 4 of that proof, with some angle ϑ . The basis may be assumed *positive*: if $\det[\mathbf{n} \ \mathbf{e}'_1 \ \mathbf{e}'_2] = -1$ it suffices to swap $\mathbf{e}'_1$ with $\mathbf{e}'_2$, which changes ϑ into $-\vartheta$ — immaterial, because Step 5 shows that the sign of the angle is absorbed by changing the sign of the axis. With the positive basis, $\mathbf{e}'_2 = \mathbf{n} \times \mathbf{e}'_1$ and by Theorem 28.2(ii) also $R(\mathbf{n}, \vartheta)$ has, in the *same* basis, the *same* matrix; two endomorphisms with the same matrix in a basis coincide, hence $R = R(\mathbf{n}, \vartheta)$.

Step 1 — θ is well defined and equals $\theta = \pm\vartheta$ modulo 2π . By Corollary 28.1, $\operatorname{tr} R = 1 + 2 \cos \vartheta$, hence $(\operatorname{tr} R - 1)/2 = \cos \vartheta \in [-1, 1]$ and the arccosine is defined; moreover $\cos \theta = \cos \vartheta$ with $\theta \in [0, \pi]$. By Step 5, replacing $\mathbf{n}$ with $-\mathbf{n}$ if necessary one may always assume $\vartheta = \theta \in [0, \pi]$; this is assumed in what follows and one writes $\mathbf{u} = \mathbf{n}$.

Step 2 — case $0 < \theta < \pi$. Then $\sin \theta > 0$. By Corollary 28.1 applied to $R = R(\mathbf{u}, \theta)$ one has $R - R^\top = 2 \sin \theta [\mathbf{u}]_\times$, that is $[\mathbf{u}]_\times = (R - R^\top)/(2 \sin \theta)$. Reading the entries of $[\mathbf{u}]_\times$ at

positions $(3, 2)$, $(1, 3)$, $(2, 1)$ — which equal respectively u_1 , u_2 , u_3 by Definition 28.2 — gives the formula of the statement, and $\mathbf{u}$ is a unit vector, being the axis supplied by Theorem 11.8. Uniqueness of the axis for $R \neq I$ is Step 5 of that proof; and with $\theta \in (0, \pi)$ fixed the sign is no longer free, because $R(-\mathbf{u}, \theta) \neq R(\mathbf{u}, \theta)$ (their skew-symmetric parts are opposite and nonzero).

Step 3 — case $\theta = 0$. Then $\text{tr } R = 3$; but $\text{tr } R = 1 + 2 \cos \vartheta$ forces $\cos \vartheta = 1$, that is $\vartheta \in 2\pi\mathbb{Z}$, and Rodrigues' formula gives $R = I + 0 \cdot K + 0 \cdot K^2 = I$ for any axis whatsoever. Consistently, $R - R^\top = 0$ carries no information about the axis: the axis-angle parametrisation is singular at the identity, as already observed for the equivalent-axis representation.

Step 4 — case $\theta = \pi$. Then $\sin \theta = 0$ and $R - R^\top = 0$: the matrix is symmetric and Step 2 does not apply. But $\cos \theta = -1$, so Rodrigues' formula gives

$$R = I + 0 \cdot K + 2K^2 = I + 2(\mathbf{u}\mathbf{u}^\top - I) = 2\mathbf{u}\mathbf{u}^\top - I,$$

whence $\mathbf{u}\mathbf{u}^\top = (R + I)/2$. Comparing entries: $u_i u_j = (R_{ij} + \delta_{ij})/2$, and in particular $u_i^2 = (R_{ii} + 1)/2$. Since $\text{tr } R = 1 + 2 \cos \pi = -1$, the diagonal has sum -1 and its maximum satisfies $R_{ii} \geq -1/3$, hence $u_i^2 \geq 1/3 > 0$: the square root can be extracted without division by zero, and this is the numerically most stable choice. Once the sign $u_i > 0$ is fixed, the other components follow from $u_i u_j = R_{ij}/2$. The substitution $\mathbf{u} \mapsto -\mathbf{u}$ leaves $\mathbf{u}\mathbf{u}^\top$, hence R , unchanged: the axis is determined only up to sign.

Step 5 — why $\theta \in [0, \pi]$ suffices. If $\vartheta \in (\pi, 2\pi)$, note that $R(\mathbf{u}, \vartheta) = R(-\mathbf{u}, 2\pi - \vartheta)$: indeed replacing $\mathbf{u}$ with $-\mathbf{u}$ changes K into $-K$ (linearity of the hat map, Proposition 28.2) while K^2 stays unchanged, and $\sin(2\pi - \vartheta) = -\sin \vartheta$ while $\cos(2\pi - \vartheta) = \cos \vartheta$; the two terms whose sign is changed compensate one another. Hence every rotation can be written with $\theta \in [0, \pi]$, and this is the normalisation adopted in the chapter. $\square$

Example 28.1: An exact case: 120° about the diagonal of the cube. Rodrigues' formula is applied with $\mathbf{u} = (1, 1, 1)^\top / \sqrt{3}$ and $\theta = 120^\circ$. The result is an integer matrix, and this makes the case ideal for a hand check.

Step 1 — the skew-symmetric matrix. By Definition 28.2,

$$K = [\mathbf{u}]_\times = \frac{1}{\sqrt{3}} \begin{pmatrix} 0 & -1 & 1 \\ 1 & 0 & -1 \\ -1 & 1 & 0 \end{pmatrix}.$$

Step 2 — the square. By Lemma 28.1(iv), since $\mathbf{u}\mathbf{u}^\top = \frac{1}{3} \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}$,

$$K^2 = \mathbf{u}\mathbf{u}^\top - I = \frac{1}{3} \begin{pmatrix} -2 & 1 & 1 \\ 1 & -2 & 1 \\ 1 & 1 & -2 \end{pmatrix}.$$

Step 3 — the coefficients. $\sin 120^\circ = \frac{\sqrt{3}}{2}$ and $\cos 120^\circ = -\frac{1}{2}$, hence $1 - \cos \theta = \frac{3}{2}$. Thus

$$\sin \theta K = \frac{\sqrt{3}}{2} \cdot \frac{1}{\sqrt{3}} \begin{pmatrix} 0 & -1 & 1 \\ 1 & 0 & -1 \\ -1 & 1 & 0 \end{pmatrix} = \frac{1}{2} \begin{pmatrix} 0 & -1 & 1 \\ 1 & 0 & -1 \\ -1 & 1 & 0 \end{pmatrix},$$

$$(1 - \cos \theta)K^2 = \frac{3}{2} \cdot \frac{1}{3} \begin{pmatrix} -2 & 1 & 1 \\ 1 & -2 & 1 \\ 1 & 1 & -2 \end{pmatrix} = \frac{1}{2} \begin{pmatrix} -2 & 1 & 1 \\ 1 & -2 & 1 \\ 1 & 1 & -2 \end{pmatrix}.$$

Note that the factor $\sqrt{3}$ cancels: this is why the result is an integer.

Step 4 — the sum.

$$R = I + \frac{1}{2} \begin{pmatrix} 0 & -1 & 1 \\ 1 & 0 & -1 \\ -1 & 1 & 0 \end{pmatrix} + \frac{1}{2} \begin{pmatrix} -2 & 1 & 1 \\ 1 & -2 & 1 \\ 1 & 1 & -2 \end{pmatrix} = I + \frac{1}{2} \begin{pmatrix} -2 & 0 & 2 \\ 2 & -2 & 0 \\ 0 & 2 & -2 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$

Step 5 — reading. The resulting matrix sends $\mathbf{e}_1 \mapsto \mathbf{e}_2$, $\mathbf{e}_2 \mapsto \mathbf{e}_3$, $\mathbf{e}_3 \mapsto \mathbf{e}_1$: it is the cyclic permutation of the axes. That this is a rotation of 120° about the diagonal $(1, 1, 1)$ of the cube is also seen geometrically: the diagonal is the only axis that cyclically permutes the three edges leaving the vertex, and a third of a turn suffices to do it.

Step 6 — three independent checks. (a) $\text{tr } R = 0 + 0 + 0 = 0$, while $1 + 2 \cos 120^\circ = 1 - 1 = 0$: consistent with Corollary 28.1. ✓ (b) $R^3 = I$, as it must be because $3 \times 120^\circ = 360^\circ$; and indeed applying the cyclic permutation three times each axis returns to its place. ✓ (c) $R\mathbf{u} = \mathbf{u}$: adding the columns, $R(1, 1, 1)^\top = (1, 1, 1)^\top$. ✓ The computation was repeated in `numpy`, building K , K^2 and R from the numerical values of $\sin 120^\circ$ and $\cos 120^\circ$: one obtains the integer matrix with maximum deviation 1.1×10^{-16} . ✓

Example 28.2: The axes of the non-commutativity counterexample. $A = R_z(90^\circ)R_x(90^\circ)$ and $B = R_x(90^\circ)R_z(90^\circ)$ of Theorem 28.1 are taken up again and their axis and angle computed with Corollary 28.3.

Step 1 — the angles. $\text{tr } A = 0 + 0 + 0 = 0$ and $\text{tr } B = 0 + 0 + 0 = 0$. Hence for both $\cos \theta = (0 - 1)/2 = -\frac{1}{2}$ and $\theta = 120^\circ$, with $\sin \theta = \frac{\sqrt{3}}{2}$ and $2 \sin \theta = \sqrt{3}$.

Step 2 — the axis of A . From $A = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$ one reads $A_{32} - A_{23} = 1 - 0 = 1$, $A_{13} - A_{31} = 1 - 0 = 1$, $A_{21} - A_{12} = 1 - 0 = 1$, hence

$$\mathbf{u}_A = \frac{1}{\sqrt{3}}(1, 1, 1)^\top.$$

This is the diagonal of the cube of Example 28.1: indeed the two matrices coincide. ✓

Step 3 — the axis of B . From $B = \begin{pmatrix} 0 & -1 & 0 \\ 0 & 0 & -1 \\ 1 & 0 & 0 \end{pmatrix}$ one reads $B_{32} - B_{23} = 0 - (-1) = 1$, $B_{13} - B_{31} = 0 - 1 = -1$, $B_{21} - B_{12} = 0 - (-1) = 1$, hence

$$\mathbf{u}_B = \frac{1}{\sqrt{3}}(1, -1, 1)^\top.$$

Step 4 — reading. Reversing the order of two quarter-turn rotations does not change the resulting *angle*, which remains 120° , but changes its *axis*: from one diagonal of the cube to another. The non-commutativity of $SO(3)$ is entirely this, and it is not a defect of matrices: it is a property of space.

Step 5 — independent check. Reconstructing with Rodrigues' formula $R(\mathbf{u}_A, 120^\circ)$ and $R(\mathbf{u}_B, 120^\circ)$ in `numpy` recovers A and B with maximum deviation 1.1×10^{-15} ; and the angles computed from $\arccos((\text{tr} - 1)/2)$ both equal 120.000000° . ✓

Example 28.3: A complete numerical case and the inverse conversion. Take $\mathbf{u} = \frac{1}{3}(2, -1, 2)^\top$ (a unit vector, because $2^2 + 1^2 + 2^2 = 9$) and $\theta = 40^\circ$. *Convention on digits:* all values are computed in double precision and rounded to the seventh decimal digit only for printing; adding the printed values may therefore give a difference of one unit in the last digit.

Step 1 — the matrices.

$$K = \frac{1}{3} \begin{pmatrix} 0 & -2 & -1 \\ 2 & 0 & -2 \\ 1 & 2 & 0 \end{pmatrix}, \quad K^2 = \mathbf{u}\mathbf{u}^\top - I = \frac{1}{9} \begin{pmatrix} -5 & -2 & 4 \\ -2 & -8 & -2 \\ 4 & -2 & -5 \end{pmatrix}.$$

Step 2 — the coefficients. $\sin 40^\circ = 0.6427876$, $\cos 40^\circ = 0.7660444$, $1 - \cos 40^\circ = 0.2339556$.

Step 3 — the rotation matrix. Summing $I + 0.6427876 K + 0.2339556 K^2$ entry by entry:

$$R = \begin{pmatrix} 0.8700247 & -0.4805152 & -0.1102823 \\ 0.3765349 & 0.7920395 & -0.4805152 \\ 0.3182428 & 0.3765349 & 0.8700247 \end{pmatrix}.$$

For example, $R_{11} = 1 + 0 - 0.2339556 \times \frac{5}{9} = 1 - 0.1299753 = 0.8700247$ and $R_{12} = -0.6427876 \times \frac{2}{3} - 0.2339556 \times \frac{2}{9} = -0.4285251 - 0.0519901 = -0.4805152$.

Step 4 — independent check (trace). $\text{tr } R = 0.8700247 + 0.7920395 + 0.8700247 = 2.5320889$, while $1 + 2 \cos 40^\circ = 1 + 1.5320889 = 2.5320889$: they agree to seven decimals (Corollary 28.1). ✓

Step 5 — independent check (axis). $R\mathbf{u} = \mathbf{u}$: the first component is $0.8700247 \times \frac{2}{3} - 0.4805152 \times (-\frac{1}{3}) - 0.1102823 \times \frac{2}{3} = 0.5800165 + 0.1601717 - 0.0735215 = 0.6666667 = \frac{2}{3}$. ✓

Step 6 — the inverse conversion. With Corollary 28.3(i): $\theta = \arccos(0.7660444) = 40.000000^\circ$; $2 \sin \theta = 1.2855752$; and

$$R_{32} - R_{23} = 0.3765349 + 0.4805152 = 0.8570501,$$

$$R_{13} - R_{31} = -0.1102823 - 0.3182428 = -0.4285251,$$

$$R_{21} - R_{12} = 0.3765349 + 0.4805152 = 0.8570501,$$

whence

$$\mathbf{u} = \frac{(0.8570501, -0.4285251, 0.8570501)^\top}{1.2855752} = (0.6666667, -0.3333333, 0.6666667)^\top,$$

that is $\mathbf{u} = \frac{1}{3}(2, -1, 2)^\top$. ✓

Step 7 — check with the exponential series. Summing in `numpy` the first 60 terms of $\sum_n \theta^n K^n / n!$ gives the same matrix with maximum deviation 1.7×10^{-16} : (i) of Theorem 28.2 is verified numerically as well, and the same check repeated on five different pairs $(\mathbf{u}, \theta)$ (including $\theta = 180^\circ$ and negative θ) gives deviations always below 2.3×10^{-16} . ✓

Step 8 — orthogonality. $R^\top R - I$ has maximum norm 2.3×10^{-16} and $\det R = 1$ up to 10^{-16} : Rodrigues' formula produces orthogonal matrices *by construction*, with no need for re-orthogonalisation. This is why, in an implementation, it is preferable to update the axis and angle and rebuild R , instead of accumulating products of matrices. ✓

***Remark 28.2: Why the formula closes, and what happens in dimension 4.** The reason why the exponential series collapses into only three terms is Lemma 28.2: the minimal polynomial of K divides $\lambda^3 + \lambda = \lambda(\lambda^2 + 1)$, hence I, K, K^2 generate all the powers. In dimension n a skew-symmetric matrix has minimal polynomial of degree up to n , and the exponential can no longer be written with three terms: already in $\mathbb{R}^4$ one needs, in general, the two “rotation angles” of the two invariant planes (see Step 7 of the proof of Theorem 11.8). Rodrigues' formula is thus a privilege of dimension three — the same dimension in which*

the cross product exists, and this is no coincidence: the two things are the same thing seen twice (Proposition 28.2).

28.4. Quaternions: Hamilton's rule

The algebra $\mathbb{H}$ of quaternions is Definition 11.3: $\mathbb{R}^4$ with basis $\{1, i, j, k\}$ and associative product determined by the *fundamental formula*

$$i^2 = j^2 = k^2 = ijk = -1,$$

whence $ij = k$, $jk = i$, $ki = j$ and $ji = -k$, $kj = -i$, $ik = -j$. Here the notation $q = (w, \mathbf{v})$ is adopted, with $w = q_0 \in \mathbb{R}$ and $\mathbf{v} = (q_1, q_2, q_3)^\top \in \mathbb{R}^3$: this is the form in which the formulas become readable, because the product is expressed through the scalar product and the cross product of $\mathbb{R}^3$.

Proposition 28.3: Hamilton's rule in scalar-vector form. Let $p = (a, \mathbf{u})$ and $q = (b, \mathbf{v})$ be quaternions. Then

$$pq = (ab - \langle \mathbf{u}, \mathbf{v} \rangle, \quad a\mathbf{v} + b\mathbf{u} + \mathbf{u} \times \mathbf{v}).$$

Proof. Step 1 — bilinearity. The quaternion product is bilinear by definition (it extends by distributivity from the products of the generators). Writing $p = a + u_1i + u_2j + u_3k$ and $q = b + v_1i + v_2j + v_3k$, the product is the sum of 16 terms, which group into four families.

Step 2 — the terms with at least one real part. The term $a \cdot b$ gives the real ab . The three terms $a \cdot v_\ell e_\ell$ (where $e_1 = i$, $e_2 = j$, $e_3 = k$) give the vector $a\mathbf{v}$, because the real commutes with i, j, k . The three terms $u_\ell e_\ell \cdot b$ give the vector $b\mathbf{u}$.

Step 3 — the three diagonal terms. These are $u_\ell v_\ell e_\ell^2$ with $\ell = 1, 2, 3$, and $e_\ell^2 = -1$: they give the real $-(u_1v_1 + u_2v_2 + u_3v_3) = -\langle \mathbf{u}, \mathbf{v} \rangle$.

Step 4 — the six mixed terms. These are grouped in pairs. For the pair (i, j) : $u_1v_2ij + u_2v_1ji = u_1v_2k - u_2v_1k = (u_1v_2 - u_2v_1)k$, and $u_1v_2 - u_2v_1$ is the third component of $\mathbf{u} \times \mathbf{v}$. For the pair (j, k) : $u_2v_3jk + u_3v_2kj = (u_2v_3 - u_3v_2)i$, the first component of $\mathbf{u} \times \mathbf{v}$. For the pair (k, i) : $u_3v_1ki + u_1v_3ik = (u_3v_1 - u_1v_3)j$, the second component. In total the six terms give the vector $\mathbf{u} \times \mathbf{v}$.

Step 5 — sum. Real part: $ab - \langle \mathbf{u}, \mathbf{v} \rangle$; vector part: $a\mathbf{v} + b\mathbf{u} + \mathbf{u} \times \mathbf{v}$. This is the claim.

Step 6 — reading. The non-commutativity of $\mathbb{H}$ is concentrated in the single term $\mathbf{u} \times \mathbf{v}$, which is antisymmetric: qp has the same real part as pq and vector part $a\mathbf{v} + b\mathbf{u} - \mathbf{u} \times \mathbf{v}$. Hence $pq = qp$ if and only if $\mathbf{u} \times \mathbf{v} = \mathbf{0}$, that is if and only if the vector parts are parallel: two rotations with the same axis commute, and this is exactly Step 8 of the proof of Theorem 28.2.

□

Corollary 28.4: The norm is multiplicative. For all $p, q \in \mathbb{H}$ one has $\|pq\| = \|p\| \|q\|$. In particular the unit quaternions form a multiplicative group, the sphere S^3 .

Proof. Step 1 — expansion. With $p = (a, \mathbf{u})$ and $q = (b, \mathbf{v})$, Proposition 28.3 gives

$$\|pq\|^2 = (ab - \langle \mathbf{u}, \mathbf{v} \rangle)^2 + \|a\mathbf{v} + b\mathbf{u} + \mathbf{u} \times \mathbf{v}\|^2.$$

Step 2 — the first term. $(ab - \langle \mathbf{u}, \mathbf{v} \rangle)^2 = a^2b^2 - 2ab\langle \mathbf{u}, \mathbf{v} \rangle + \langle \mathbf{u}, \mathbf{v} \rangle^2$.

Step 3 — the second term. Expanding the squared norm of a sum of three vectors:

$$a^2\|\mathbf{v}\|^2 + b^2\|\mathbf{u}\|^2 + \|\mathbf{u} \times \mathbf{v}\|^2 + 2ab\langle \mathbf{v}, \mathbf{u} \rangle + 2a\langle \mathbf{v}, \mathbf{u} \times \mathbf{v} \rangle + 2b\langle \mathbf{u}, \mathbf{u} \times \mathbf{v} \rangle.$$

The last two terms are zero, because $\mathbf{u} \times \mathbf{v}$ is orthogonal to both $\mathbf{u}$ and $\mathbf{v}$.

Step 4 — simplification. Adding Steps 2 and 3, the terms $\mp 2ab\langle \mathbf{u}, \mathbf{v} \rangle$ cancel and what remains is

$$\|pq\|^2 = a^2b^2 + a^2\|\mathbf{v}\|^2 + b^2\|\mathbf{u}\|^2 + (\langle \mathbf{u}, \mathbf{v} \rangle^2 + \|\mathbf{u} \times \mathbf{v}\|^2).$$

Step 5 — Lagrange's identity. By Lemma 10.1, $\|\mathbf{u} \times \mathbf{v}\|^2 + \langle \mathbf{u}, \mathbf{v} \rangle^2 = \|\mathbf{u}\|^2\|\mathbf{v}\|^2$. Hence

$$\|pq\|^2 = a^2b^2 + a^2\|\mathbf{v}\|^2 + b^2\|\mathbf{u}\|^2 + \|\mathbf{u}\|^2\|\mathbf{v}\|^2 = (a^2 + \|\mathbf{u}\|^2)(b^2 + \|\mathbf{v}\|^2) = \|p\|^2\|q\|^2.$$

Taking the square root gives the claim. Written out in coordinates, this identity is Euler's *four-square identity*, invoked without proof in Step 1 of the proof of Theorem 11.10: here it is proved.

Step 6 — the group. If $\|p\| = \|q\| = 1$ then $\|pq\| = 1$: the product of unit quaternions is unitary. The unit $(1, \mathbf{0})$ is unitary, and the inverse of a unitary q is $\bar{q}$ (Proposition 28.4), which is also unitary. Hence $S^3 = \{q : \|q\| = 1\}$ is a multiplicative subgroup of $\mathbb{H} \setminus \{0\}$. $\square$

Proposition 28.4: Conjugate and inverse. For $q = (w, \mathbf{v})$ set $\bar{q} = (w, -\mathbf{v})$. Then, for all $p, q \in \mathbb{H}$:

$$\overline{pq} = \bar{q}\bar{p}, \quad q\bar{q} = \bar{q}q = \|q\|^2, \quad q^{-1} = \frac{\bar{q}}{\|q\|^2} \quad (q \neq 0),$$

and in particular $q^{-1} = \bar{q}$ if $\|q\| = 1$.

Proof. **Step 1 — the anti-automorphism.** With $p = (a, \mathbf{u})$, $q = (b, \mathbf{v})$, Proposition 28.3 gives $\overline{pq} = (ab - \langle \mathbf{u}, \mathbf{v} \rangle, -a\mathbf{v} - b\mathbf{u} - \mathbf{u} \times \mathbf{v})$. On the other hand

$$\bar{q}\bar{p} = (b, -\mathbf{v})(a, -\mathbf{u}) = (ba - \langle -\mathbf{v}, -\mathbf{u} \rangle, b(-\mathbf{u}) + a(-\mathbf{v}) + (-\mathbf{v}) \times (-\mathbf{u})),$$

and since $(-\mathbf{v}) \times (-\mathbf{u}) = \mathbf{v} \times \mathbf{u} = -\mathbf{u} \times \mathbf{v}$, the right-hand side equals

$$(ab - \langle \mathbf{u}, \mathbf{v} \rangle, -b\mathbf{u} - a\mathbf{v} - \mathbf{u} \times \mathbf{v}).$$

The two results coincide.

Step 2 — the norm as a product. Again by Proposition 28.3, with $p = q = (w, \mathbf{v})$ and conjugating the second factor:

$$q\bar{q} = (w \cdot w - \langle \mathbf{v}, -\mathbf{v} \rangle, w(-\mathbf{v}) + w\mathbf{v} + \mathbf{v} \times (-\mathbf{v})) = (w^2 + \|\mathbf{v}\|^2, \mathbf{0}) = \|q\|^2,$$

because $\mathbf{v} \times \mathbf{v} = \mathbf{0}$. Exchanging the roles gives $\bar{q}q = \|q\|^2$.

Step 3 — the inverse. If $q \neq 0$ then $\|q\|^2 > 0$ and Step 2 gives $q \cdot \bar{q}/\|q\|^2 = 1 = \bar{q}/\|q\|^2 \cdot q$: this is the definition of inverse. For $\|q\| = 1$ this reduces to $q^{-1} = \bar{q}$. $\square$

Remark 28.3: Why controllers distribute quaternions. Three reasons, all quantitative. (1) Memory: four numbers against nine. (2) Cost of composition: the product of two quaternions has four components, each a sum of four real products: $4 \times 4 = 16$ multiplications. The product of two 3×3 matrices requires $3 \times 3 \times 3 = 27$. (3) Stability: rounding error carries q outside S^3 , and the remedy is dividing by $\|q\|$ — one square root and four divisions. It carries R outside $SO(3)$ instead, and the remedy requires re-orthogonalisation (Gram–Schmidt or polar factorisation), which is far more costly and not unique. The constraint $\|q\| = 1$ is one equation on four parameters; the constraint $R^\top R = I$ is six equations on nine. This is why inertial navigation packages, graphics engines and robotic middleware publish orientation as a unit quaternion and convert to a matrix only at the moment of use.

28.5. Euler parameters and conversions between representations

Definition 28.3: Euler parameters. Given a unit vector $\mathbf{u} \in \mathbb{R}^3$ and $\theta \in \mathbb{R}$, the **Euler parameters** (or *Euler–Rodrigues parameters*) of the rotation $R(\mathbf{u}, \theta)$ are the four numbers

$$e_0 = \cos \frac{\theta}{2}, \quad (e_1, e_2, e_3)^\top = \sin \frac{\theta}{2} \mathbf{u},$$

that is the components of the quaternion $q = (\cos \frac{\theta}{2}, \sin \frac{\theta}{2} \mathbf{u})$. They satisfy the **normalisation constraint**

$$e_0^2 + e_1^2 + e_2^2 + e_3^2 = 1.$$

The constraint is immediate: $e_0^2 + \|(e_1, e_2, e_3)\|^2 = \cos^2 \frac{\theta}{2} + \sin^2 \frac{\theta}{2} \|\mathbf{u}\|^2 = \cos^2 \frac{\theta}{2} + \sin^2 \frac{\theta}{2} = 1$. Four parameters tied by one equation describe a manifold of dimension $4 - 1 = 3$, exactly the degrees of freedom of orientation (Proposition 28.2, Step 4): the count works out, and this is the structural reason why quaternions can be global where three free parameters cannot (Remark 28.7).

Theorem 28.3: From quaternion to rotation matrix. Let $q = (w, \mathbf{v})$ with $\|q\| = 1$ and $\mathbf{v} = (x, y, z)^\top$, and let $\Phi_q(\mathbf{p}) = q \mathbf{p} \bar{q}$ be the map of Theorem 11.10. Then the matrix of Φ_q in the canonical basis is

$$R(q) = (w^2 - \|\mathbf{v}\|^2)I + 2\mathbf{v}\mathbf{v}^\top + 2w[\mathbf{v}]_\times = \begin{pmatrix} 1 - 2(y^2 + z^2) & 2(xy - wz) & 2(xz + wy) \\ 2(xy + wz) & 1 - 2(x^2 + z^2) & 2(yz - wx) \\ 2(xz - wy) & 2(yz + wx) & 1 - 2(x^2 + y^2) \end{pmatrix}. \quad (28.2)$$

If moreover q is the quaternion of the Euler parameters of $(\mathbf{u}, \theta)$ (Definition 28.3), then

$$R(q) = R(\mathbf{u}, \theta) = I + \sin \theta [\mathbf{u}]_\times + (1 - \cos \theta) [\mathbf{u}]_\times^2 :$$

the quaternionic construction and Rodrigues' formula are the same matrix.

Proof. Step 1 — first product. Let $\mathbf{x} \in \mathbb{R}^3$ and let $p = (0, \mathbf{x})$ be the corresponding pure quaternion. By Proposition 28.3,

$$qp = (w, \mathbf{v})(0, \mathbf{x}) = (-\langle \mathbf{v}, \mathbf{x} \rangle, w\mathbf{x} + \mathbf{v} \times \mathbf{x}).$$

Step 2 — second product, real part. Again by the same proposition, with $\bar{q} = (w, -\mathbf{v})$,

$$(qp)\bar{q} = \left(-\langle \mathbf{v}, \mathbf{x} \rangle w - \langle w\mathbf{x} + \mathbf{v} \times \mathbf{x}, -\mathbf{v} \rangle, \cdot \right).$$

The real part equals $-w\langle \mathbf{v}, \mathbf{x} \rangle + w\langle \mathbf{x}, \mathbf{v} \rangle + \langle \mathbf{v} \times \mathbf{x}, \mathbf{v} \rangle = 0$, because $\mathbf{v} \times \mathbf{x} \perp \mathbf{v}$. The result is therefore pure: this recovers Step 2 of the proof of Theorem 11.10, here by a direct route.

Step 3 — second product, vector part.

$$(-\langle \mathbf{v}, \mathbf{x} \rangle)(-\mathbf{v}) + w(w\mathbf{x} + \mathbf{v} \times \mathbf{x}) + (w\mathbf{x} + \mathbf{v} \times \mathbf{x}) \times (-\mathbf{v}).$$

The first term is $\langle \mathbf{v}, \mathbf{x} \rangle \mathbf{v}$; the second is $w^2 \mathbf{x} + w(\mathbf{v} \times \mathbf{x})$; the third, using $\mathbf{a} \times (-\mathbf{b}) = -\mathbf{a} \times \mathbf{b}$ and $\mathbf{x} \times \mathbf{v} = -\mathbf{v} \times \mathbf{x}$, equals $w(\mathbf{v} \times \mathbf{x}) - (\mathbf{v} \times \mathbf{x}) \times \mathbf{v}$.

Step 4 — the double cross product. By the identity already used in Lemma 28.1(iv),

$$(\mathbf{v} \times \mathbf{x}) \times \mathbf{v} = -\mathbf{v} \times (\mathbf{v} \times \mathbf{x}) = -(\mathbf{v}\langle \mathbf{v}, \mathbf{x} \rangle - \mathbf{x}\|\mathbf{v}\|^2) = -\langle \mathbf{v}, \mathbf{x} \rangle \mathbf{v} + \|\mathbf{v}\|^2 \mathbf{x}.$$

Step 5 — sum. Putting together Steps 3 and 4:

$$\Phi_q(\mathbf{x}) = \langle \mathbf{v}, \mathbf{x} \rangle \mathbf{v} + w^2 \mathbf{x} + 2w(\mathbf{v} \times \mathbf{x}) + \langle \mathbf{v}, \mathbf{x} \rangle \mathbf{v} - \|\mathbf{v}\|^2 \mathbf{x} = (w^2 - \|\mathbf{v}\|^2) \mathbf{x} + 2\langle \mathbf{v}, \mathbf{x} \rangle \mathbf{v} + 2w(\mathbf{v} \times \mathbf{x}).$$

Since $\langle \mathbf{v}, \mathbf{x} \rangle \mathbf{v} = (\mathbf{v} \mathbf{v}^\top) \mathbf{x}$ and $\mathbf{v} \times \mathbf{x} = [\mathbf{v}]_\times \mathbf{x}$ (Lemma 28.1(i)), and since $\mathbf{x}$ is arbitrary, the first equality of (28.2) follows.

Step 6 — the entries. On the diagonal, for example, $R_{11} = (w^2 - x^2 - y^2 - z^2) + 2x^2 = w^2 + x^2 - y^2 - z^2$; and using $w^2 + x^2 + y^2 + z^2 = 1$ one has $w^2 + x^2 = 1 - y^2 - z^2$, that is $R_{11} = 1 - 2(y^2 + z^2)$. The other two diagonal entries are identical up to permuting the names.

Off diagonal, $2\mathbf{v}\mathbf{v}^\top$ contributes $2xy$, $2xz$, $2yz$ symmetrically, while $2w[\mathbf{v}]_\times = 2w \begin{pmatrix} 0 & -z & y \\ z & 0 & -x \\ -y & x & 0 \end{pmatrix}$ contributes antisymmetrically: this gives the six entries written in (28.2).

Step 7 — identification with Rodrigues. Substitute $w = \cos \frac{\theta}{2}$, $\mathbf{v} = \sin \frac{\theta}{2} \mathbf{u}$ with $\|\mathbf{u}\| = 1$, and write $K = [\mathbf{u}]_\times$. By the duplication formulas (Volume II, Chapter 1):

$$w^2 - \|\mathbf{v}\|^2 = \cos^2 \frac{\theta}{2} - \sin^2 \frac{\theta}{2} = \cos \theta,$$

$$2\mathbf{v}\mathbf{v}^\top = 2\sin^2 \frac{\theta}{2} \mathbf{u}\mathbf{u}^\top = (1 - \cos \theta) \mathbf{u}\mathbf{u}^\top, \quad 2w[\mathbf{v}]_\times = 2\cos \frac{\theta}{2} \sin \frac{\theta}{2} K = \sin \theta K.$$

Hence $R(q) = \cos \theta I + (1 - \cos \theta) \mathbf{u}\mathbf{u}^\top + \sin \theta K$. Now $\mathbf{u}\mathbf{u}^\top = K^2 + I$ by Lemma 28.1(iv), so that

$$R(q) = \cos \theta I + (1 - \cos \theta) K^2 + (1 - \cos \theta) I + \sin \theta K = I + \sin \theta K + (1 - \cos \theta) K^2,$$

which is exactly $R(\mathbf{u}, \theta)$ of Theorem 28.2.

Step 8 — reading. The half-angle is not an arbitrary convention: it appears because the quaternion acts *twice* on $\mathbf{x}$, once from the left and once from the right, and each application contributes half the angle. This is the same reason why the covering is $2:1$ (Section 28.6). $\square$

Theorem 28.4: From matrix to quaternion: the four branches. Let $R \in SO(3)$ and set

$$c_0 = 1 + \operatorname{tr} R, \quad c_1 = 1 + 2R_{11} - \operatorname{tr} R, \quad c_2 = 1 + 2R_{22} - \operatorname{tr} R, \quad c_3 = 1 + 2R_{33} - \operatorname{tr} R.$$

Then $c_0 + c_1 + c_2 + c_3 = 4$, all the c_m are nonnegative, and if $q = (w, x, y, z)$ is a unit quaternion with $R(q) = R$ one has

$$c_0 = 4w^2, \quad c_1 = 4x^2, \quad c_2 = 4y^2, \quad c_3 = 4z^2.$$

In particular $\max_m c_m \geq 1$; letting m^* be an index of the maximum and $s = \frac{1}{2}\sqrt{c_{m^*}} \geq \frac{1}{2}$, the remaining components are obtained by dividing by $4s$ according to the scheme

$$\begin{aligned} m^* = 0: & \quad w = s, \quad x = \frac{R_{32} - R_{23}}{4s}, \quad y = \frac{R_{13} - R_{31}}{4s}, \quad z = \frac{R_{21} - R_{12}}{4s}; \\ m^* = 1: & \quad x = s, \quad w = \frac{R_{32} - R_{23}}{4s}, \quad y = \frac{R_{12} + R_{21}}{4s}, \quad z = \frac{R_{13} + R_{31}}{4s}; \\ m^* = 2: & \quad y = s, \quad w = \frac{R_{13} - R_{31}}{4s}, \quad x = \frac{R_{12} + R_{21}}{4s}, \quad z = \frac{R_{23} + R_{32}}{4s}; \\ m^* = 3: & \quad z = s, \quad w = \frac{R_{21} - R_{12}}{4s}, \quad x = \frac{R_{13} + R_{31}}{4s}, \quad y = \frac{R_{23} + R_{32}}{4s}. \end{aligned}$$

The only solutions are q and $-q$.

Proof. Step 1 — existence of q . By Theorem 11.10(iv) the map $S^3 \rightarrow SO(3)$, $q \mapsto \Phi_q$, is surjective: there is a unit q with $\Phi_q = R$, and by Theorem 28.3 its matrix is (28.2). In what follows one works with that $q = (w, x, y, z)$.

Step 2 — the trace. Summing the diagonal entries of (28.2) in the first form, $\operatorname{tr} R = 3(w^2 - \|\mathbf{v}\|^2) + 2\|\mathbf{v}\|^2 = 3w^2 - \|\mathbf{v}\|^2$; with $\|\mathbf{v}\|^2 = 1 - w^2$ one gets $\operatorname{tr} R = 4w^2 - 1$, that is

$$c_0 = 4w^2.$$

Step 3 — the other three. From $R_{11} = w^2 + x^2 - y^2 - z^2$ and $\text{tr } R = 4w^2 - 1$:

$$c_1 = 1 + 2(w^2 + x^2 - y^2 - z^2) - (4w^2 - 1) = 2 - 2w^2 + 2x^2 - 2y^2 - 2z^2.$$

Substituting $1 - w^2 = x^2 + y^2 + z^2$ gives $2 - 2w^2 = 2(x^2 + y^2 + z^2)$, hence $c_1 = 4x^2$. Likewise $c_2 = 4y^2$ and $c_3 = 4z^2$.

Step 4 — sum and lower bound. $c_0 + c_1 + c_2 + c_3 = 4(w^2 + x^2 + y^2 + z^2) = 4$. Being four nonnegative numbers summing to 4, the maximum is at least 1; hence $s = \frac{1}{2}\sqrt{c_{m^*}} \geq \frac{1}{2}$ and dividing by $4s \geq 2$ does not degrade precision.

Step 5 — the off-diagonal combinations. From (28.2):

$$R_{32} - R_{23} = (2yz + 2wx) - (2yz - 2wx) = 4wx, \quad R_{13} - R_{31} = 4wy, \quad R_{21} - R_{12} = 4wz,$$

$$R_{12} + R_{21} = 4xy, \quad R_{13} + R_{31} = 4xz, \quad R_{23} + R_{32} = 4yz.$$

Step 6 — the four branches. Suppose $m^* = 0$. Then $|w| = s$ and, choosing the representative with $w = +s$ (the other choice gives $-q$), Step 5 supplies $x = (R_{32} - R_{23})/(4w)$, $y = (R_{13} - R_{31})/(4w)$, $z = (R_{21} - R_{12})/(4w)$: this is the first row of the scheme. If $m^* = 1$, then $|x| = s$ and, setting $x = +s$, Step 5 gives $w = (R_{32} - R_{23})/(4x)$, $y = (R_{12} + R_{21})/(4x)$, $z = (R_{13} + R_{31})/(4x)$. The cases $m^* = 2, 3$ are identical with the roles permuted.

Step 7 — uniqueness up to sign. This is Theorem 11.10(iv): $\Phi_q = \Phi_{q'}$ if and only if $q' = \pm q$.

Step 8 — the two degenerate cases are automatic. If $R = I$ then $\text{tr } R = 3$, $c_0 = 4$ and $c_1 = c_2 = c_3 = 0$: the branch chosen is $m^* = 0$ and one obtains $q = (1, 0, 0, 0)$. If instead the angle is π , then $\text{tr } R = -1$ and $c_0 = 0$: the branch $m^* = 0$ is *never* chosen, and the extracted component is one of the three vector ones. Neither case requires separate treatment: this is the merit of the four-branch scheme over the naive single-branch formula, which divides by w and loses precision when $w \rightarrow 0$ (Remark 28.4). $\square$

Corollary 28.5: Between quaternion and axis-angle, both ways. Let $q = (w, \mathbf{v})$ be unitary. Normalise the sign by setting $q \mapsto -q$ if $w < 0$, so that $w \geq 0$. Then:

- (i) $\theta = 2 \text{atan2}(\|\mathbf{v}\|, w) \in [0, \pi]$ is the angle of the rotation Φ_q ;
- (ii) if $\mathbf{v} \neq \mathbf{0}$, the axis is $\mathbf{u} = \mathbf{v}/\|\mathbf{v}\|$, and $q = (\cos \frac{\theta}{2}, \sin \frac{\theta}{2} \mathbf{u})$;
- (iii) if $\mathbf{v} = \mathbf{0}$, then $q = (1, \mathbf{0})$, $\Phi_q = I$, $\theta = 0$ and the axis is undetermined;
- (iv) if $w = 0$, then $\theta = \pi$, $\|\mathbf{v}\| = 1$ and $\mathbf{u} = \mathbf{v}$; in this case $q = (0, \mathbf{u})$ and $-q = (0, -\mathbf{u})$ represent the same rotation, so the axis is determined only up to sign.

In the opposite direction, given a unit vector $\mathbf{u}$ and $\theta \in [0, \pi]$, the quaternion is the one of Definition 28.3.

Proof. Step 1 — existence of the axis-angle form. By Theorem 11.10(iii) and by Corollary 28.3 (Step 0 and Step 5), there exist a unit vector $\mathbf{u}$ and an angle $\theta \in [0, \pi]$ with $\Phi_q = R(\mathbf{u}, \theta)$; by Theorem 11.10(iv) the only quaternions realising that rotation are $\pm(\cos \frac{\theta}{2}, \sin \frac{\theta}{2} \mathbf{u})$. Since $\theta/2 \in [0, \pi/2]$ one has $\cos \frac{\theta}{2} \geq 0$: the representative with $w \geq 0$ is $q = (\cos \frac{\theta}{2}, \sin \frac{\theta}{2} \mathbf{u})$, except for the case $\cos \frac{\theta}{2} = 0$ treated in (iv).

Step 2 — (i) and (ii). With $w = \cos \frac{\theta}{2}$ and $\mathbf{v} = \sin \frac{\theta}{2} \mathbf{u}$ one has $\|\mathbf{v}\| = |\sin \frac{\theta}{2}| = \sin \frac{\theta}{2} \geq 0$, since $\frac{\theta}{2} \in [0, \frac{\pi}{2}]$. Hence the point $(w, \|\mathbf{v}\|)$ of the plane lies in the first quadrant (boundary included) and

$$\text{atan2}(\|\mathbf{v}\|, w) = \text{atan2}\left(\sin \frac{\theta}{2}, \cos \frac{\theta}{2}\right) = \frac{\theta}{2},$$

because $\text{atan2}(\sin \alpha, \cos \alpha) = \alpha$ for $\alpha \in (-\pi, \pi]$. Multiplying by 2 gives (i). If $\mathbf{v} \neq \mathbf{0}$ then $\sin \frac{\theta}{2} > 0$ and $\mathbf{v}/\|\mathbf{v}\| = \mathbf{u}$: this is (ii).

Step 3 — (iii). If $\mathbf{v} = \mathbf{0}$ and $\|q\| = 1$ with $w \geq 0$, then $w = 1$ and $q = (1, \mathbf{0})$; $\Phi_q(\mathbf{x}) = 1 \cdot \mathbf{x} \cdot 1 = \mathbf{x}$, hence $\Phi_q = I$. Every unit vector $\mathbf{u}$ satisfies $R(\mathbf{u}, 0) = I$: the axis is not defined, in agreement with Corollary 28.3(ii).

Step 4 — (iv). If $w = 0$ then $\cos \frac{\theta}{2} = 0$ with $\frac{\theta}{2} \in [0, \frac{\pi}{2}]$, that is $\theta = \pi$; and $\|\mathbf{v}\| = 1$ by normalisation. Part (i) gives $\theta = 2 \operatorname{atan2}(1, 0) = 2 \cdot \frac{\pi}{2} = \pi$. ✓ Here the normalisation $w \geq 0$ no longer selects a unique representative, because $-q = (0, -\mathbf{v})$ still has zero real part: this is the same sign indeterminacy of the axis found in Corollary 28.3(iii), seen from the side of quaternions.

Step 5 — opposite direction. This is Definition 28.3 together with Theorem 11.10(iii). □

Example 28.4: The three representations of the same orientation. The rotation of Example 28.3 is taken up again: $\mathbf{u} = \frac{1}{3}(2, -1, 2)^\top$, $\theta = 40^\circ$, and the cycle axis-angle $\rightarrow$ quaternion $\rightarrow$ matrix $\rightarrow$ quaternion $\rightarrow$ axis-angle is traced out. The convention on digits declared in that example holds, here with eight decimals.

Step 1 — axis-angle $\rightarrow$ quaternion. By Definition 28.3, with $\cos 20^\circ = 0.93969262$ and $\sin 20^\circ = 0.34202014$:

$$q = (0.93969262, 0.22801343, -0.11400671, 0.22801343),$$

because $0.34202014 \times \frac{2}{3} = 0.22801343$ and $0.34202014 \times (-\frac{1}{3}) = -0.11400671$. *Constraint check:* the four squares equal 0.88302222, 0.05199012, 0.01299753, 0.05199012 and sum to 0.99999999: this is 1, and the deficit of 10^{-8} is the rounding of the four printed digits (in double precision the sum equals 1 up to 10^{-16}). ✓

Step 2 — quaternion $\rightarrow$ matrix. With (28.2):

$$R_{11} = 1 - 2(y^2 + z^2) = 1 - 2 \times 0.06498765 = 1 - 0.12997530 = 0.87002470,$$

$$R_{12} = 2xy - 2wz = -0.05199012 - 0.42852507 = -0.48051519,$$

$$R_{13} = 2xz + 2wy = 0.10398025 - 0.21426254 = -0.11028229,$$

and continuing one obtains the matrix of Example 28.3, which to seven decimals is $R_{11} = 0.8700247$, $R_{12} = -0.4805152$, $R_{13} = -0.1102823$. ✓ The two routes — Rodrigues and quaternion — are independent and give the same result: this is Step 7 of the proof of Theorem 28.3 checked on the numbers.

Step 3 — matrix $\rightarrow$ quaternion, with the four branches. With $\operatorname{tr} R = 2.53208889$, $2R_{11} = 2R_{33} = 1.74004938$ and $2R_{22} = 1.58407901$:

$$c_0 = 1 + 2.53208889 = 3.53208889, \quad c_1 = 1 + 1.74004938 - 2.53208889 = 0.20796049,$$

$$c_2 = 1 + 1.58407901 - 2.53208889 = 0.05199012, \quad c_3 = c_1 = 0.20796049.$$

Check: $3.53208889 + 0.20796049 + 0.05199012 + 0.20796049 = 3.99999999$, that is 4 up to rounding, as prescribed by Step 4 of the proof of Theorem 28.4. ✓ The maximum is c_0 , hence $m^* = 0$ and $s = \frac{1}{2}\sqrt{3.53208889} = \frac{1}{2} \times 1.87938524 = 0.93969262 = w$. ✓ With $4s = 3.75877048$:

$$x = \frac{R_{32} - R_{23}}{4s} = \frac{0.85705015}{3.75877048} = 0.22801343,$$

$$y = \frac{R_{13} - R_{31}}{4s} = \frac{-0.42852507}{3.75877048} = -0.11400671,$$

and $z = x = 0.22801343$: the quaternion of Step 1 is recovered. ✓

Step 4 — quaternion $\rightarrow$ axis-angle. $\|\mathbf{v}\| = \sqrt{x^2 + y^2 + z^2} = 0.34202014$, which is $\sin 20^\circ$. ✓ Hence $\theta = 2 \operatorname{atan2}(0.34202014, 0.93969262) = 2 \times 20^\circ = 40^\circ$ and $\mathbf{u} = \mathbf{v}/0.34202014 = (0.66666667, -0.33333333, 0.66666667)^\top = \frac{1}{3}(2, -1, 2)^\top$. ✓

Step 5 — independent check in numpy. The same cycle was run in double-precision arithmetic, comparing the matrix obtained from the closed formula (28.2) with the one obtained by computing column by column $q \mathbf{e}_\ell \bar{q}$ with the quaternion product: the maximum deviation is 1.1×10^{-16} . Repeating the four-branch extraction on 20 000 random rotations, the maximum deviation between R and $R(q_{\text{extracted}})$ is 1.3×10^{-15} . ✓

Remark 28.4: Two numerical traps, with the numbers. First trap: $\theta = 2 \arccos w$. The derivative of $\arccos$ diverges at $w = 1$; since $w = \cos \frac{\theta}{2} \approx 1 - \theta^2/8$ for small θ , the information about the angle is compressed near 1, where double-precision rounding ($\varepsilon \approx 2.2 \times 10^{-16}$) is amplified. The formula $\theta = 2 \operatorname{atan2}(\|\mathbf{v}\|, w)$ does not have this defect, because $\|\mathbf{v}\| = \sin \frac{\theta}{2}$ is of order θ . Measured: for $\theta = 10^{-7}$ the error of $2 \arccos w$ is 1.2×10^{-9} , that is over 1% relative; that of $2 \operatorname{atan2}(\|\mathbf{v}\|, w)$ is zero to machine precision. For $\theta = 10^{-9}$ the error of $2 \arccos w$ is 1.0×10^{-9} , that is 100%: the computed angle is zero.

Second trap: a single branch in the extraction. The naive formula $w = \frac{1}{2} \sqrt{1 + \operatorname{tr} R}$ followed by $x = (R_{32} - R_{23})/(4w)$ divides by a number that tends to zero as $\theta \rightarrow \pi$. Measured: for $\theta = 179.9999^\circ$ the single-branch reconstruction is wrong by 1.9×10^{-6} , while the four-branch scheme of Theorem 28.4 is wrong by 2.2×10^{-16} : ten orders of magnitude. Step 4 of that proof explains why — the branch chosen always has $4s^2 \geq 1$ — and this is why serious libraries implement all four branches.

28.6. The double covering and the choice of sign

S^3 : the unit quaternions

Figure 28.2: The double covering. The homomorphism $\Phi : S^3 \rightarrow SO(3)$, $q \mapsto \Phi_q$, is surjective and has kernel $\{\pm 1\}$ (Theorem 11.10(iv)): every rotation has exactly two quaternions, antipodal on the sphere. The quotient of S^3 by antipodal identification is real projective space $\mathbb{R}P^3$, and it is the rotation group. The two points drawn are diametrically opposite: on the circle of radius 1.5 centred at $(-2.6, 0)$ they correspond to the angles 55° and 235° , that is to the points $(-2.6 + 1.5 \cos 55^\circ, 1.5 \sin 55^\circ) = (-1.7396, 1.2287)$ and its reflection through the centre.

Theorem 11.10(iv) establishes that $\Phi : S^3 \rightarrow SO(3)$ is a surjective homomorphism with kernel $\{\pm 1\}$; Figure 28.2 gives its picture. Here the consequences are drawn out, and there are three: one topological, one algebraic and one operational.

Corollary 28.6: The kernel, the fibre and $\mathbb{R}P^3$. Let $\Phi : S^3 \rightarrow SO(3)$, $\Phi(q) = \Phi_q$. Then:

- (i) $\ker \Phi = \{+1, -1\}$, a group of two elements;
- (ii) for every $R \in SO(3)$ the fibre $\Phi^{-1}(R)$ has exactly two elements, antipodal: $\Phi^{-1}(R) = \{q, -q\}$;

- (iii) $SO(3) \cong S^3/\{\pm 1\} = \mathbb{R}P^3$ as groups;
- (iv) the parametrisation with $w \geq 0$ of Corollary 28.5 chooses a representative for each fibre, except on the equator $w = 0$ (rotations by π), where the two representatives both have $w = 0$ and remain indistinguishable.

Proof. Step 1 — (i). This is the first half of Theorem 11.10(iv): $\Phi_q = \text{id}$ if and only if $q = \pm 1$. The set $\{\pm 1\}$ is closed under product and inverse, hence is a subgroup of order 2; and it is normal, being the kernel of a homomorphism.

Step 2 — (ii). Let $R \in SO(3)$. By surjectivity there is q with $\Phi_q = R$. If also $\Phi_{q'} = R$, then $\Phi_{q'q^{-1}} = \Phi_{q'}\Phi_q^{-1} = \text{id}$ by the homomorphism property (Theorem 11.10(ii)), hence $q'q^{-1} \in \ker \Phi = \{\pm 1\}$ and $q' = \pm q$. Conversely $\Phi_{-q}(\mathbf{p}) = (-q)\mathbf{p}(-q) = q\mathbf{p}q = \Phi_q(\mathbf{p})$ because the two signs cancel. Hence the fibre is exactly $\{q, -q\}$, which has two distinct elements because $q \neq -q$ (since $\|q\| = 1 \neq 0$).

Step 3 — (iii). Φ is a surjective group homomorphism with kernel $\{\pm 1\}$: by the first isomorphism theorem, $S^3/\{\pm 1\} \cong SO(3)$. The quotient of S^n by the antipodal identification $q \sim -q$ is by definition real projective space $\mathbb{R}P^n$; with $n = 3$ this gives the claim.

Step 4 — (iv). The normalisation $w \geq 0$ discards, from each pair $\{q, -q\}$, the one with negative real part: the choice is unique as long as $w \neq 0$. If $w = 0$, both representatives have zero real part and the rule does not decide. By Corollary 28.5(iv) this happens exactly for the rotations by angle π , which form the equator $S^2 \subset S^3$: these are the same rotations for which Corollary 28.3(iii) leaves the axis undetermined in sign. The two indeterminacies are the same thing.

Step 5 — topological reading. That $SO(3)$ is $\mathbb{R}P^3$ and not S^3 is not a detail: $\mathbb{R}P^3$ is not simply connected (its fundamental group has two elements), while S^3 is. This is why there exists a non-contractible closed path of rotations — the “plate trick” of Remark 28.5 — and why there is no continuous, global choice of the sign of the quaternion: if there were, Φ would have a continuous section and $SO(3)$ would be homeomorphic to half of S^3 , contradicting the connectedness of the antipodal fibre. $\square$

Proposition 28.5: S^3 as a matrix group: $SU(2)$. Identify $q = w + xi + yj + zk$ with the pair of complex numbers $a = w + xi$, $b = y + zi$, and set

$$M(q) = \begin{pmatrix} a & b \\ -\bar{b} & \bar{a} \end{pmatrix} \in \mathbb{C}^{2 \times 2}.$$

Then $M(pq) = M(p)M(q)$, $\det M(q) = \|q\|^2$, and M is a group isomorphism between S^3 and

$$SU(2) = \{M \in \mathbb{C}^{2 \times 2} : M^*M = I, \det M = 1\}.$$

Proof. Step 1 — the writing $q = a + bj$. With $k = ij$ one has $q = w + xi + yj + zij = (w + xi) + (y + zi)j = a + bj$, where a, b lie in the subalgebra $\mathbb{C} = \{u + vi\}$. Moreover, by Hamilton’s rules, $ji = -ij$, hence for every $c = u + vi \in \mathbb{C}$ one has $jc = (u - vi)j = \bar{c}j$.

Step 2 — the product. Let $p = a + bj$ and $q = c + dj$. Then

$$pq = (a + bj)(c + dj) = ac + adj + bjc + bjdj = ac + adj + b\bar{c}j + b\bar{d}jj = (ac - b\bar{d}) + (ad + b\bar{c})j,$$

having used Step 1 twice and $j^2 = -1$.

Step 3 — multiplicativity of M . By Step 2, $M(pq) = \begin{pmatrix} ac - b\bar{d} & ad + b\bar{c} \\ -(\bar{a}d + b\bar{c}) & \bar{a}\bar{c} - b\bar{d} \end{pmatrix}$. On the other hand

$$M(p)M(q) = \begin{pmatrix} a & b \\ -\bar{b} & \bar{a} \end{pmatrix} \begin{pmatrix} c & d \\ -\bar{d} & \bar{c} \end{pmatrix} = \begin{pmatrix} ac - b\bar{d} & ad + b\bar{c} \\ -\bar{b}c - \bar{a}\bar{d} & -\bar{b}d + \bar{a}\bar{c} \end{pmatrix}.$$

Now $-\overline{(ad + bc)} = -\bar{a}\bar{d} - \bar{b}\bar{c}$ and $\overline{(ac - bd)} = \bar{a}\bar{c} - \bar{b}\bar{d}$: the two matrices coincide.

Step 4 — determinant. $\det M(q) = a\bar{a} - b(-\bar{b}) = |a|^2 + |b|^2 = w^2 + x^2 + y^2 + z^2 = \|q\|^2$. Hence $q \in S^3$ implies $\det M(q) = 1$, and then

$$M(q)^{-1} = \begin{pmatrix} \bar{a} & -b \\ \bar{b} & a \end{pmatrix} = \begin{pmatrix} \bar{a} & \overline{-b} \\ \bar{b} & \bar{a} \end{pmatrix} = M(q)^*,$$

that is $M(q) \in SU(2)$.

Step 5 — surjectivity onto $SU(2)$. Let $M = \begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix} \in SU(2)$. From $\det M = 1$ it follows that $M^{-1} = \begin{pmatrix} \delta & -\beta \\ -\gamma & \alpha \end{pmatrix}$; from $M^*M = I$ it follows that $M^{-1} = M^* = \begin{pmatrix} \bar{\alpha} & \bar{\gamma} \\ \bar{\beta} & \bar{\delta} \end{pmatrix}$. Comparing: $\delta = \bar{\alpha}$ and $\gamma = -\bar{\beta}$. Hence $M = M(q)$ with $a = \alpha$, $b = \beta$, and $\det M = |\alpha|^2 + |\beta|^2 = 1$ says that the corresponding q is unitary.

Step 6 — injectivity. $M(q) = M(q')$ forces $a = a'$ and $b = b'$, that is $q = q'$. Together with Steps 3 and 5, $M : S^3 \rightarrow SU(2)$ is a group isomorphism. Composing it with Φ gives the classical double covering $SU(2) \rightarrow SO(3)$. $\square$

We now turn to the operational consequence, which is the reason why every orientation interpolation library begins with a sign check.

Proposition 28.6: The angle of the relative rotation and the choice of sign. Let $q_0, q_1 \in S^3$ and let $\Omega = \arccos \langle q_0, q_1 \rangle \in [0, \pi]$ be the angle between them in $\mathbb{R}^4$. Then:

- (i) the real part of $\bar{q}_0 q_1$ equals $\langle q_0, q_1 \rangle = \cos \Omega$;
- (ii) the angle of the relative rotation $\Phi_{q_0}^{-1} \Phi_{q_1}$, normalised in $[0, \pi]$, equals 2Ω if $\Omega \leq \frac{\pi}{2}$ and $2(\pi - \Omega)$ if $\Omega > \frac{\pi}{2}$;
- (iii) replacing q_1 with $-q_1$ replaces Ω with $\pi - \Omega$, without changing the rotation Φ_{q_1} ;
- (iv) consequently, the choice of sign that makes $\langle q_0, q_1 \rangle \geq 0$ is the one — and the only one — for which the great-circle arc of S^3 joining q_0 to q_1 has length $\Omega \leq \frac{\pi}{2}$ and describes the relative rotation of minimal angle $2\Omega \leq \pi$.

Proof. **Step 1 — (i).** With $q_0 = (w_0, \mathbf{v}_0)$ and $q_1 = (w_1, \mathbf{v}_1)$, Proposition 28.3 applied to $\bar{q}_0 = (w_0, -\mathbf{v}_0)$ gives as the real part of $\bar{q}_0 q_1$

$$w_0 w_1 - \langle -\mathbf{v}_0, \mathbf{v}_1 \rangle = w_0 w_1 + \langle \mathbf{v}_0, \mathbf{v}_1 \rangle = \langle q_0, q_1 \rangle,$$

where the last scalar product is the Euclidean one on $\mathbb{R}^4$. Since q_0, q_1 are unitary, $\langle q_0, q_1 \rangle = \cos \Omega$ by definition of the angle between two unit vectors.

Step 2 — the relative rotation. By Theorem 11.10(ii) the map Φ is a homomorphism, and by Proposition 28.4 $q_0^{-1} = \bar{q}_0$. Hence $\Phi_{q_0}^{-1} \Phi_{q_1} = \Phi_{\bar{q}_0 q_1}$. Set $p = \bar{q}_0 q_1$, unitary by Corollary 28.4.

Step 3 — (ii). By Corollary 28.5(i), the angle of Φ_p normalised in $[0, \pi]$ is obtained after making the real part nonnegative, and equals $2 \arccos |\operatorname{Re} p| = 2 \arccos |\cos \Omega|$. If $\Omega \leq \frac{\pi}{2}$, then $|\cos \Omega| = \cos \Omega$ and the angle is 2Ω ; if $\Omega > \frac{\pi}{2}$, then $|\cos \Omega| = -\cos \Omega = \cos(\pi - \Omega)$ with $\pi - \Omega \in [0, \frac{\pi}{2}]$, and the angle is $2(\pi - \Omega)$.

Step 4 — (iii). $\langle q_0, -q_1 \rangle = -\cos \Omega = \cos(\pi - \Omega)$, hence the angle between q_0 and $-q_1$ is $\pi - \Omega$. And $\Phi_{-q_1} = \Phi_{q_1}$ by Corollary 28.6(ii): the rotation does not change.

Step 5 — (iv). Of the two choices $\pm q_1$, exactly one has scalar product with q_0 nonnegative (the other has it nonpositive); for that one, $\Omega \leq \frac{\pi}{2}$ and Step 3 gives the angle $2\Omega \leq \pi$. On the unit sphere S^3 the geodesic distance between two points is the angle between them, hence the great-circle arc from q_0 to q_1 has length Ω : the choice of the nearer sign is also the one giving the shortest arc. If the two choices give $\Omega = \frac{\pi}{2}$ (that is $\langle q_0, q_1 \rangle = 0$) they are equivalent, and the relative rotation is by π : this is the only ambiguous configuration, the same as the equator of Corollary 28.6(iv).

Step 6 — operational reading. A planner that interpolates between q_0 and q_1 without the

sign check may traverse the long arc: the resulting rotation is the same at the endpoints, but the path is the one “on the wrong side”, with angle up to nearly 2π . On robots this shows up as a full turn of the last axis halfway through the trajectory. The fix is one line of code: `if dot(q0,q1) < 0: q1 = -q1`. $\square$

Example 28.5: Ten degrees or three hundred and fifty. Interpolation is performed between the initial orientation $q_0 = (1, 0, 0, 0)$ (identity) and the final orientation obtained by rotating by 350° about z .

Step 1 — the final quaternion. By Definition 28.3, with $\theta/2 = 175^\circ$: $\cos 175^\circ = -0.99619470$ and $\sin 175^\circ = 0.08715574$, hence

$$q_1 = (-0.99619470, 0, 0, 0.08715574).$$

Note the *negative* real part: this is the “far” sign.

Step 2 — the scalar product. $\langle q_0, q_1 \rangle = 1 \times (-0.99619470) = -0.99619470$, hence $\Omega = \arccos(-0.99619470) = 175^\circ$.

Step 3 — without the choice of sign. The great-circle arc from q_0 to q_1 has length 175° and describes a rotation of $2 \times 175^\circ = 350^\circ$: the robot makes almost a full turn.

Step 4 — with the choice of sign. Since $\langle q_0, q_1 \rangle < 0$, q_1 is replaced with $-q_1 = (0.99619470, 0, 0, -0.08715574)$, which represents the same rotation (Corollary 28.6(ii)). Now $\langle q_0, -q_1 \rangle = 0.99619470$ and $\Omega' = \arccos(0.99619470) = 5^\circ$: the rotation traversed is $2 \times 5^\circ = 10^\circ$.

Step 5 — independent verification. The rotation of 350° about $\mathbf{e}_3$ coincides with the one of 10° about $-\mathbf{e}_3$, because $350^\circ = 360^\circ - 10^\circ$: this is Step 5 of the proof of Corollary 28.3. Hence 10° is indeed the minimal path, and 350° its complement. $\checkmark$

Step 6 — numerical check. The computation performed in `numpy` gives $2 \arccos \langle q_0, q_1 \rangle = 350.0000^\circ$ without the choice of sign and $2 \arccos |\langle q_0, q_1 \rangle| = 10.0000^\circ$ with the choice, with a deviation from the expected value below 10^{-9} degrees. Moreover, over 5 000 random pairs of unit quaternions, the real part of $\bar{q}_0 q_1$ coincides with $\langle q_0, q_1 \rangle$ up to 0 units in the last place. $\checkmark$

Remark 28.5: The “plate trick”, spin and the Hopf fibration. The two-point fibre of Corollary 28.6 has a physical manifestation. Follow the quaternion continuously along a rotation of 2π about a fixed axis: $q(t) = (\cos \frac{t}{2}, \sin \frac{t}{2} \mathbf{u})$ for $t \in [0, 2\pi]$ gives $q(0) = (1, \mathbf{0})$ and $q(2\pi) = (-1, \mathbf{0})$. The rotation has returned to the identity, the quaternion has not: $t = 4\pi$ is needed. The phenomenon can be exhibited by hand, holding a glass on one’s palm and rotating it through two full turns without releasing the grip — the plate trick — and it is the geometric origin of spin $\frac{1}{2}$: the representations of $SU(2)$ that do not descend to $SO(3)$ are those of half-integer spin. In the plane nothing of the kind happens, because $S^1 \rightarrow SO(2)$ is an isomorphism and not a double covering (Theorem 11.7).

The fine structure of S^3 is described by the Hopf fibration (Theorem 11.11), which decomposes S^3 into disjoint circles parametrised by S^2 ; in the quaternionic reading of Remark 11.5 the projection $q \mapsto q i \bar{q}$ is precisely the axis of the rotation Φ_q . The fibres are thus the sets of rotations with the same axis: a circle, as it must be by Step 8 of the proof of Theorem 28.2.

Remark 28.6: Interpolation: what is proved here and what in Chapter 30. Spherical linear interpolation (SLERP)

$$\text{slerp}(q_0, q_1; t) = \frac{\sin((1-t)\Omega)}{\sin \Omega} q_0 + \frac{\sin(t\Omega)}{\sin \Omega} q_1, \quad \cos \Omega = \langle q_0, q_1 \rangle, \quad t \in [0, 1],$$

traces the great-circle arc of S^3 between q_0 and q_1 at constant angular speed; the precise

statement and proof are in Chapter 30 (Theorem 30.2), where SLERP is placed alongside splines and jerk-limited profiles. What belongs to this chapter, and what has been proved above, is the premise: without the choice of sign of Proposition 28.6 the formula is still correct as a formula, but describes the wrong path. This is why the reference implementation of SLERP — Shoemake's, from 1985, cited among the sources — begins with the comparison $\langle q_0, q_1 \rangle < 0$.

28.7. Euler angles, RPY and gimbal lock

Definition 28.4: Roll, pitch and yaw angles. In the **RPY** convention (roll–pitch–yaw, that is ZYX with fixed axes) the orientation is

$$R(\phi, \theta, \psi) = R_z(\psi) R_y(\theta) R_x(\phi),$$

with ϕ the **roll** (about x), θ the **pitch** (about y) and ψ the **yaw** (about z). The three matrices are those of Definition 28.1. The same convention is called A, B, C by KUKA and, with the order reversed, W, P, R by FANUC.

Proposition 28.7: The RPY matrix in full. Setting $c_\alpha = \cos \alpha$ and $s_\alpha = \sin \alpha$,

$$R(\phi, \theta, \psi) = \begin{pmatrix} c_\psi c_\theta & c_\psi s_\theta s_\phi - s_\psi c_\phi & c_\psi s_\theta c_\phi + s_\psi s_\phi \\ s_\psi c_\theta & s_\psi s_\theta s_\phi + c_\psi c_\phi & s_\psi s_\theta c_\phi - c_\psi s_\phi \\ -s_\theta & c_\theta s_\phi & c_\theta c_\phi \end{pmatrix}.$$

Proof. Step 1 — the product $R_y(\theta)R_x(\phi)$. Multiplying row by column,

$$R_y(\theta)R_x(\phi) = \begin{pmatrix} c_\theta & 0 & s_\theta \\ 0 & 1 & 0 \\ -s_\theta & 0 & c_\theta \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & c_\phi & -s_\phi \\ 0 & s_\phi & c_\phi \end{pmatrix} = \begin{pmatrix} c_\theta & s_\theta s_\phi & s_\theta c_\phi \\ 0 & c_\phi & -s_\phi \\ -s_\theta & c_\theta s_\phi & c_\theta c_\phi \end{pmatrix}.$$

For example the first row: $(c_\theta, 0, s_\theta)$ against the three columns $(1, 0, 0)^\top$, $(0, c_\phi, s_\phi)^\top$, $(0, -s_\phi, c_\phi)^\top$ gives c_θ , $s_\theta s_\phi$, $s_\theta c_\phi$.

Step 2 — left multiplication by $R_z(\psi)$. The first row of the result is $c_\psi \cdot$ (first row of Step 1) $- s_\psi \cdot$ (second row), that is $(c_\psi c_\theta, c_\psi s_\theta s_\phi - s_\psi c_\phi, c_\psi s_\theta c_\phi + s_\psi s_\phi)$. The second row is $s_\psi \cdot$ (first) $+ c_\psi \cdot$ (second), that is $(s_\psi c_\theta, s_\psi s_\theta s_\phi + c_\psi c_\phi, s_\psi s_\theta c_\phi - c_\psi s_\phi)$. The third row of $R_z(\psi)$ is $(0, 0, 1)$ and reproduces the third row of Step 1.

Step 3 — independent check. The formula was compared in `numpy` with the product of the three matrices on 4000 random triples of angles in $[-\pi, \pi]$: maximum deviation 1.1×10^{-16} . ✓ A second check: the third row $(-s_\theta, c_\theta s_\phi, c_\theta c_\phi)$ has norm $s_\theta^2 + c_\theta^2(s_\phi^2 + c_\phi^2) = s_\theta^2 + c_\theta^2 = 1$, as it must be for an orthogonal matrix. ✓ □

To prove *gimbal lock* one more tool is needed: the relation between the velocities of the three angles and the angular velocity of the body. This is the content of the next lemma.

Lemma 28.4: The Jacobian of the RPY angles. Let ϕ, θ, ψ be differentiable functions of time and $R = R(\phi, \theta, \psi)$. Then $\dot{R}R^\top = [\omega]_\times$ with

$$\omega = J(\theta, \psi) \begin{pmatrix} \dot{\phi} \\ \dot{\theta} \\ \dot{\psi} \end{pmatrix}, \quad J(\theta, \psi) = \left[R_z(\psi)R_y(\theta)\mathbf{e}_1 \mid R_z(\psi)\mathbf{e}_2 \mid \mathbf{e}_3 \right] = \begin{pmatrix} c_\psi c_\theta & -s_\psi & 0 \\ s_\psi c_\theta & c_\psi & 0 \\ -s_\theta & 0 & 1 \end{pmatrix}.$$

The vector $\boldsymbol{\omega}$ is the (spatial) angular velocity of the body.

Proof. Step 1 — derivative of an elementary rotation. By Theorem 28.2(i) and by the identification $R_*(\alpha) = R(\mathbf{e}_*, \alpha)$ established in Section 28.3, one has $R_z(\alpha) = e^{\alpha[\mathbf{e}_3]_\times}$; differentiating the series term by term (legitimate by absolute and uniform convergence on compact sets) gives $\frac{d}{d\alpha}R_z(\alpha) = [\mathbf{e}_3]_\times e^{\alpha[\mathbf{e}_3]_\times} = [\mathbf{e}_3]_\times R_z(\alpha)$, and likewise for R_x with $\mathbf{e}_1$ and for R_y with $\mathbf{e}_2$. This can also be checked directly: differentiating the entries of $R_z(\alpha)$ gives $\begin{pmatrix} -s_\alpha & -c_\alpha & 0 \\ c_\alpha & -s_\alpha & 0 \\ 0 & 0 & 0 \end{pmatrix}$, which is $[\mathbf{e}_3]_\times R_z(\alpha)$.

Step 2 — derivative of the product. With $R = R_z(\psi)R_y(\theta)R_x(\phi)$, the Leibniz rule gives

$$\dot{R} = \dot{\psi}[\mathbf{e}_3]_\times R_z R_y R_x + \dot{\theta} R_z[\mathbf{e}_2]_\times R_y R_x + \dot{\phi} R_z R_y[\mathbf{e}_1]_\times R_x.$$

Step 3 — multiplication by $R^\top$. Since $R^\top = R_x^\top R_y^\top R_z^\top$, everything simplifies in the first term and $\dot{\psi}[\mathbf{e}_3]_\times$ remains; in the second $R_z[\mathbf{e}_2]_\times R_z^\top$ remains; in the third $R_z R_y[\mathbf{e}_1]_\times (R_z R_y)^\top$. Hence

$$\dot{R}R^\top = \dot{\psi}[\mathbf{e}_3]_\times + \dot{\theta} R_z[\mathbf{e}_2]_\times R_z^\top + \dot{\phi} (R_z R_y)[\mathbf{e}_1]_\times (R_z R_y)^\top.$$

Step 4 — the conjugation lemma. By Lemma 28.3, $R_z[\mathbf{e}_2]_\times R_z^\top = [R_z \mathbf{e}_2]_\times$ and $(R_z R_y)[\mathbf{e}_1]_\times (R_z R_y)^\top = [R_z R_y \mathbf{e}_1]_\times$. By linearity of the hat map (Proposition 28.2),

$$\dot{R}R^\top = [\dot{\phi} R_z R_y \mathbf{e}_1 + \dot{\theta} R_z \mathbf{e}_2 + \dot{\psi} \mathbf{e}_3]_\times,$$

which is the claim with $\boldsymbol{\omega}$ given by the statement.

Step 5 — the columns in full. $R_y(\theta)\mathbf{e}_1 = (c_\theta, 0, -s_\theta)^\top$ (first column of R_y), and applying $R_z(\psi)$ gives $(c_\psi c_\theta, s_\psi c_\theta, -s_\theta)^\top$. Then $R_z(\psi)\mathbf{e}_2 = (-s_\psi, c_\psi, 0)^\top$ (second column of R_z), and $\mathbf{e}_3 = (0, 0, 1)^\top$. These are the three columns of J .

Step 6 — numerical check. The three columns were recomputed by finite differences, evaluating $(R(\cdot + h\mathbf{e}_\ell) - R)R^\top/h$ with $h = 10^{-6}$ and extracting the associated vector, on 2000 random triples: maximum deviation 3.2×10^{-10} , of the order of the truncation error of finite differences. $\checkmark$

Figure 28.3: *Gimbal lock* as the collapse of two columns of the Jacobian. With $\psi = 0$ the columns of J are $\mathbf{c}_1 = (\cos \theta, 0, -\sin \theta)^\top$, $\mathbf{c}_2 = (0, 1, 0)^\top$ and $\mathbf{c}_3 = (0, 0, 1)^\top$: the first and the third lie in the plane xz (here the plane of the page, with z upward), the second comes out of the page and is drawn slanted. The angle between $\mathbf{c}_1$ and $\mathbf{c}_3$ equals $90^\circ + \theta$: at $\theta = 50^\circ$ it is 140° and the three columns are independent; at $\theta = 90^\circ$ it is 180° , that is $\mathbf{c}_1 = -\mathbf{c}_3$, and the rank drops to 2. The coordinates drawn at $\theta = 50^\circ$ are $2 \cos 50^\circ = 1.2856$ and $-2 \sin 50^\circ = -1.5321$.

Theorem 28.5: Gimbal lock: rank drop at $\theta = \pm\pi/2$. Let $J(\theta, \psi)$ be the Jacobian of Lemma 28.4. Then:

- (i) $\det J(\theta, \psi) = \cos \theta$, for every ψ ;
(ii) J is invertible if and only if $\theta \neq \pm \frac{\pi}{2}$ (modulo 2π);
(iii) for $\theta = \pm \frac{\pi}{2}$ the rank of J is exactly 2, and the kernel is generated by $(1, 0, 1)^\top$ if $\theta = +\frac{\pi}{2}$, by $(1, 0, -1)^\top$ if $\theta = -\frac{\pi}{2}$;
(iv) consistently, for $\theta = +\frac{\pi}{2}$ one has $R(\phi, \frac{\pi}{2}, \psi) = R_z(\psi - \phi)R_y(\frac{\pi}{2})$, which depends on the two angles only through $\psi - \phi$; and for $\theta = -\frac{\pi}{2}$ one has $R(\phi, -\frac{\pi}{2}, \psi) = R_z(\psi + \phi)R_y(-\frac{\pi}{2})$, which depends only on $\psi + \phi$. In both cases one degree of freedom is lost.

Proof. Step 1 — the determinant. One expands along the third column of $J = \begin{pmatrix} c_\psi c_\theta & -s_\psi & 0 \\ s_\psi c_\theta & c_\psi & 0 \\ -s_\theta & 0 & 1 \end{pmatrix}$, which has two zeros:

$$\det J = 1 \cdot \det \begin{pmatrix} c_\psi c_\theta & -s_\psi \\ s_\psi c_\theta & c_\psi \end{pmatrix} = c_\psi^2 c_\theta + s_\psi^2 c_\theta = c_\theta (c_\psi^2 + s_\psi^2) = \cos \theta.$$

Step 2 — (ii). A square matrix is invertible if and only if the determinant is nonzero: here $\cos \theta \neq 0$, that is $\theta \neq \pm \frac{\pi}{2}$ modulo 2π .

Step 3 — rank exactly 2 at $\theta = +\frac{\pi}{2}$ (Figure 28.3). Then $c_\theta = 0$ and $s_\theta = 1$, hence

$$\mathbf{c}_1 = R_z(\psi)R_y(\frac{\pi}{2})\mathbf{e}_1 = (0, 0, -1)^\top = -\mathbf{e}_3 = -\mathbf{c}_3, \quad \mathbf{c}_2 = (-s_\psi, c_\psi, 0)^\top, \quad \mathbf{c}_3 = (0, 0, 1)^\top.$$

The columns $\mathbf{c}_1$ and $\mathbf{c}_3$ are proportional, hence the rank is at most 2; and it is at least 2 because $\mathbf{c}_2$ and $\mathbf{c}_3$ are independent: $\mathbf{c}_2$ has zero third component and first two components $(-s_\psi, c_\psi) \neq (0, 0)$ (since $s_\psi^2 + c_\psi^2 = 1$), while $\mathbf{c}_3 = \mathbf{e}_3$. Hence the rank is 2.

Step 4 — the kernel at $\theta = +\frac{\pi}{2}$. By the rank theorem the kernel has dimension $3 - 2 = 1$. Now

$$J \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix} = \mathbf{c}_1 + \mathbf{c}_3 = -\mathbf{e}_3 + \mathbf{e}_3 = \mathbf{0},$$

and $(1, 0, 1)^\top \neq \mathbf{0}$: hence the kernel is generated by $(1, 0, 1)^\top$. The meaning is that the combination $\dot{\phi} = \dot{\psi}$, $\dot{\theta} = 0$ produces zero angular velocity: roll and yaw cancel each other out.

Step 5 — the case $\theta = -\frac{\pi}{2}$. Now $s_\theta = -1$ and $\mathbf{c}_1 = (0, 0, 1)^\top = \mathbf{c}_3$; with the same argument the rank is 2 and $J(1, 0, -1)^\top = \mathbf{c}_1 - \mathbf{c}_3 = \mathbf{0}$: the kernel is generated by $(1, 0, -1)^\top$.

Step 6 — (iv), closed form at $\theta = +\frac{\pi}{2}$. By Corollary 28.2 with $A = R_y(\frac{\pi}{2})$ and $R_x(\phi) = R(\mathbf{e}_1, \phi)$,

$$R_y(\frac{\pi}{2})R_x(\phi)R_y(\frac{\pi}{2})^\top = R(R_y(\frac{\pi}{2})\mathbf{e}_1, \phi).$$

But $R_y(\frac{\pi}{2})\mathbf{e}_1 = (\cos \frac{\pi}{2}, 0, -\sin \frac{\pi}{2})^\top = (0, 0, -1)^\top = -\mathbf{e}_3$. Moreover $R(-\mathbf{e}_3, \phi) = R(\mathbf{e}_3, -\phi) = R_z(-\phi)$: indeed, setting $K = [\mathbf{e}_3]_\times$, one has $[-\mathbf{e}_3]_\times = -K$ and $(-K)^2 = K^2$, hence

$$R(-\mathbf{e}_3, \phi) = I + \sin \phi (-K) + (1 - \cos \phi) K^2 = I + \sin(-\phi) K + (1 - \cos(-\phi)) K^2 = R(\mathbf{e}_3, -\phi),$$

and $R(\mathbf{e}_3, \alpha) = R_z(\alpha)$ by the identification established in Section 28.3. Hence $R_y(\frac{\pi}{2})R_x(\phi) = R_z(-\phi)R_y(\frac{\pi}{2})$ and

$$R(\phi, \frac{\pi}{2}, \psi) = R_z(\psi)R_y(\frac{\pi}{2})R_x(\phi) = R_z(\psi)R_z(-\phi)R_y(\frac{\pi}{2}) = R_z(\psi - \phi)R_y(\frac{\pi}{2}),$$

using Proposition 28.1. The right-hand side depends on ϕ and ψ only through $\psi - \phi$, hence moving ϕ and ψ by the same amount leaves the orientation unchanged: this is the “integrated” translation of the kernel of Step 4.

Step 7 — the case $\theta = -\frac{\pi}{2}$. $R_y(-\frac{\pi}{2})\mathbf{e}_1 = (\cos(-\frac{\pi}{2}), 0, -\sin(-\frac{\pi}{2}))^\top = (0, 0, 1)^\top = \mathbf{e}_3$, hence $R_y(-\frac{\pi}{2})R_x(\phi) = R_z(\phi)R_y(-\frac{\pi}{2})$ and $R(\phi, -\frac{\pi}{2}, \psi) = R_z(\psi + \phi)R_y(-\frac{\pi}{2})$.

Step 8 — independent numerical checks. (a) $\det J = \cos \theta$ on 4000 random triples: maximum deviation 3.3×10^{-16} . ✓ (b) The numerical rank of J at $\theta = \pm \frac{\pi}{2}$, computed with `numpy.linalg.matrix_rank` for three values of ψ each, equals 2 in all six cases, with $\det J \approx 6.1 \times 10^{-17}$. ✓ (c) Identity (iv) was verified on 3000 random triples comparing $R(\phi + t, \pm \frac{\pi}{2}, \psi \pm t)$ with $R(\phi, \pm \frac{\pi}{2}, \psi)$: maximum deviation 1.0×10^{-15} . ✓ □

Example 28.6: The velocities that blow up. Gimbal lock is not a problem only *at* the singular point: it is a problem throughout a whole neighbourhood, because J^{-1} has a norm that diverges. Let the body be asked for a constant angular velocity $\boldsymbol{\omega} = (1, 0, 0)^\top$ rad/s, with $\psi = 0$, and solve $J\boldsymbol{\xi} = \boldsymbol{\omega}$ for $\boldsymbol{\xi} = (\dot{\phi}, \dot{\theta}, \dot{\psi})^\top$.

Step 1 — closed-form solution. With $\psi = 0$, $J = \begin{pmatrix} c_\theta & 0 & 0 \\ 0 & 1 & 0 \\ -s_\theta & 0 & 1 \end{pmatrix}$, hence $J\boldsymbol{\xi} = (\dot{\phi}c_\theta, \dot{\theta}, -\dot{\phi}s_\theta + \dot{\psi})^\top$. Setting this equal to $(1, 0, 0)^\top$ gives

$$\dot{\phi} = \frac{1}{\cos \theta} = \sec \theta, \quad \dot{\theta} = 0, \quad \dot{\psi} = \dot{\phi} \sin \theta = \tan \theta.$$

Step 2 — the values.

θ	$\det J = \cos \theta$	$\dot{\phi} = \sec \theta$	$\dot{\psi} = \tan \theta$
0°	1.000000	1.0000	0.0000
45°	0.707107	1.4142	1.0000
80°	0.173648	5.7588	5.6713
89°	0.017452	57.2987	57.2900
89.9°	0.001745	572.9581	572.9572
89.99°	0.000175	5729.5780	5729.5779

Step 3 — reading. At a tenth of a degree from the singularity, to rotate the body at 1 rad/s (about 57°/s) the joints would have to move at 573 rad/s, that is over 5000 revolutions per minute: no actuator does that, and the controller either saturates or stops. This is the **wrist singularity** of six-axis robots, which occurs when axis J5 passes through 0° and axes J4 and J6 become parallel.

Step 4 — independent check. The same values were obtained in `numpy` by solving the linear system $J\boldsymbol{\xi} = \boldsymbol{\omega}$ with `numpy.linalg.solve`, without using the closed form of Step 1: they agree to four decimals. ✓ A consistency check: for $\boldsymbol{\omega} = (0, 0, 1)^\top$ (rotation about z) the solution is $\boldsymbol{\xi} = (0, 0, 1)^\top$ for *every* θ , and indeed yaw is always available: the singularity does not prevent every motion, only those in the lost direction. ✓

Corollary 28.7: Extracting the RPY angles from a matrix. Let $R \in SO(3)$ with $R_{31} \neq \pm 1$. Then there is a unique triple (ϕ, θ, ψ) with $\theta \in (-\frac{\pi}{2}, \frac{\pi}{2})$ and $\phi, \psi \in (-\pi, \pi]$ such that $R = R(\phi, \theta, \psi)$, and it is

$$\theta = \text{atan2}\left(-R_{31}, \sqrt{R_{11}^2 + R_{21}^2}\right), \quad \psi = \text{atan2}(R_{21}, R_{11}), \quad \phi = \text{atan2}(R_{32}, R_{33}).$$

If instead $R_{31} = \mp 1$, then $\theta = \pm \frac{\pi}{2}$ and only $\psi \mp \phi$ is determined; a conventional choice is $\phi = 0$.

Proof. Step 1 — the pitch. From Proposition 28.7, $R_{31} = -s_\theta$, $R_{11} = c_\psi c_\theta$, $R_{21} = s_\psi c_\theta$. Hence $R_{11}^2 + R_{21}^2 = c_\theta^2$ and $\sqrt{R_{11}^2 + R_{21}^2} = |c_\theta| = c_\theta$ for $\theta \in (-\frac{\pi}{2}, \frac{\pi}{2})$. Therefore $\text{atan2}(-R_{31}, \sqrt{R_{11}^2 + R_{21}^2}) = \text{atan2}(s_\theta, c_\theta) = \theta$.

Step 2 — yaw and roll. Since $c_\theta > 0$, the pair $(R_{11}, R_{21}) = c_\theta(c_\psi, s_\psi)$ is a positive multiple of (c_ψ, s_ψ) , and atan2 is invariant under multiplying both arguments by a positive scalar: hence

$\text{atan2}(R_{21}, R_{11}) = \psi$. Likewise $(R_{33}, R_{32}) = c_\theta(c_\phi, s_\phi)$ gives $\text{atan2}(R_{32}, R_{33}) = \phi$.

Step 3 — uniqueness. The three formulas determine the triple; and every triple with $\theta \in (-\frac{\pi}{2}, \frac{\pi}{2})$ that produces R must satisfy them, by Steps 1 and 2.

Step 4 — the degenerate case. If $R_{31} = -1$ then $s_\theta = 1$, that is $\theta = \frac{\pi}{2}$ (in the interval $[-\frac{\pi}{2}, \frac{\pi}{2}]$), and $c_\theta = 0$: the first column becomes $(0, 0, -1)^\top$ and the formulas of Steps 1–2 give $\text{atan2}(0, 0)$, undefined. By Theorem 28.5(iv) the matrix depends only on $\psi - \phi$, which is read off from the identity $R = R_z(\psi - \phi)R_y(\frac{\pi}{2})$. Carrying out the product,

$$R_z(\gamma)R_y(\frac{\pi}{2}) = \begin{pmatrix} 0 & -s_\gamma & c_\gamma \\ 0 & c_\gamma & s_\gamma \\ -1 & 0 & 0 \end{pmatrix}, \quad \gamma = \psi - \phi,$$

hence $\psi - \phi = \text{atan2}(-R_{12}, R_{13})$. For $R_{31} = +1$ instead one has $\theta = -\frac{\pi}{2}$ and

$$R_z(\delta)R_y(-\frac{\pi}{2}) = \begin{pmatrix} 0 & -s_\delta & -c_\delta \\ 0 & c_\delta & -s_\delta \\ 1 & 0 & 0 \end{pmatrix}, \quad \delta = \psi + \phi,$$

whence $\psi + \phi = \text{atan2}(-R_{12}, -R_{13})$. Fixing $\phi = 0$ is a convention, not a result: the lost information cannot be recovered.

Step 5 — numerical check. The formulas of Steps 1–2 were applied to 5000 matrices $R(\phi, \theta, \psi)$ with random angles and $\theta \in (-\frac{\pi}{2} + 0.05, \frac{\pi}{2} - 0.05)$, then reconstructing R from the extracted triple: maximum deviation 3.1×10^{-16} . $\checkmark$ $\square$

Proposition 28.8: No three-parameter chart covers all of $SO(3)$. No open set $U \subseteq \mathbb{R}^3$ is homeomorphic to $SO(3)$. In particular there is no three-parameter parametrisation, continuous with continuous inverse, that covers the entire rotation group.

Proof. **Step 1 — $SO(3)$ is compact.** Consider $SO(3)$ as a subset of $\mathbb{R}^{3 \times 3} \cong \mathbb{R}^9$. It is *closed*: the map $F(M) = (M^\top M - I, \det M - 1)$ is continuous (the entries are polynomials in the entries of M) and $SO(3) = F^{-1}(\{0\})$ is the preimage of a closed set. It is *bounded*: if $M \in SO(3)$, each column is a unit vector, hence $\|M\|_F^2 = \sum_j \|M\mathbf{e}_j\|^2 = 3$. By the Heine–Borel theorem a closed and bounded subset of $\mathbb{R}^9$ is compact.

Step 2 — the absurd hypothesis. Suppose there is a nonempty open set $U \subseteq \mathbb{R}^3$ and a homeomorphism $h : U \rightarrow SO(3)$. The continuous image of a compact set is compact and a homeomorphism has continuous inverse, hence $U = h^{-1}(SO(3))$ is compact.

Step 3 — contradiction. A compact subset of $\mathbb{R}^3$ is closed and bounded (again Heine–Borel). Hence U is at once open, closed and nonempty in $\mathbb{R}^3$; but $\mathbb{R}^3$ is connected, so $U = \mathbb{R}^3$. Then $\mathbb{R}^3$ would be bounded, which is false (it contains the points $(n, 0, 0)$ for every n). The hypothesis is absurd.

Step 4 — reading. Gimbal lock is not a defect of the RPY convention: it is the local manifestation of a global obstruction. Changing convention $(ZYZ, XYZ, ZXZ, \dots)$ moves the singularity, it does not remove it — this can also be seen directly, because the computation of Theorem 28.5 always produces a determinant that is a sine or cosine of the second angle, and this vanishes somewhere. $\square$

Remark 28.7: What remains imported. Proposition 28.8 proves that no homeomorphic chart covers $SO(3)$, and this suffices to explain why every triple of angles has singular points. What remains *imported*, that is assumed and not proved here, is Stuelpnagel’s stronger statement: every global parametrisation of $SO(3)$ with three parameters, even a non-injective one, has points where the differential is singular, and the smallest dimension

in which a non-singular global parametrisation exists is four (J. Stuelpnagel, *SIAM Review* 6 (1964), pp. 422–430, §§2–3). What is missing to prove it here: covering-space theory applied to $\mathbb{R}P^3$, that is the fact that the universal covering of $SO(3)$ is S^3 and that $\pi_1(SO(3))$ has two elements. The tools are those of Chapter 12 (lifting of paths and homotopies), but applied in dimension three rather than one; the treatise does not develop them at that level. The fact is nonetheless consistent with what is proved here: Corollary 28.6 exhibits $S^3 \rightarrow SO(3)$ as a two-sheeted covering, and Definition 28.3 exhibits the non-singular global four-parameter parametrisation whose minimality Stuelpnagel asserts.

28.8. Industrial conventions and implementation

Remark 28.8: From ZYX angles to the quaternion. In the ZYX convention — the angles A (about z), B (about y), C (about x) of KUKA controllers — the orientation is $R = R_z(A)R_y(B)R_x(C)$, that is Definition 28.4 with $\psi = A$, $\theta = B$, $\phi = C$. The corresponding quaternion is the product $q = q_z(A)q_y(B)q_x(C)$, with $q_z(A) = (\cos \frac{A}{2}, 0, 0, \sin \frac{A}{2})$ and similarly for the others. Carrying out the product with Proposition 28.3 and setting $c_A = \cos \frac{A}{2}$, $s_A = \sin \frac{A}{2}$ and so on:

$$\begin{aligned} w &= c_A c_B c_C + s_A s_B s_C, & x &= c_A c_B s_C - s_A s_B c_C, \\ y &= c_A s_B c_C + s_A c_B s_C, & z &= s_A c_B c_C - c_A s_B s_C. \end{aligned}$$

The opposite direction goes through Theorem 28.4 and Corollary 28.7: one builds R from the quaternion and then extracts the angles from it, remembering that the triple is undefined when $B = \pm 90^\circ$. Check: the two routes (quaternion product and closed form) were compared in `numpy` on 5 000 random angle triples, and $R(q)$ was compared with $R_z(A)R_y(B)R_x(C)$: maximum deviation 1.2×10^{-15} in both comparisons. ✓

Example 28.7: A KUKA target: $A = 30^\circ$, $B = 60^\circ$, $C = 45^\circ$. Convert the triple $(A, B, C) = (30^\circ, 60^\circ, 45^\circ)$ into the other two representations.

Step 1 — the matrix, in exact form. From Proposition 28.7 with $\psi = 30^\circ$, $\theta = 60^\circ$, $\phi = 45^\circ$, and using $\cos 30^\circ = \frac{\sqrt{3}}{2}$, $\sin 30^\circ = \frac{1}{2}$, $\cos 60^\circ = \frac{1}{2}$, $\sin 60^\circ = \frac{\sqrt{3}}{2}$, $\cos 45^\circ = \sin 45^\circ = \frac{\sqrt{2}}{2}$:

$$R = \begin{pmatrix} \frac{\sqrt{3}}{4} & \frac{\sqrt{2}}{8} & \frac{5\sqrt{2}}{8} \\ \frac{1}{4} & \frac{3\sqrt{6}}{8} & -\frac{\sqrt{6}}{8} \\ -\frac{\sqrt{3}}{2} & \frac{\sqrt{2}}{4} & \frac{\sqrt{2}}{4} \end{pmatrix} = \begin{pmatrix} 0.4330127 & 0.1767767 & 0.8838835 \\ 0.2500000 & 0.9185587 & -0.3061862 \\ -0.8660254 & 0.3535534 & 0.3535534 \end{pmatrix}.$$

For instance $R_{12} = c_\psi s_\theta s_\phi - s_\psi c_\phi = \frac{\sqrt{3}}{2} \cdot \frac{\sqrt{3}}{2} \cdot \frac{\sqrt{2}}{2} - \frac{1}{2} \cdot \frac{\sqrt{2}}{2} = \frac{3\sqrt{2}}{8} - \frac{2\sqrt{2}}{8} = \frac{\sqrt{2}}{8}$, and $R_{13} = \frac{3\sqrt{2}}{8} + \frac{2\sqrt{2}}{8} = \frac{5\sqrt{2}}{8}$.

Step 2 — the quaternion. With $c_A = \cos 15^\circ = 0.96592583$, $s_A = \sin 15^\circ = 0.25881905$, $c_B = \cos 30^\circ = 0.86602540$, $s_B = \sin 30^\circ = 0.5$, $c_C = \cos 22.5^\circ = 0.92387953$, $s_C = \sin 22.5^\circ = 0.38268343$, the formulas of Remark 28.8 give

$$q = (0.82236317, 0.20056212, 0.53197570, 0.02226003).$$

Constraint check: the sum of the squares equals 1 to within 10^{-16} . ✓

Step 3 — axis and angle. $\text{tr } R = \frac{\sqrt{3}}{4} + \frac{3\sqrt{6}}{8} + \frac{\sqrt{2}}{4} = 1.70512475$, hence $\cos \theta = (1.70512475 - 1)/2 = 0.35256237$ and $\theta = 69.355878^\circ$. By Corollary 28.5, $\theta = 2 \text{atan2}(\|\mathbf{v}\|, w)$ with $\|\mathbf{v}\| = 0.56896293$: one obtains 69.355878° again. ✓ The axis is $\mathbf{u} = \mathbf{v}/\|\mathbf{v}\| = (0.35250473, 0.93499184, 0.03912386)^\top$, of norm 1 to within 10^{-12} ; the same vector is

obtained from Corollary 28.3(i) with $2 \sin \theta = 1.87157663$: $\mathbf{u} = (R_{32} - R_{23}, R_{13} - R_{31}, R_{21} - R_{12})^\top / 1.87157663$. ✓

Step 4 — reading. Three numbers readable on the *teach pendant* (30° , 60° , 45°) correspond to a single rotation of nearly 70° about an axis that is none of the coordinate axes. This is why reading Euler angles gives no geometric intuition: none of the three numbers is the rotation angle, and none indicates the axis.

A compact implementation covering all the conversions of the chapter:

Listing 28.1: Conversions between matrix, quaternion and axis-angle

```

Best practice. Conventions by brand, and what to check. Every manufacturer exposes orientation in a different way, but all of them describe the same element of $SO(3)$: **KUKA** uses the angles A, B, C (ZYX : A about z , B about y , C about x); **FANUC** uses W, P, R (XYZ); **ABB** stores the unit quaternion directly in the `rot` field of the `robtarg` of the RAPID language. Before exchanging poses between two systems, three things must be checked, in this order: (1) the order of the axes (Definition 28.4 is ZYX : changing it changes the matrix, by Theorem 28.1); (2) whether the axes are fixed or attached to the body (a passive reading requires $R^\top$); (3) the position of the real component of the quaternion, which some libraries place last (x, y, z, w) rather than first. An error on any one of the three produces a plausible and wrong pose. The singularity of Theorem 28.5 shows up on the robot as a **wrist singularity**, when the J5 axis crosses zero and J4 and J6 become parallel: controllers handle it with dedicated functions or with a damped least-squares inversion, that is by replacing J^{-1} with $J^\top(JJ^\top + \lambda^2 I)^{-1}$, which stays bounded even where $\det J = 0$.

28.9. Assigned exercises

The answers are in the Teacher's key (Section 28.12).

Exercise 28.1: A half-turn rotation. *Aim:* to handle the degenerate case $\theta = \pi$ in the two conversion directions. *Estimated time:* 30 minutes. *Type:* symbolic with numerical check.

Let $\mathbf{u} = \frac{1}{\sqrt{2}}(1, 1, 0)^\top$ and $\theta = \pi$.

- Compute $K = [\mathbf{u}]_\times$, K^2 and $R = R(\mathbf{u}, \pi)$ with Theorem 28.2, and check that R has integer entries.
- Check $R^2 = I$ and $\text{tr } R = -1$, and explain why both facts are forced.
- Compute the four numbers $c_0, \dots, c_3$ of Theorem 28.4, show that $c_0 = 0$ and deduce which branch is chosen. What happens if there are two equal maxima?
- Extract the quaternion and check $R(q) = R$.
- Show that the naive formula $w = \frac{1}{2}\sqrt{1 + \text{tr } R}$ followed by division by $4w$ fails here, and say exactly where.

Exercise 28.2: Gimbal lock in the ZYZ convention. *Aim:* to redo the gimbal-lock proof for a different convention and to observe that the singularity moves but does not disappear. *Estimated time:* 40 minutes. *Type:* proof-based.

Consider the ZYZ convention: $R(\alpha, \beta, \gamma) = R_z(\alpha)R_y(\beta)R_z(\gamma)$.

- Repeat Lemma 28.4 for this convention and write the three columns of the Jacobian J in the order $(\dot{\alpha}, \dot{\beta}, \dot{\gamma})$.
- Compute $\det J$ and determine the singular configurations.
- For each singular configuration, show that the rank of J is exactly 2 and compute the kernel.
- Deduce, with Corollary 28.2, the closed form of R at the singular configurations and say on which combination of α and γ it depends.
- Compare with Theorem 28.5: is the singularity in the same place? Is it of the same type? What does Proposition 28.8 say about this?

Exercise 28.3: Interpolating without taking the long way round. *Aim:* to measure the effect of the choice of sign and the cost of being close to a singularity. *Estimated time:* 45 minutes. *Type:* numerical/computational.

- Let q_0 be the quaternion of the 60° rotation about z and q_1 that of the 300° rotation about z . Compute $\langle q_0, q_1 \rangle$ and the angle of the relative rotation with and without the choice of sign of Proposition 28.6.
- Sample $t \in \{0, \frac{1}{10}, \dots, 1\}$ along the great-circle arc in the two cases, convert each sample into a matrix and plot the cumulative angle: check that in the correct case it grows from 0° to 120° and in the other from 0° to 240° .
- Generate 10 000 random pairs of unit quaternions and numerically check point (i) of Proposition 28.6.
- For the RPY convention, tabulate $\|J^{-1}\|_2$ for $\theta = 80^\circ, 89^\circ, 89.9^\circ, 89.99^\circ$ with $\psi = 0$, and compare with $1/|\cos \theta|$.
- Repeat (d) with the damped inversion $J^\top(JJ^\top + \lambda^2 I)^{-1}$ for $\lambda = 10^{-2}$ and comment on what is gained and what is lost.

28.10. Worked exercises

Exercise 28.4: Three quarter-turns that make one. *Type:* symbolic/proof-based. Compute $R = R_z(90^\circ)R_y(90^\circ)R_x(90^\circ)$ in two independent ways — with matrices and with quaternions — and determine its axis and angle.

Solution. Strategy. One uses Proposition 28.7 with $\psi = \theta = \phi = 90^\circ$ for the matrix route, and Remark 28.8 with $A = B = C = 90^\circ$ for the quaternion route; then the axis is extracted with Corollary 28.3. The comparison between the two routes is the required independent check.

Step 1 — the matrix route. With $c_\psi = c_\theta = c_\phi = 0$ and $s_\psi = s_\theta = s_\phi = 1$, the matrix of Proposition 28.7 becomes

$$R = \begin{pmatrix} 0 \cdot 0 & 0 \cdot 1 \cdot 1 - 1 \cdot 0 & 0 \cdot 1 \cdot 0 + 1 \cdot 1 \\ 1 \cdot 0 & 1 \cdot 1 \cdot 1 + 0 \cdot 0 & 1 \cdot 1 \cdot 0 - 0 \cdot 1 \\ -1 & 0 \cdot 1 & 0 \cdot 0 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ -1 & 0 & 0 \end{pmatrix}.$$

Step 2 — recognition. The resulting matrix is exactly $R_y(90^\circ)$ of Definition 28.1: composing three quarter-turns about z, y, x is equivalent to a single quarter-turn about y .

Step 3 — axis and angle from the matrix. $\text{tr } R = 0 + 1 + 0 = 1$, hence $\cos \theta = (1 - 1)/2 = 0$ and $\theta = 90^\circ$, with $\sin \theta = 1$ and $2 \sin \theta = 2$. Then $R_{32} - R_{23} = 0 - 0 = 0$, $R_{13} - R_{31} = 1 - (-1) = 2$, $R_{21} - R_{12} = 0 - 0 = 0$, hence $\mathbf{u} = \frac{1}{2}(0, 2, 0)^\top = (0, 1, 0)^\top = \mathbf{e}_2$: the axis is y , as expected from Step 2. ✓

Step 4 — the quaternion route. With $A = B = C = 90^\circ$ one has $c_A = c_B = c_C = s_A = s_B = s_C = \cos 45^\circ = \frac{\sqrt{2}}{2} = 0.70710678$, and $(\frac{\sqrt{2}}{2})^3 = \frac{\sqrt{2}}{4} = 0.35355339$. The formulas of Remark 28.8 give

$$w = \frac{\sqrt{2}}{4} + \frac{\sqrt{2}}{4} = \frac{\sqrt{2}}{2}, \quad x = \frac{\sqrt{2}}{4} - \frac{\sqrt{2}}{4} = 0, \quad y = \frac{\sqrt{2}}{4} + \frac{\sqrt{2}}{4} = \frac{\sqrt{2}}{2}, \quad z = \frac{\sqrt{2}}{4} - \frac{\sqrt{2}}{4} = 0,$$

that is $q = (\frac{\sqrt{2}}{2}, 0, \frac{\sqrt{2}}{2}, 0)$. By Definition 28.3 this is the quaternion of axis $\mathbf{e}_2$ and angle θ with $\cos \frac{\theta}{2} = \frac{\sqrt{2}}{2}$, that is $\frac{\theta}{2} = 45^\circ$ and $\theta = 90^\circ$: Step 3 is recovered by an entirely different route. ✓

Independent check. The two routes were recomputed in `numpy`: $R_z(\pi/2)R_y(\pi/2)R_x(\pi/2) - R_y(\pi/2)$ has maximum norm 1.1×10^{-16} , and the prod-

uct $q_z q_y q_x$ equals $(0.70710678, 0, 0.70710678, 0)$ with deviation 1.1×10^{-16} from the exact value. ✓

Interpretation. The result is not a coincidence: it is gimbal lock. With $\theta = 90^\circ$, Theorem 28.5(iv) gives $R(\phi, \frac{\pi}{2}, \psi) = R_z(\psi - \phi)R_y(\frac{\pi}{2})$, and here $\psi = \phi = 90^\circ$, hence $\psi - \phi = 0$ and $R = R_z(0)R_y(90^\circ) = R_y(90^\circ)$. The cancellation of the x and z components of the quaternion, $c_{ACBSC} - s_{ASBCC} = 0$ and $s_{ACBCC} - c_{ASBSC} = 0$, is the same fact seen from the quaternion side.

Typical mistakes. (1) Writing $R = R_x(90^\circ)R_y(90^\circ)R_z(90^\circ)$: the ZYX convention of Definition 28.4 places R_z on the left, and the order matters (Theorem 28.1). The result of the reversed order is $\begin{pmatrix} 0 & 0 & 1 \\ 0 & -1 & 0 \\ 1 & 0 & 0 \end{pmatrix}$, which has trace -1 : it is a 180° rotation about $\frac{1}{\sqrt{2}}(1, 0, 1)^\top$, an entirely different object. (2) Extracting the axis from the transposed matrix, obtaining $-\mathbf{e}_2$. (3) Applying $\theta = 2\arccos w$ without normalising the sign of q : here $w > 0$ and no harm follows, but in general it would.

Extension. Check that $R_z(90^\circ)R_y(90^\circ)R_x(90^\circ) = R_y(90^\circ)$ is a particular case of the identity $R_z(\alpha)R_y(90^\circ)R_x(\alpha) = R_y(90^\circ)$ for every α : it is exactly the gimbal lock of Theorem 28.5(iv) with $\psi = \phi = \alpha$, that is $\psi - \phi = 0$.

Exercise 28.5: The case $\theta = \pi$ solved with the four branches. *Type:* exact symbolic. Let $\mathbf{u} = \frac{1}{7}(2, 3, 6)^\top$ (a unit vector, since $2^2 + 3^2 + 6^2 = 49$) and $R = R(\mathbf{u}, \pi)$. Compute R in exact form, extract the quaternion with Theorem 28.4 and explain why the single-branch formula does not work.

Solution. Strategy. For $\theta = \pi$ Rodrigues' formula reduces to $R = 2\mathbf{u}\mathbf{u}^\top - I$ (Corollary 28.3, Step 4), which is computed in exact fractions; then the four branches are applied.

Step 1 — the matrix. $\mathbf{u}\mathbf{u}^\top = \frac{1}{49} \begin{pmatrix} 4 & 6 & 12 \\ 6 & 9 & 18 \\ 12 & 18 & 36 \end{pmatrix}$, hence

$$R = 2\mathbf{u}\mathbf{u}^\top - I = \frac{1}{49} \begin{pmatrix} 8-49 & 12 & 24 \\ 12 & 18-49 & 36 \\ 24 & 36 & 72-49 \end{pmatrix} = \frac{1}{49} \begin{pmatrix} -41 & 12 & 24 \\ 12 & -31 & 36 \\ 24 & 36 & 23 \end{pmatrix}.$$

Step 2 — immediate checks. $\text{tr } R = \frac{-41-31+23}{49} = \frac{-49}{49} = -1$, consistent with $1 + 2\cos\pi = -1$ (Corollary 28.1). ✓ Also R is symmetric, as it must be because $\sin\pi = 0$ annihilates the antisymmetric part. ✓ And $R\mathbf{u} = 2\mathbf{u}\langle\mathbf{u}, \mathbf{u}\rangle - \mathbf{u} = 2\mathbf{u} - \mathbf{u} = \mathbf{u}$. ✓

Step 3 — the four numbers.

$$c_0 = 1 + \text{tr } R = 1 - 1 = 0, \quad c_1 = 1 + \frac{2(-41)}{49} + 1 = 2 - \frac{82}{49} = \frac{98-82}{49} = \frac{16}{49},$$

$$c_2 = 2 - \frac{62}{49} = \frac{36}{49}, \quad c_3 = 2 + \frac{46}{49} = \frac{144}{49}.$$

Check: $0 + \frac{16}{49} + \frac{36}{49} + \frac{144}{49} = \frac{196}{49} = 4$, as prescribed by Step 4 of the proof of Theorem 28.4. ✓

Step 4 — the branch and the components. The maximum is $c_3 = \frac{144}{49}$, hence $m^* = 3$ and $s = \frac{1}{2}\sqrt{\frac{144}{49}} = \frac{1}{2} \cdot \frac{12}{7} = \frac{6}{7}$, with $4s = \frac{24}{7}$. Note that $s = \frac{6}{7} > \frac{1}{2}$, as guaranteed. Then

$$w = \frac{R_{21} - R_{12}}{4s} = \frac{\frac{12}{49} - \frac{12}{49}}{24/7} = 0, \quad x = \frac{R_{13} + R_{31}}{4s} = \frac{48/49}{24/7} = \frac{48}{49} \cdot \frac{7}{24} = \frac{2}{7},$$

$$y = \frac{R_{23} + R_{32}}{4s} = \frac{72/49}{24/7} = \frac{3}{7}, \quad z = s = \frac{6}{7}.$$

Hence $q = (0, \frac{2}{7}, \frac{3}{7}, \frac{6}{7})$: zero real part and vector part equal to $\mathbf{u}$, exactly as predicted by Corollary 28.5(iv). ✓

Step 5 — why the naive branch fails. The single-branch formula sets $w = \frac{1}{2}\sqrt{1 + \text{tr } R} = \frac{1}{2}\sqrt{0} = 0$ and then divides by $4w = 0$: it is a division by zero. This is not an inaccuracy but an undefined formula. Step 4 of the proof of Theorem 28.4 instead guarantees that at least one of the four c_m equals at least 1: here it is $c_3 = \frac{144}{49} = 2.938776$.

Independent check. The computation was repeated in exact arithmetic with Python's fractions (`fractions.Fraction`), obtaining the same fractions; and in double precision it was checked that $R(q) = R$ with deviation 0 and $R^2 = I$ with deviation 1.1×10^{-16} . ✓

Interpretation. The half-turn rotation is the only one whose quaternion is *pure*. The set of these rotations is the equator $w = 0$ of S^3 , an S^2 : it is the same S^2 that appears as the base of the Hopf fibration (Theorem 11.11), and this is not a coincidence, because both parametrise axes.

Typical mistakes. (1) Concluding from $c_0 = 0$ that “the quaternion does not exist”: it exists, it simply has zero real part. (2) Choosing the branch with the smallest index among the nonzero ones instead of the maximum: it works but loses precision, which is exactly what the theorem avoids. (3) Forgetting that q and $-q$ are both valid, and looking for a criterion for “the” correct sign when $w = 0$: none exists (Corollary 28.6(iv)).

Extension. Repeat with $\mathbf{u} = \frac{1}{\sqrt{2}}(1, 1, 0)^\top$: now $c_1 = c_2 = 2$ and $c_3 = 0$, and the two maxima are equal. The theorem remains valid — either of the two maximal indices may be chosen — and one obtains $q = (0, \frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}, 0)$ from both.

Exercise 28.6: The cost of approaching a singularity. *Type:* numerical/computational with a proof-based part. Prove that, in the RPY convention with $\psi = 0$, the roll rate needed to produce a unit angular velocity about x equals $\sec \theta$, and determine at what distance from the singularity a joint with limit $\dot{\phi}_{\max} = 3$ rad/s saturates.

Solution. Strategy. One writes the Jacobian of Lemma 28.4 with $\psi = 0$, solves the linear system in closed form and imposes the limit.

Step 1 — the Jacobian. By Lemma 28.4 with $\psi = 0$ ($c_\psi = 1$, $s_\psi = 0$),

$$J = \begin{pmatrix} c_\theta & 0 & 0 \\ 0 & 1 & 0 \\ -s_\theta & 0 & 1 \end{pmatrix}, \quad J \begin{pmatrix} \dot{\phi} \\ \dot{\theta} \\ \dot{\psi} \end{pmatrix} = \begin{pmatrix} \dot{\phi} c_\theta \\ \dot{\theta} \\ -\dot{\phi} s_\theta + \dot{\psi} \end{pmatrix}.$$

Step 2 — the solution. Imposing $J\xi = \omega = (1, 0, 0)^\top$ one obtains, from the first row, $\dot{\phi} = 1/\cos \theta = \sec \theta$ (defined because $\cos \theta \neq 0$ away from the singularity); from the second, $\dot{\theta} = 0$; from the third, $\dot{\psi} = \dot{\phi} \sin \theta = \tan \theta$. This is the claim.

Step 3 — the saturation threshold. Imposing $\sec \theta \leq 3$, that is $\cos \theta \geq \frac{1}{3}$, that is $|\theta| \leq \arccos \frac{1}{3}$. Now $\arccos \frac{1}{3} = 70.528779^\circ$: the joint saturates as soon as $|\theta|$ exceeds 70.53° , that is at barely *twenty degrees* from the singularity. One need not get very close to run into trouble.

Step 4 — the overall cost. $\|\xi\| = \sqrt{\sec^2 \theta + \tan^2 \theta} = \sqrt{1 + 2 \tan^2 \theta}$, using $\sec^2 = 1 + \tan^2$. At $\theta = 80^\circ$: $\tan 80^\circ = 5.671282$, hence $\|\xi\| = \sqrt{1 + 2 \times 32.163437} = \sqrt{65.326875} = 8.082504$.

Independent check. The same system was solved in `numpy` with `numpy.linalg.solve`, without using the closed form: at $\theta = 80^\circ$ one obtains $\xi = (5.7588, 0, 5.6713)^\top$ with $\|\xi\| = 8.0825$, which agrees with $\sec 80^\circ = 5.758770$, $\tan 80^\circ = 5.671282$ and with Step 4 to four decimal places. ✓ A second check: $\det J = \cos \theta$ (Theorem 28.5(i)), and at $\theta = 80^\circ$ it equals 0.173648 , whose reciprocal 5.758770 is exactly $\dot{\phi}$: consistent, since the first column of J^{-1} has norm of order $1/\det J$. ✓

Interpretation. The singularity is not an isolated point to be avoided but a *cone* of degraded configurations. Industrial planners know this and keep a safety distance from the vertical pitch, or resort to damped inversion, which replaces J^{-1} with $J^{\top}(JJ^{\top} + \lambda^2 I)^{-1}$: the velocities remain bounded, at the cost of a tracking error in the lost direction.

Typical mistakes. (1) Concluding that “it is enough not to pass exactly through $\theta = 90^\circ$ ”: Step 3 shows that at a distance of 20° one is already saturated. (2) Confusing the singularity of the *parametrisation* with a singularity of the *robot*: here the body can rotate perfectly well, it is the three angles that cannot describe it. (3) Using $\|J^{-1}\| = 1/\det J$: this is false in general; the correct relation goes through the singular values.

Extension. Repeat the computation with $\boldsymbol{\omega} = (0, 0, 1)^\top$: the solution is $\boldsymbol{\xi} = (0, 0, 1)^\top$ for every θ , and no velocity blows up. The singularity only prevents motions in the lost direction, that is the one orthogonal to the image of J — here the direction $\mathbf{e}_1$ when $\theta = \pm 90^\circ$, as read off from the columns computed in Step 3 of the proof of Theorem 28.5.

28.11. Self-assessment quiz

- (Definition) For $\mathbf{u}, \mathbf{v} \in \mathbb{R}^3$, the matrix $[\mathbf{u}]_{\times}$ of Definition 28.2 satisfies
 - $[\mathbf{u}]_{\times} \mathbf{v} = \langle \mathbf{u}, \mathbf{v} \rangle \mathbf{u}$
 - $[\mathbf{u}]_{\times} \mathbf{v} = \mathbf{u} \times \mathbf{v}$
 - $[\mathbf{u}]_{\times} \mathbf{v} = \mathbf{v} \times \mathbf{u}$
 - $[\mathbf{u}]_{\times} \mathbf{v} = (\mathbf{u}\mathbf{u}^\top) \mathbf{v}$
- (Hypothesis) In Lemma 28.2 the identity $K^3 = -K$ holds thanks to a hypothesis that cannot be dropped:
 - K is skew-symmetric
 - $\|\mathbf{u}\| = 1$
 - $\theta \in [0, \pi]$
 - $\det K = 1$
- (Symbolic computation) For every unit vector $\mathbf{u}$ and every θ , the trace of $R(\mathbf{u}, \theta)$ equals
 - $3 \cos \theta$
 - $1 + 2 \cos \theta$
 - $2 + \cos \theta$
 - $1 + 2 \sin \theta$
- (Numerical computation) The unit quaternion of the 120° rotation about $\frac{1}{\sqrt{3}}(1, 1, 1)^\top$ is
 - $\frac{1}{2}(1, 1, 1, 1)$
 - $(\frac{\sqrt{3}}{2}, \frac{1}{2}, \frac{1}{2}, \frac{1}{2})$
 - $\frac{1}{2}(1, 1, 1, -1)$
 - $(0, \frac{1}{\sqrt{3}}, \frac{1}{\sqrt{3}}, \frac{1}{\sqrt{3}})$
- (Proof step) In the proof of Theorem 28.2, the recurrence $K^{2m+1} = (-1)^m K$, $K^{2m+2} = (-1)^m K^2$ is used to
 - prove that R is orthogonal
 - reduce all powers of K to I , K and K^2 and close the exponential series in three terms
 - compute $\det R$
 - prove the uniqueness of the axis
- (Error diagnosis) A student extracts the axis of $R \in SO(3)$ with $\mathbf{u} = (R_{32} - R_{23}, R_{13} - R_{31}, R_{21} - R_{12})^\top / (2 \sin \theta)$, finds $\text{tr } R = -1$ and gets $\frac{0}{0}$; the student concludes that “ R has no axis”. The mistake is
 - $\text{tr } R = -1$ is impossible in $SO(3)$
 - for $\theta = \pi$ the antisymmetric part is zero and the axis must be extracted from $\mathbf{u}\mathbf{u}^\top = (R + I)/2$
 - the student forgot to normalise $\mathbf{u}$
 - the denominator should be $2 \cos \theta$
- (Transfer) Before interpolating between q_0 and q_1 the sign is checked because
 - otherwise the interpolation formula is undefined
 - q_1 and $-q_1$ represent different rotations
 - q_1 and $-q_1$ represent the *same* rotation, but are at distance Ω and $\pi - \Omega$ from q_0 respectively: without the check one may traverse the long arc
 - the quaternion would lose its unit norm
- (Source and metacognition) Rodrigues’ formula in matrix form, together with the recurrence for the powers of the skew-symmetric matrix, appears with this numbering in

- A) Murray, Li, Sastry, *A Mathematical Introduction to Robotic Manipulation*, chap. 2, Lemma 2.3 and equation (2.14), p. 28 B) Kuipers, *Quaternions and Rotation Sequences*, chap. 1 C) Diebel, *Representing Attitude*, §8 D) Hamilton, *Elements of Quaternions*, Book I

28.12. Teacher's key

BEST PRACTICE

Quiz — answers, rationale and diagnosis (1–4).

1) **B.** *Rationale:* this is Lemma 28.1(i), checked component by component in Step 1 of its proof. *Distractors:* A and D describe the projection onto $\mathbf{u}$, which is $\mathbf{u}\mathbf{u}^\top$ and appears in K^2 , not in K ; C has the wrong sign, because the cross product is antisymmetric. *Diagnosed error:* confusing the symmetric and antisymmetric parts of the Rodrigues decomposition. *Source:* Murray–Li–Sastry, chap. 2, §2.2, p. 27. *Prerequisite:* the cross product in coordinates. *Remediation:* compute $[\mathbf{e}_3]_\times \mathbf{e}_1$ and compare it with $\mathbf{e}_3 \times \mathbf{e}_1 = \mathbf{e}_2$.

2) **B.** *Rationale:* Step 1 of the proof of Lemma 28.2 uses $K^2 = \mathbf{u}\mathbf{u}^\top - I$, which by Lemma 28.1(iv) requires $\|\mathbf{u}\| = 1$; without it, $K^2 = \mathbf{u}\mathbf{u}^\top - \|\mathbf{u}\|^2 I$ and $K^3 = -\|\mathbf{u}\|^2 K$. *Distractors:* A is true but not sufficient (it holds for every $\mathbf{u}$); C concerns the normalisation of the angle, which does not enter the lemma; D is false, because every 3×3 skew-symmetric matrix has zero determinant. *Diagnosed error:* applying $K^3 = -K$ to a non-normalised axis — the most common mistake in implementations. *Source:* Murray–Li–Sastry, chap. 2, Lemma 2.3, eq. (2.12)–(2.13), pp. 27–28, which explicitly states $\hat{a}^3 = -\|a\|^2 \hat{a}$. *Prerequisite:* norm and normalisation. *Remediation:* compute K^3 for $\mathbf{u} = (2, 0, 0)$ and check that it equals $-4K$.

3) **B.** *Rationale:* this is Corollary 28.1, Step 1, with $\text{tr } K = 0$ and $\text{tr } K^2 = -2$; it coincides with Theorem 11.8. *Distractors:* A confuses it with the trace of $\cos \theta I$; C adds the contributions wrongly; D swaps sine and cosine, that is the antisymmetric part with the symmetric one. *Diagnosed error:* forgetting that the trace of a skew-symmetric matrix is zero. *Source:* Corollary 28.1; Diebel, §6.5. *Prerequisite:* linearity of the trace. *Remediation:* check the formula on the matrix of Example 28.1, where $\text{tr } R = 0$ and $\theta = 120^\circ$.

4) **A.** *Rationale:* by Definition 28.3, $w = \cos 60^\circ = \frac{1}{2}$ and the vector part is $\sin 60^\circ \cdot \frac{1}{\sqrt{3}}(1, 1, 1)^\top = \frac{\sqrt{3}}{2} \cdot \frac{1}{\sqrt{3}}(1, 1, 1)^\top = \frac{1}{2}(1, 1, 1)^\top$. *Distractors:* B uses the full angle instead of the half-angle ($\cos 120^\circ \neq \frac{\sqrt{3}}{2}$, and in any case the norm would not be 1); C gets the sign of one component wrong, obtaining the axis $(1, 1, -1)$; D is the quaternion of a 180° rotation, not 120° . *Diagnosed error:* using θ instead of $\theta/2$: this is the single most frequent quaternion mistake. *Source:* Example 28.1 and Example 28.2; Murray–Li–Sastry, p. 34. *Prerequisite:* double-angle formulas. *Remediation:* check that quaternion A, cubed, gives -1 , consistent with $3 \times 120^\circ = 360^\circ$ and with the double covering.

BEST PRACTICE

Quiz — answers, rationale and diagnosis (5–8).

5) **B.** *Rationale:* Step 3 of the proof of Theorem 28.2 substitutes the powers and recognises the series for sin and cos; without the recurrence the series would not close. *Distractors:* A instead follows from Step 6 (block matrix in an orthonormal basis); C follows from A; D is Theorem 11.8, proved elsewhere and by other means. *Diagnosed error:* attributing to one lemma the role of a different step. *Source:* Murray–Li–Sastry, chap. 2, eq. (2.14), p. 28. *Prerequisite:* the exponential series of matrices. *Remediation:* redo Step 3 writing out explicitly the first six terms of the series.

6) **B.** *Rationale:* this is Corollary 28.3(iii): for $\theta = \pi$ one has $R = R^\top$, the antisymmetric

part is zero and the axis is read from $(R + I)/2 = \mathbf{u}\mathbf{u}^\top$. *Distractors*: A is false, $\text{tr } R = -1$ corresponds to $\theta = \pi$ and is very common; C is irrelevant, the vector obtained is already zero; D makes no sense, because Corollary 28.1 gives $R - R^\top = 2\sin\theta K$. *Diagnosed error*: not recognising the degenerate case and concluding that the object does not exist. *Source*: Corollary 28.3; Theorem 28.4, Step 8; Diebel, §5.8. *Prerequisite*: the symmetric and antisymmetric parts of a matrix. *Remediation*: redo Worked exercise 28.5.

7) C. *Rationale*: this is Proposition 28.6(iii)–(iv) together with Example 28.5: ten degrees against three hundred and fifty. *Distractors*: A is false, the formula is defined for every pair with $\sin\Omega \neq 0$; B contradicts Corollary 28.6(ii); D is false, $-q_1$ is as unit as q_1 . *Diagnosed error*: believing that “same rotation” implies “same path”. *Source*: Proposition 28.6; Shoemake, SIGGRAPH 1985, pp. 245–254. *Prerequisite*: the double covering (Theorem 11.10(iv)). *Remediation*: compute $\langle q_0, q_1 \rangle$ for the two pairs of Assigned exercise 28.3(a).

8) A. *Rationale*: Murray–Li–Sastry’s Lemma 2.3 gives the recurrence (equations 2.12–2.13) and equation (2.14) is Rodrigues’ formula, both on p. 28. *Distractors*: B, Kuipers’s text is an introduction to rotation sequences and does not use this numbering; C, §8 of Diebel is the catalogue of the twelve Euler parametrisations, not Rodrigues; D, Book I of Hamilton’s *Elements* treats vectors “without reference to angles or rotations” — the title of the book itself says so. *Diagnosed error*: citing from memory without checking the exact location. *Source*: list at the end of the chapter, entries [1] and [3]. *Prerequisite*: none. *Remediation*: open the three sources and locate in each of them where, if at all, the recurrence and the formula appear.

BEST PRACTICE

Assigned exercises — answers.

Exercise 28.1. (a) $K = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & -1 \\ -1 & 1 & 0 \end{pmatrix}$, $K^2 = \mathbf{u}\mathbf{u}^\top - I = \begin{pmatrix} -\frac{1}{2} & \frac{1}{2} & 0 \\ \frac{1}{2} & -\frac{1}{2} & 0 \\ 0 & 0 & -1 \end{pmatrix}$, and with $\sin\pi = 0$, $1 - \cos\pi = 2$: $R = I + 2K^2 = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix}$, with integer entries. (b) $R^2 = I$ because two half-turns make a full turn (Theorem 28.2, Step 8: $R(\mathbf{u}, \pi)^2 = R(\mathbf{u}, 2\pi) = I$); $\text{tr } R = 0 + 0 - 1 = -1 = 1 + 2\cos\pi$ (Corollary 28.1). (c) $c_0 = 1 - 1 = 0$, $c_1 = 1 + 0 + 1 = 2$, $c_2 = 1 + 0 + 1 = 2$, $c_3 = 1 - 2 + 1 = 0$; sum 4. ✓ There are *two* maxima, $c_1 = c_2 = 2$: Theorem 28.4 calls for a maximal index, not a unique maximum, and the two branches give the same quaternion (up to the global sign). (d) With $m^* = 1$: $s = \frac{\sqrt{2}}{2}$, $4s = 2\sqrt{2} = 2.82842712$, $x = s$, $w = (R_{32} - R_{23})/(4s) = 0$, $y = (R_{12} + R_{21})/(4s) = 2/(2\sqrt{2}) = \frac{1}{\sqrt{2}}$, $z = (R_{13} + R_{31})/(4s) = 0$; hence $q = (0, \frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}, 0) = (0, \mathbf{u})$, and $R(q) = R$ by Theorem 28.3. With $m^* = 2$ one obtains the same q . (e) The single-branch formula sets $w = \frac{1}{2}\sqrt{1 + \text{tr } R} = 0$ and then divides by $4w = 0$: it fails at the division, not at the extraction of the root.

Exercise 28.2. (a) With the same scheme as Lemma 28.4 (derivative, multiplication by $R^\top$, Lemma 28.3) one obtains $\boldsymbol{\omega} = \dot{\alpha} \mathbf{e}_3 + \dot{\beta} R_z(\alpha) \mathbf{e}_2 + \dot{\gamma} R_z(\alpha) R_y(\beta) \mathbf{e}_3$, that is

$$J = \begin{pmatrix} 0 & -s_\alpha & c_\alpha s_\beta \\ 0 & c_\alpha & s_\alpha s_\beta \\ 1 & 0 & c_\beta \end{pmatrix}.$$

(b) Expanding along the first column, $\det J = 1 \cdot \det \begin{pmatrix} -s_\alpha & c_\alpha s_\beta \\ c_\alpha & s_\alpha s_\beta \end{pmatrix} = -s_\alpha^2 s_\beta - c_\alpha^2 s_\beta = -\sin\beta$. The singular configurations are $\beta = 0$ and $\beta = \pi$. (c) For $\beta = 0$: $R_y(0) = I$, hence the third column is $R_z(\alpha) \mathbf{e}_3 = \mathbf{e}_3$, equal to the first: rank 2 (the second column $(-s_\alpha, c_\alpha, 0)^\top$ is independent of $\mathbf{e}_3$), kernel spanned by $(1, 0, -1)^\top$. For $\beta = \pi$: $R_y(\pi) \mathbf{e}_3 = (\sin\pi, 0, \cos\pi)^\top = -\mathbf{e}_3$, hence the third column is $-\mathbf{e}_3$: rank 2, kernel spanned by $(1, 0, 1)^\top$. (d) For $\beta = 0$,

$R = R_z(\alpha)R_z(\gamma) = R_z(\alpha + \gamma)$ (Proposition 28.1): it depends only on $\alpha + \gamma$. For $\beta = \pi$, Corollary 28.2 gives $R_y(\pi)R_z(\gamma)R_y(\pi)^\top = R(R_y(\pi)\mathbf{e}_3, \gamma) = R(-\mathbf{e}_3, \gamma) = R_z(-\gamma)$, hence $R = R_z(\alpha)R_z(-\gamma)R_y(\pi) = R_z(\alpha - \gamma)R_y(\pi)$: it depends only on $\alpha - \gamma$. (e) The singularity has moved from $\theta = \pm \frac{\pi}{2}$ to $\beta \in \{0, \pi\}$ and is of the same type (rank drops to 2, loss of one degree of freedom); the fact that it cannot be removed by changing convention is Proposition 28.8. Note the practical difference: in ZYZ the singularity lies at the “rest” configuration $\beta = 0$, which makes this convention worse than RPY for a manipulator working about the vertical. *Numerical check:* $\det J + \sin \beta$ on 4 000 random pairs has maximum deviation 3.3×10^{-16} ; the columns of J recomputed by finite differences differ by at most 3.3×10^{-10} ; the identities of (d) are checked on 3 000 triples with maximum deviation 1.0×10^{-15} ; the rank at $\beta = 0$ and $\beta = \pi$ equals 2 in every case tested. ✓

Exercise 28.3. (a) $q_0 = (\cos 30^\circ, 0, 0, \sin 30^\circ) = (0.8660254, 0, 0, 0.5)$ and $q_1 = (\cos 150^\circ, 0, 0, \sin 150^\circ) = (-0.8660254, 0, 0, 0.5)$, hence $\langle q_0, q_1 \rangle = -0.75 + 0.25 = -0.5$ and $\Omega = 120^\circ$: without the choice of sign the rotation traversed is $2\Omega = 240^\circ$; with the choice ($q_1 \mapsto -q_1$) one has $\Omega = 60^\circ$ and the rotation is 120° . (b) The samples with the correct sign give cumulative angles $0^\circ, 12^\circ, 24^\circ, \dots, 120^\circ$; without it, $0^\circ, 24^\circ, 48^\circ, \dots, 240^\circ$. In both cases the endpoints are the same orientations. (c) The real part of $\bar{q}_0 q_1$ coincides with $\langle q_0, q_1 \rangle$ up to machine error (measured: maximum deviation 0 on 5 000 pairs). (d) $\|J^{-1}\|_2$ equals 8.1131, 81.0295, 810.2848, 8102.8469 for $\theta = 80^\circ, 89^\circ, 89.9^\circ, 89.99^\circ$, against $1/|\cos \theta| = 5.7588, 57.2987, 572.9581, 5729.5780$: the ratio tends to $\sqrt{2}$, hence $\|J^{-1}\|_2$ diverges like $1/|\cos \theta|$, the reciprocal of the determinant (Theorem 28.5(i)). (e) With $\lambda = 10^{-2}$, the norm of the damped inverse $J^\top(JJ^\top + \lambda^2 I)^{-1}$ equals 8.0601, 48.9138, 12.1562, 1.2339 at the same four points: it grows up to a maximum around $\theta = 89^\circ$ (where the smallest singular value is comparable to λ) and then *decreases*, because the deeper one goes into the singularity the more the term $\lambda^2 I$ dominates. It diverges nowhere: this is exactly the property sought. One gains boundedness of the joint velocities; one loses tracking accuracy, because in the lost direction the angular velocity produced is smaller than the one requested by a factor $\sigma^2/(\sigma^2 + \lambda^2)$, with σ the singular value tending to zero.

28.13. Chapter formulary

Rotation group and elementary rotations.

$$SO(3) = \{R : R^\top R = I, \det R = +1\}, \quad R_*(\alpha)R_*(\beta) = R_*(\alpha + \beta),$$

$$R_*(\alpha)^{-1} = R_*(-\alpha) = R_*(\alpha)^\top.$$

$$R_x(\alpha) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & c_\alpha & -s_\alpha \\ 0 & s_\alpha & c_\alpha \end{pmatrix}, \quad R_y(\alpha) = \begin{pmatrix} c_\alpha & 0 & s_\alpha \\ 0 & 1 & 0 \\ -s_\alpha & 0 & c_\alpha \end{pmatrix}, \quad R_z(\alpha) = \begin{pmatrix} c_\alpha & -s_\alpha & 0 \\ s_\alpha & c_\alpha & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Non-commutativity: $R_z(90^\circ)R_x(90^\circ) = R(\frac{1}{\sqrt{3}}(1, 1, 1), 120^\circ)$ and $R_x(90^\circ)R_z(90^\circ) = R(\frac{1}{\sqrt{3}}(1, -1, 1), 120^\circ)$.

Hat map and Rodrigues' formula. For $\|\mathbf{u}\| = 1$ and $K = [\mathbf{u}]_\times$:

$$K^\top = -K, \quad K\mathbf{u} = \mathbf{0}, \quad K^2 = \mathbf{u}\mathbf{u}^\top - I, \quad K^3 = -K,$$

$$K^{2m+1} = (-1)^m K, \quad K^{2m+2} = (-1)^m K^2.$$

$$R(\mathbf{u}, \theta) = e^{\theta K} = I + \sin \theta K + (1 - \cos \theta)K^2,$$

$$R(\mathbf{u}, \theta)\mathbf{v} = \cos \theta \mathbf{v} + \sin \theta (\mathbf{u} \times \mathbf{v}) + (1 - \cos \theta)\langle \mathbf{u}, \mathbf{v} \rangle \mathbf{u},$$

$$\operatorname{tr} R = 1 + 2 \cos \theta, \quad R - R^\top = 2 \sin \theta K, \quad A R(\mathbf{u}, \theta) A^\top = R(A\mathbf{u}, \theta) \quad (A \in SO(3)).$$

Inverse (logarithm). $\theta = \arccos \frac{\operatorname{tr} R - 1}{2} \in [0, \pi]$; if $0 < \theta < \pi$, $\mathbf{u} = \frac{1}{2 \sin \theta} (R_{32} - R_{23}, R_{13} - R_{31}, R_{21} - R_{12})^\top$; if $\theta = 0$, $R = I$ and the axis is undetermined; if $\theta = \pi$, $\mathbf{u}\mathbf{u}^\top = (R + I)/2$ and $\mathbf{u}$ is determined up to sign.

Quaternions. With $p = (a, \mathbf{u})$, $q = (b, \mathbf{v})$:

$$pq = (ab - \langle \mathbf{u}, \mathbf{v} \rangle, a\mathbf{v} + b\mathbf{u} + \mathbf{u} \times \mathbf{v}), \quad \overline{pq} = \bar{q}\bar{p}, \quad q\bar{q} = \|q\|^2, \quad q^{-1} = \frac{\bar{q}}{\|q\|^2},$$

$$\|pq\| = \|p\| \|q\| \quad (\text{four-square identity}).$$

Euler parameters. $q = (\cos \frac{\theta}{2}, \sin \frac{\theta}{2} \mathbf{u})$, with $e_0^2 + e_1^2 + e_2^2 + e_3^2 = 1$; four parameters, one constraint, three degrees of freedom.

Conversions. From $q = (w, x, y, z)$ unitary:

$$R(q) = (w^2 - \|\mathbf{v}\|^2)I + 2\mathbf{v}\mathbf{v}^\top + 2w[\mathbf{v}]_\times = \begin{pmatrix} 1 - 2(y^2 + z^2) & 2(xy - wz) & 2(xz + wy) \\ 2(xy + wz) & 1 - 2(x^2 + z^2) & 2(yz - wx) \\ 2(xz - wy) & 2(yz + wx) & 1 - 2(x^2 + y^2) \end{pmatrix}.$$

From R to q (four branches): $c_0 = 1 + \operatorname{tr} R$, $c_m = 1 + 2R_{mm} - \operatorname{tr} R$; $c_0 + c_1 + c_2 + c_3 = 4$, $c_0 = 4w^2$, $c_m = 4(m\text{-th component})^2$; the maximal m^* is chosen, $s = \frac{1}{2}\sqrt{c_{m^*}} \geq \frac{1}{2}$, and one divides by $4s$ the combinations

$$R_{32} - R_{23} = 4wx, \quad R_{13} - R_{31} = 4wy, \quad R_{21} - R_{12} = 4wz,$$

$$R_{12} + R_{21} = 4xy, \quad R_{13} + R_{31} = 4xz, \quad R_{23} + R_{32} = 4yz.$$

From q to axis-angle (after making $w \geq 0$): $\theta = 2 \operatorname{atan2}(\|\mathbf{v}\|, w)$ and $\mathbf{u} = \mathbf{v}/\|\mathbf{v}\|$; $\mathbf{v} = \mathbf{0}$ gives $R = I$, $w = 0$ gives $\theta = \pi$ with the axis determined up to sign.

Double covering and interpolation.

$$\Phi : S^3 \rightarrow SO(3), \quad \ker \Phi = \{\pm 1\}, \quad \Phi^{-1}(R) = \{q, -q\},$$

$$SO(3) \cong S^3 / \{\pm 1\} = \mathbb{R}P^3 \cong SU(2) / \{\pm I\}.$$

$$\operatorname{Re}(\bar{q}_0 q_1) = \langle q_0, q_1 \rangle = \cos \Omega; \quad \text{relative angle} = 2\Omega \quad (\Omega \leq \frac{\pi}{2}), \quad 2(\pi - \Omega) \quad (\Omega > \frac{\pi}{2}).$$

Operating rule: if $\langle q_0, q_1 \rangle < 0$, replace q_1 with $-q_1$ before interpolating.

RPY angles (ZYX) and gimbal lock. $R = R_z(\psi)R_y(\theta)R_x(\phi)$:

$$R = \begin{pmatrix} c_\psi c_\theta & c_\psi s_\theta s_\phi - s_\psi c_\phi & c_\psi s_\theta c_\phi + s_\psi s_\phi \\ s_\psi c_\theta & s_\psi s_\theta s_\phi + c_\psi c_\phi & s_\psi s_\theta c_\phi - c_\psi s_\phi \\ -s_\theta & c_\theta s_\phi & c_\theta c_\phi \end{pmatrix}, \quad J = \begin{pmatrix} c_\psi c_\theta & -s_\psi & 0 \\ s_\psi c_\theta & c_\psi & 0 \\ -s_\theta & 0 & 1 \end{pmatrix},$$

$$\dot{R}R^\top = [\boldsymbol{\omega}]_\times, \quad \boldsymbol{\omega} = J(\dot{\phi}, \dot{\theta}, \dot{\psi})^\top, \quad \det J = \cos \theta.$$

Gimbal lock: at $\theta = \pm \frac{\pi}{2}$ the rank of J is 2, the kernel is $(1, 0, \pm 1)^\top$, and $R(\phi, \pm \frac{\pi}{2}, \psi) = R_z(\psi \mp \phi)R_y(\pm \frac{\pi}{2})$. Extraction (for $\cos \theta \neq 0$): $\theta = \operatorname{atan2}(-R_{31}, \sqrt{R_{11}^2 + R_{21}^2})$, $\psi = \operatorname{atan2}(R_{21}, R_{11})$, $\phi = \operatorname{atan2}(R_{32}, R_{33})$. From ZYX angles to quaternion, with $c_A = \cos \frac{A}{2}$

and so on:

$$\begin{aligned} w &= c_A c_B c_C + s_A s_B s_C, & x &= c_A c_B s_C - s_A s_B c_C, \\ y &= c_A s_B c_C + s_A c_B s_C, & z &= s_A c_B c_C - c_A s_B s_C. \end{aligned}$$

Lie groups and kinematics: from $SE(3)$ to the product of exponentials

Rodrigues' formula and the unit quaternions of Chapter 28 describe the *orientation* of a rigid body. A robot, however, does not only orient itself: it moves. The complete pose of the tool is a pair (rotation, position), and the set of all poses is a group, $SE(3)$, which is neither a direct product of $SO(3)$ by $\mathbb{R}^3$ nor something more exotic: it is a *semidirect product*, and the twist that the semidirect product introduces is exactly what makes the kinematics of manipulators a nontrivial problem.

The thread running through the chapter is a single one, and it is the same one as for the circle: the exponential map. On the circle $t \mapsto e^{it}$ unrolled S^1 onto the line (Chapter 12); on $SO(3)$ the exponential of a skew-symmetric matrix gave Rodrigues' formula; on $SE(3)$ the exponential of a *twist* gives a **screw motion**, that is, a rotation about an axis composed with a translation along that same axis. Chasles' theorem (1830) states that *every* rigid motion of space is of this form: the exponential is surjective. From there the forward kinematics of an open kinematic chain is written as a product of exponentials, the geometric Jacobian is obtained by differentiating that product instead of postulating it, and singularities become a rank condition on a $6 \times n$ matrix whose columns are twists. The gimbal lock of Chapter 28 reappears here in its mechanical incarnation: wrist singularity.

INFO

Level and prerequisites. Level C–D (undergraduate/graduate).

Internal prerequisites. Rotations in space, the skew-symmetric matrix associated with a vector and Rodrigues' formula (Chapter 28); groups of isometries and the classification of $O(2)$, $O(3)$ (Chapter 5); the exponential as a homomorphism of one-parameter groups (Chapter 13); the notions of rank, determinant and singular value decomposition of a real matrix (basic linear algebra, Volume II, Chapter 1).

External prerequisites, assumed and not reproved:

- the matrix exponential series $e^A = \sum_{k \geq 0} A^k/k!$ converges absolutely in every submultiplicative norm, can be differentiated term by term, and satisfies $\frac{d}{dt}e^{tA} = Ae^{tA} = e^{tA}A$ and $\det e^A = e^{\text{tr} A}$;
- if $AB = BA$ then $e^{A+B} = e^Ae^B$; in general not;
- the double cross product identity $\mathbf{a} \times (\mathbf{b} \times \mathbf{c}) = \mathbf{b}(\mathbf{a} \cdot \mathbf{c}) - \mathbf{c}(\mathbf{a} \cdot \mathbf{b})$;
- the existence of the singular value decomposition $A = U\Sigma V^T$ and the fact that the number of nonzero singular values is the rank of A .

Everything else — including the closed form of the exponential of a twist, the inverse of the matrix $G(\theta)$, Chasles' theorem with explicit axis and pitch, the product-of-exponentials formula and the two Jacobians — is proved here.

What one learns. Recognising $SE(3)$ as a matrix Lie group and as a semidirect product; computing the exponential of a twist in closed form and its logarithm; decomposing a given rigid motion into axis, angle and pitch; writing the forward kinematics of an open chain with no intermediate frames; deriving (not postulating) the spatial and the body Jacobian;

identifying singular configurations and verifying them with singular values.

Warning. Conventions of this chapter.

- Vectors of $\mathbb{R}^3$ are columns; $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$ is the canonical basis; I is the identity of size inferred from context.
- A rigid motion is written either as a pair $(R, \mathbf{p})$ or as a 4×4 homogeneous matrix; the two languages are used interchangeably.
- The coordinates of a twist are ordered **angular-first**: $\xi = (\omega, \mathbf{v}) \in \mathbb{R}^6$. This is the Lynch–Park convention; Murray–Li–Sastry uses the opposite order $\xi = (\mathbf{v}, \omega)$, and with it the adjoint matrix Ad_g appears block-transposed. When comparing formulas with the literature, the first thing to check is the order.
- θ always denotes the parameter of the screw motion (angle if $\omega \neq 0$, length if $\omega = 0$); θ_i is the variable of joint i .
- “Axis” means an oriented line in $\mathbb{R}^3$; its direction is that of ω .
- Numerical values are rounded to six decimal places, with the decimal point as separator.

29.1. The group of rigid motions $SE(3)$

Definition 29.1: Rigid motion and the group $SE(3)$. A map $f : \mathbb{R}^3 \rightarrow \mathbb{R}^3$ is a **direct rigid motion** if there exist $R \in SO(3)$ and $\mathbf{p} \in \mathbb{R}^3$ such that

$$f(\mathbf{x}) = R\mathbf{x} + \mathbf{p} \quad \text{for every } \mathbf{x} \in \mathbb{R}^3.$$

The set of such maps is denoted $SE(3)$ (*special Euclidean group*). To $f = (R, \mathbf{p})$ one associates the **homogeneous matrix**

$$T = \begin{pmatrix} R & \mathbf{p} \\ \mathbf{0}^\top & 1 \end{pmatrix} \in \mathbb{R}^{4 \times 4},$$

which acts on points through *homogeneous coordinates* $\tilde{\mathbf{x}} = \begin{pmatrix} \mathbf{x} \\ 1 \end{pmatrix}$: $T\tilde{\mathbf{x}} = \begin{pmatrix} R\mathbf{x} + \mathbf{p} \\ 1 \end{pmatrix}$.

The correspondence $f \leftrightarrow T$ is a bijection: R and $\mathbf{p}$ are read off from T , and conversely. From here on, $SE(3)$ denotes indifferently the set of maps or the set of homogeneous matrices.

Proposition 29.1: $SE(3)$ is a group. $SE(3)$, with matrix multiplication, is a group. Explicitly:

$$(R_1, \mathbf{p}_1) \cdot (R_2, \mathbf{p}_2) = (R_1 R_2, R_1 \mathbf{p}_2 + \mathbf{p}_1), \quad (R, \mathbf{p})^{-1} = (R^\top, -R^\top \mathbf{p}),$$

and the identity element is $(I, \mathbf{0})$.

Proof. Step 1 — closure. Multiply the homogeneous matrices in block form:

$$\begin{pmatrix} R_1 & \mathbf{p}_1 \\ \mathbf{0}^\top & 1 \end{pmatrix} \begin{pmatrix} R_2 & \mathbf{p}_2 \\ \mathbf{0}^\top & 1 \end{pmatrix} = \begin{pmatrix} R_1 R_2 & R_1 \mathbf{p}_2 + \mathbf{p}_1 \\ \mathbf{0}^\top & 1 \end{pmatrix}.$$

The bottom-left block is $\mathbf{0}^\top R_2 + 1 \cdot \mathbf{0}^\top = \mathbf{0}^\top$ and the bottom-right one is $\mathbf{0}^\top \mathbf{p}_2 + 1 = 1$: the homogeneous form is preserved. It remains to see that $R_1 R_2 \in SO(3)$: indeed $(R_1 R_2)^\top (R_1 R_2) = R_2^\top R_1^\top R_1 R_2 = R_2^\top R_2 = I$ and $\det(R_1 R_2) = \det R_1 \det R_2 = 1$. Hence the product lies in

$SE(3)$. (In terms of maps: $f_1(f_2(\mathbf{x})) = R_1(R_2\mathbf{x} + \mathbf{p}_2) + \mathbf{p}_1 = R_1R_2\mathbf{x} + R_1\mathbf{p}_2 + \mathbf{p}_1$, the same formula.)

Step 2 — associativity. This is the associativity of 4×4 matrix multiplication, which holds in $\mathbb{R}^{4 \times 4}$ and is inherited by any subset closed under the product.

Step 3 — identity. $(I, \mathbf{0})$ has homogeneous matrix I_4 and satisfies $(I, \mathbf{0})(R, \mathbf{p}) = (R, \mathbf{p}) = (R, \mathbf{p})(I, \mathbf{0})$ by the formula of Step 1.

Step 4 — inverse. Set $S = (R^\top, -R^\top \mathbf{p})$; since $R^\top = R^{-1} \in SO(3)$ (the inverse of a special orthogonal matrix is special orthogonal: $(R^\top)^\top R^\top = RR^\top = I$ and $\det R^\top = \det R = 1$), $S \in SE(3)$. Applying Step 1 twice:

$$(R, \mathbf{p})S = (RR^\top, R(-R^\top \mathbf{p}) + \mathbf{p}) = (I, -\mathbf{p} + \mathbf{p}) = (I, \mathbf{0}),$$

$$S(R, \mathbf{p}) = (R^\top R, R^\top \mathbf{p} - R^\top \mathbf{p}) = (I, \mathbf{0}).$$

Thus S is the two-sided inverse. All group axioms are verified. $\square$

Before speaking of a Lie algebra we need a definition of Lie group that can be used without building differentiable manifolds. We adopt the *matrix* definition, standard in introductory texts (Hall, *An Elementary Introduction to Groups and Representations*, Definition 2.2): a matrix Lie group is a subgroup of $GL(n, \mathbb{R})$ that is *closed* in $GL(n, \mathbb{R})$.

Definition 29.2: Matrix Lie group. Let $GL(n, \mathbb{R}) = \{A \in \mathbb{R}^{n \times n} : \det A \neq 0\}$, with the topology induced from $\mathbb{R}^{n \times n}$. A subgroup $G \subseteq GL(n, \mathbb{R})$ is a **matrix Lie group** if it is closed in $GL(n, \mathbb{R})$: every sequence $(A_k) \subset G$ that converges to some $A \in GL(n, \mathbb{R})$ has limit $A \in G$.

Theorem 29.1: $SE(3)$ is a matrix Lie group. $SE(3)$, viewed as a set of 4×4 matrices, is a closed subgroup of $GL(4, \mathbb{R})$; in particular it is a matrix Lie group.

Proof. **Step 1 — $SE(3) \subseteq GL(4, \mathbb{R})$.** Expanding the determinant along the last row of the homogeneous matrix gives $\det T = 1 \cdot \det R = 1 \neq 0$.

Step 2 — it is a subgroup. This is Proposition 29.1: $SE(3)$ is closed under the product and the inverse and contains I_4 .

Step 3 — it is closed. Let $T_k = \begin{pmatrix} R_k & \mathbf{p}_k \\ \mathbf{0}^\top & 1 \end{pmatrix} \in SE(3)$ with $T_k \rightarrow T \in GL(4, \mathbb{R})$. Convergence in $\mathbb{R}^{4 \times 4}$ is entrywise convergence; hence the last row of T is the limit of the last rows, that is $(0, 0, 0, 1)$, and T has the form $\begin{pmatrix} R & \mathbf{p} \\ \mathbf{0}^\top & 1 \end{pmatrix}$ with $R_k \rightarrow R$ and $\mathbf{p}_k \rightarrow \mathbf{p}$. The maps $A \mapsto A^\top A$ and $A \mapsto \det A$ are continuous (they are polynomial in the entries), so

$$R^\top R = \lim_k R_k^\top R_k = I, \quad \det R = \lim_k \det R_k = 1,$$

that is $R \in SO(3)$ and $T \in SE(3)$. Closedness is proved, and with it the statement. $\square$

Theorem 29.2: $SE(3)$ as a semidirect product. Let $N = \{(I, \mathbf{p}) : \mathbf{p} \in \mathbb{R}^3\}$ be the subset of translations and $H = \{(R, \mathbf{0}) : R \in SO(3)\}$ that of rotations about the origin. Then:

- (i) N is a normal subgroup of $SE(3)$, isomorphic to the additive group $(\mathbb{R}^3, +)$;
- (ii) H is a subgroup isomorphic to $SO(3)$;
- (iii) $N \cap H = \{(I, \mathbf{0})\}$ and $NH = SE(3)$;
- (iv) every $g \in SE(3)$ can be written uniquely as $g = (I, \mathbf{p})(R, \mathbf{0})$, and the product is

computed by the rule

$$(\mathbf{p}_1, R_1) \cdot (\mathbf{p}_2, R_2) = (\mathbf{p}_1 + R_1 \mathbf{p}_2, R_1 R_2).$$

Hence $SE(3) = \mathbb{R}^3 \rtimes SO(3)$, a semidirect product with respect to the natural action of $SO(3)$ on $\mathbb{R}^3$.

Proof. (i). That N is a subgroup follows from Proposition 29.1: $(I, \mathbf{p}_1)(I, \mathbf{p}_2) = (I, \mathbf{p}_1 + \mathbf{p}_2)$ and $(I, \mathbf{p})^{-1} = (I, -\mathbf{p})$. The same formula shows that $\mathbf{p} \mapsto (I, \mathbf{p})$ is an isomorphism of $(\mathbb{R}^3, +)$ onto N (it is a bijection and turns the sum into the product). For normality we compute the conjugate:

$$(R, \mathbf{q})(I, \mathbf{p})(R, \mathbf{q})^{-1} = (R, R\mathbf{p} + \mathbf{q})(R^\top, -R^\top \mathbf{q}) = (RR^\top, -RR^\top \mathbf{q} + R\mathbf{p} + \mathbf{q}) = (I, R\mathbf{p}),$$

which belongs to N . Hence $gNg^{-1} \subseteq N$ for every g , and applying the same inclusion to g^{-1} gives $gNg^{-1} = N$: N is normal. Note already the key formula

$$(R, \mathbf{q})(I, \mathbf{p})(R, \mathbf{q})^{-1} = (I, R\mathbf{p}), \quad (29.1)$$

which is exactly the action of $SO(3)$ on $\mathbb{R}^3$ by rotation.

(ii). $(R_1, \mathbf{0})(R_2, \mathbf{0}) = (R_1 R_2, \mathbf{0})$ and $(R, \mathbf{0})^{-1} = (R^\top, \mathbf{0})$: H is a subgroup and $R \mapsto (R, \mathbf{0})$ is an isomorphism onto $SO(3)$.

(iii). If $(I, \mathbf{p}) = (R, \mathbf{0})$ then $R = I$ and $\mathbf{p} = \mathbf{0}$: the intersection is trivial. Moreover, for every $(R, \mathbf{p})$,

$$(I, \mathbf{p})(R, \mathbf{0}) = (R, \mathbf{p}),$$

hence $NH = SE(3)$.

(iv). Existence is the formula just written. For uniqueness, if $(I, \mathbf{p})(R, \mathbf{0}) = (I, \mathbf{p}')(R', \mathbf{0})$ then $(R, \mathbf{p}) = (R', \mathbf{p}')$, that is $R = R'$ and $\mathbf{p} = \mathbf{p}'$. Identifying g with the pair $(\mathbf{p}, R)$ and again using Proposition 29.1:

$$(\mathbf{p}_1, R_1)(\mathbf{p}_2, R_2) = (R_1, \mathbf{p}_1)(R_2, \mathbf{p}_2) = (R_1 R_2, R_1 \mathbf{p}_2 + \mathbf{p}_1) \longleftrightarrow (\mathbf{p}_1 + R_1 \mathbf{p}_2, R_1 R_2).$$

This is, by definition, the multiplication of the semidirect product $\mathbb{R}^3 \rtimes SO(3)$ associated with the homomorphism $SO(3) \rightarrow \text{Aut}(\mathbb{R}^3)$, $R \mapsto (\mathbf{p} \mapsto R\mathbf{p})$, which is a homomorphism because $(R_1 R_2)\mathbf{p} = R_1(R_2 \mathbf{p})$. $\square$

Remark 29.1: Why “semidirect” and not “direct”. If the product were direct one would have $(\mathbf{p}_1, R_1)(\mathbf{p}_2, R_2) = (\mathbf{p}_1 + \mathbf{p}_2, R_1 R_2)$: translations and rotations would not see each other. Instead $R_1 \mathbf{p}_2$ appears: the translation of the second factor gets rotated by the first. It is the same asymmetry by which “advance one metre, then turn 90° ” is not the same command as “turn 90° , then advance one metre”; and it is the reason a robotic arm cannot be programmed by separately summing rotations and translations. Formally: H is not normal in $SE(3)$, because for $\mathbf{q} \neq \mathbf{0}$ and $R \neq I$

$$(I, \mathbf{q})(R, \mathbf{0})(I, -\mathbf{q}) = (R, \mathbf{q} - R\mathbf{q}) \notin H \quad \text{if } R\mathbf{q} \neq \mathbf{q}.$$

Remark 29.2: What we import: from the closed subgroup to the manifold. With Definition 29.2, Theorem 29.1 is complete: everything needed in the rest of the chapter (Lie algebra, exponential, one-parameter subgroups) is built from closedness alone. What remains, however, is an **imported** statement, used only to connect the matrix language with that of differentiable manifolds:

Closed subgroup theorem (Cartan). *Every closed subgroup of a Lie group is a closed embedded submanifold, hence a Lie group in the abstract sense, and its Lie algebra coincides with $\{X : e^{tX} \in G \ \forall t \in \mathbb{R}\}$.*

What is missing to prove it here: *the construction of local charts by means of the exponential and the technical lemma that rules out “spurious directions” of the group (in Lee’s proof: that a sequence $h_i \rightarrow e$ in H produces, after reparametrisation, a vector of the algebra), which require the inverse function theorem on manifolds — tools outside the scope of this volume.*
Source: J. M. Lee, *Introduction to Smooth Manifolds*, 2nd ed., Springer (GTM 218), New York 2013, Theorem 20.12, p. 522 (see the “Sources” section). In what follows the imported result is never used: when we write “ $\mathfrak{se}(3)$ has dimension 6” we mean the dimension as a real vector space, which is computed explicitly in Theorem 29.3.

29.2. The Lie algebra $\mathfrak{se}(3)$ and twists

Definition 29.3: Hat and vee maps on $\mathbb{R}^3$. For $\omega = (\omega_1, \omega_2, \omega_3)^\top \in \mathbb{R}^3$ set

$$[\omega]_\times = \begin{pmatrix} 0 & -\omega_3 & \omega_2 \\ \omega_3 & 0 & -\omega_1 \\ -\omega_2 & \omega_1 & 0 \end{pmatrix} \in \mathbb{R}^{3 \times 3},$$

the unique matrix such that $[\omega]_\times \mathbf{x} = \omega \times \mathbf{x}$ for every $\mathbf{x}$. The map $\omega \mapsto [\omega]_\times$ is a linear isomorphism of $\mathbb{R}^3$ onto the space $\mathfrak{so}(3) = \{A \in \mathbb{R}^{3 \times 3} : A^\top = -A\}$ of skew-symmetric matrices; the inverse map is denoted $A \mapsto A^\vee$.

That it is an isomorphism is seen at once: the map is linear in the entries, it is injective (if $[\omega]_\times = 0$ then $\omega = 0$, reading off the entries), and $\mathfrak{so}(3)$ has dimension 3 (a 3×3 skew-symmetric matrix has zero diagonal and three free entries above the diagonal), equal to that of $\mathbb{R}^3$.

Lemma 29.1: Powers of $[\omega]_\times$. For every $\omega \in \mathbb{R}^3$, setting $K = [\omega]_\times$:

$$(i) \ K^2 = \omega \omega^\top - \|\omega\|^2 I, \quad (ii) \ K^3 = -\|\omega\|^2 K, \quad (iii) \ K \omega = 0.$$

In particular, if $\|\omega\| = 1$ then $K^3 = -K$, $K^4 = -K^2$, $K^5 = K$, and in general the powers of K reduce cyclically to K and K^2 .

Proof. (iii) $K \omega = \omega \times \omega = 0$.

(i) For every $\mathbf{x} \in \mathbb{R}^3$,

$$K^2 \mathbf{x} = \omega \times (\omega \times \mathbf{x}) = \omega(\omega \cdot \mathbf{x}) - \mathbf{x}(\omega \cdot \omega) = (\omega \omega^\top - \|\omega\|^2 I) \mathbf{x},$$

where the double cross product identity (prerequisite) was used with $\mathbf{a} = \mathbf{b} = \omega$, $\mathbf{c} = \mathbf{x}$. Two matrices agreeing on every $\mathbf{x}$ are equal.

(ii) Multiplying (i) on the left by K :

$$K^3 = K \omega \omega^\top - \|\omega\|^2 K = (K \omega) \omega^\top - \|\omega\|^2 K = -\|\omega\|^2 K,$$

because $K \omega = 0$ by (iii).

For $\|\omega\| = 1$: $K^3 = -K$; hence $K^4 = K \cdot K^3 = -K^2$, $K^5 = K \cdot K^4 = -K^3 = K$, and the sequence of powers is periodic with period 4 starting from K . $\square$

Lemma 29.2: *The hat map turns the cross product into the commutator. For every $\mathbf{a}, \mathbf{b} \in \mathbb{R}^3$,*

$$[[\mathbf{a}]_{\times}, [\mathbf{b}]_{\times}] := [\mathbf{a}]_{\times}[\mathbf{b}]_{\times} - [\mathbf{b}]_{\times}[\mathbf{a}]_{\times} = [\mathbf{a} \times \mathbf{b}]_{\times}.$$

Hence $\mathfrak{so}(3)$, with the commutator, is a Lie algebra isomorphic to $(\mathbb{R}^3, \times)$.

Proof. Apply both sides to a generic $\mathbf{x} \in \mathbb{R}^3$ and use the double cross product identity twice:

$$\mathbf{a} \times (\mathbf{b} \times \mathbf{x}) = \mathbf{b}(\mathbf{a} \cdot \mathbf{x}) - \mathbf{x}(\mathbf{a} \cdot \mathbf{b}), \quad \mathbf{b} \times (\mathbf{a} \times \mathbf{x}) = \mathbf{a}(\mathbf{b} \cdot \mathbf{x}) - \mathbf{x}(\mathbf{a} \cdot \mathbf{b}).$$

Subtracting, the terms in $\mathbf{x}(\mathbf{a} \cdot \mathbf{b})$ cancel:

$$[[\mathbf{a}]_{\times}, [\mathbf{b}]_{\times}]\mathbf{x} = \mathbf{b}(\mathbf{a} \cdot \mathbf{x}) - \mathbf{a}(\mathbf{b} \cdot \mathbf{x}).$$

On the other hand, again by the same identity applied to $\mathbf{x} \times (\mathbf{a} \times \mathbf{b}) = \mathbf{a}(\mathbf{x} \cdot \mathbf{b}) - \mathbf{b}(\mathbf{x} \cdot \mathbf{a})$, one has

$$[\mathbf{a} \times \mathbf{b}]_{\times}\mathbf{x} = (\mathbf{a} \times \mathbf{b}) \times \mathbf{x} = -\mathbf{x} \times (\mathbf{a} \times \mathbf{b}) = \mathbf{b}(\mathbf{a} \cdot \mathbf{x}) - \mathbf{a}(\mathbf{b} \cdot \mathbf{x}).$$

The two results agree for every $\mathbf{x}$, hence the matrices are equal. Since $\omega \mapsto [\omega]_{\times}$ is a linear isomorphism (Definition 29.3) that turns $\times$ into $[\cdot, \cdot]$, it is an isomorphism of Lie algebras. $\square$

Example 29.1: The commutator of the canonical generators. With $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$ the canonical basis:

$$[\mathbf{e}_1]_{\times} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}, \quad [\mathbf{e}_2]_{\times} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{pmatrix}, \quad [\mathbf{e}_3]_{\times} = \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

The two products, computed row by column, are

$$[\mathbf{e}_1]_{\times}[\mathbf{e}_2]_{\times} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

$$[\mathbf{e}_2]_{\times}[\mathbf{e}_1]_{\times} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

(for instance, entry (1, 2) of the second product is $0 \cdot 0 + 0 \cdot 0 + 1 \cdot 1 = 1$). The difference is

$$[[\mathbf{e}_1]_{\times}, [\mathbf{e}_2]_{\times}] = \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} = [\mathbf{e}_3]_{\times} = [\mathbf{e}_1 \times \mathbf{e}_2]_{\times},$$

in agreement with Lemma 29.2. $\checkmark$

Structural check. The commutator of two skew-symmetric matrices is skew-symmetric: $[A, B]^{\top} = B^{\top}A^{\top} - A^{\top}B^{\top} = BA - AB = -[A, B]$. If the result of such a computation comes out symmetric, the computation is wrong — and it is the most frequent sign error, because $[\mathbf{e}_2]_{\times}[\mathbf{e}_1]_{\times}$ has its single 1 *above* the diagonal, not below. The same three matrices satisfy, by the same lemma, $[[\mathbf{e}_2]_{\times}, [\mathbf{e}_3]_{\times}] = [\mathbf{e}_1]_{\times}$ and $[[\mathbf{e}_3]_{\times}, [\mathbf{e}_1]_{\times}] = [\mathbf{e}_2]_{\times}$: these are the structure relations of $\mathfrak{so}(3)$. Independent check in double precision on 2 000 randomly drawn pairs $(\mathbf{a}, \mathbf{b})$: maximum discrepancy $|[[\mathbf{a}]_{\times}, [\mathbf{b}]_{\times}] - [\mathbf{a} \times \mathbf{b}]_{\times}| = 0$ (the entries are sums and differences of exact floating-point products). $\checkmark$

Definition 29.4: The Lie algebra of a matrix Lie group. Let $G \subseteq GL(n, \mathbb{R})$ be a matrix Lie group. Its **Lie algebra** is

$$\mathfrak{g} = \{X \in \mathbb{R}^{n \times n} : e^{tX} \in G \text{ for every } t \in \mathbb{R}\}.$$

For $G = SE(3)$ one writes $\mathfrak{se}(3)$; for $G = SO(3)$ one writes $\mathfrak{so}(3)$ (the notation is consistent, as shown by Theorem 29.3).

Theorem 29.3: Structure of $\mathfrak{se}(3)$: twists. With $SE(3)$ as in Definition 29.1 and $\mathfrak{se}(3)$ as in Definition 29.4,

$$\mathfrak{se}(3) = \left\{ [\xi] := \begin{pmatrix} [\omega]_{\times} & \mathbf{v} \\ \mathbf{0}^{\top} & 0 \end{pmatrix} : \omega, \mathbf{v} \in \mathbb{R}^3 \right\},$$

and likewise $\mathfrak{so}(3) = \{[\omega]_{\times} : \omega \in \mathbb{R}^3\}$ is the space of skew-symmetric matrices. In particular:

- (i) $\mathfrak{se}(3)$ is a real vector subspace of $\mathbb{R}^{4 \times 4}$ of dimension 6; the map $\xi = (\omega, \mathbf{v}) \mapsto [\xi]$ is a linear isomorphism $\mathbb{R}^6 \rightarrow \mathfrak{se}(3)$, and ξ is called a **twist** (or twist coordinate vector);
- (ii) $\mathfrak{se}(3)$ is closed under the commutator, and

$$[[\xi_1], [\xi_2]] = [\xi_3], \quad \xi_3 = (\omega_1 \times \omega_2, \omega_1 \times \mathbf{v}_2 - \omega_2 \times \mathbf{v}_1);$$

- (iii) $\{[\xi] : \omega = 0\}$ is an abelian ideal of $\mathfrak{se}(3)$ isomorphic to $\mathbb{R}^3$: it is the infinitesimal counterpart of the normal subgroup of translations of Theorem 29.2.

Proof. Step 1 — structure of the powers. Let $X = \begin{pmatrix} A & \mathbf{v} \\ \mathbf{0}^{\top} & 0 \end{pmatrix}$ with $A \in \mathbb{R}^{3 \times 3}$. By induction on $k \geq 1$,

$$X^k = \begin{pmatrix} A^k & A^{k-1}\mathbf{v} \\ \mathbf{0}^{\top} & 0 \end{pmatrix}. \quad (29.2)$$

The case $k = 1$ is the definition (with $A^0 = I$). If it holds for k , then

$$X^{k+1} = X^k X = \begin{pmatrix} A^k & A^{k-1}\mathbf{v} \\ \mathbf{0}^{\top} & 0 \end{pmatrix} \begin{pmatrix} A & \mathbf{v} \\ \mathbf{0}^{\top} & 0 \end{pmatrix} = \begin{pmatrix} A^{k+1} & A^k\mathbf{v} \\ \mathbf{0}^{\top} & 0 \end{pmatrix}.$$

Summing the exponential series gives, for every $t \in \mathbb{R}$,

$$e^{tX} = I_4 + \sum_{k \geq 1} \frac{t^k}{k!} X^k = \begin{pmatrix} e^{tA} & \left(\sum_{k \geq 1} \frac{t^k}{k!} A^{k-1} \right) \mathbf{v} \\ \mathbf{0}^{\top} & 1 \end{pmatrix}, \quad (29.3)$$

where the block series converges because the series for e^{tX} converges and the blocks are continuous projections.

Step 2 — inclusion $\supseteq$. Let $A = [\omega]_{\times}$, so $A^{\top} = -A$. Then

$$(e^{tA})^{\top} e^{tA} = e^{tA^{\top}} e^{tA} = e^{-tA} e^{tA} = e^{-tA+tA} = I,$$

where the penultimate step uses that $-tA$ and tA commute, and

$$\det e^{tA} = e^{t \operatorname{tr} A} = e^0 = 1$$

because a skew-symmetric matrix has zero diagonal. Hence $e^{tA} \in SO(3)$ and, by (29.3), $e^{tX} \in SE(3)$ for every t : $X \in \mathfrak{se}(3)$.

Step 3 — inclusion $\subseteq$. Let $X \in \mathbb{R}^{4 \times 4}$ with $e^{tX} \in SE(3)$ for every t . Differentiating at $t = 0$ (the exponential series can be differentiated term by term, a prerequisite) gives $X = \frac{d}{dt}\big|_{t=0} e^{tX}$. The last row of e^{tX} is constantly $(0, 0, 0, 1)$, hence its derivative vanishes and the last row of X is $(0, 0, 0, 0)$. Therefore $X = \begin{pmatrix} A & \mathbf{v} \\ \mathbf{0}^\top & 0 \end{pmatrix}$, and by (29.3) the top-left 3×3 block of e^{tX} is e^{tA} , which must therefore lie in $SO(3)$ for every t . From $(e^{tA})^\top e^{tA} = I$, differentiating at $t = 0$ with the product rule,

$$0 = \frac{d}{dt}\bigg|_{t=0} (e^{tA^\top} e^{tA}) = A^\top + A,$$

so A is skew-symmetric, that is $A = [\omega]_\times$ for a unique ω (Definition 29.3). The two inclusions give equality. The same argument, applied in $\mathbb{R}^{3 \times 3}$, gives $\mathfrak{so}(3) = \{[\omega]_\times\}$.

(i). The set described is the image of the injective linear map $(\omega, \mathbf{v}) \mapsto [\xi]$, hence it is a subspace of dimension $3 + 3 = 6$; injectivity follows from that of the hat map.

(ii). With $X_i = \begin{pmatrix} [\omega_i]_\times & \mathbf{v}_i \\ \mathbf{0}^\top & 0 \end{pmatrix}$ one computes

$$X_1 X_2 = \begin{pmatrix} [\omega_1]_\times [\omega_2]_\times & [\omega_1]_\times \mathbf{v}_2 \\ \mathbf{0}^\top & 0 \end{pmatrix}, \quad X_2 X_1 = \begin{pmatrix} [\omega_2]_\times [\omega_1]_\times & [\omega_2]_\times \mathbf{v}_1 \\ \mathbf{0}^\top & 0 \end{pmatrix},$$

hence

$$[X_1, X_2] = \begin{pmatrix} [[\omega_1]_\times, [\omega_2]_\times] & \omega_1 \times \mathbf{v}_2 - \omega_2 \times \mathbf{v}_1 \\ \mathbf{0}^\top & 0 \end{pmatrix} = \begin{pmatrix} [\omega_1 \times \omega_2]_\times & \omega_1 \times \mathbf{v}_2 - \omega_2 \times \mathbf{v}_1 \\ \mathbf{0}^\top & 0 \end{pmatrix},$$

using Lemma 29.2. The result has the required form, hence $\mathfrak{se}(3)$ is closed under the commutator.

(iii). Let $\mathfrak{n} = \{[\xi] : \omega = 0\}$. It is a subspace of dimension 3. By (ii), with ω_1 arbitrary and $\omega_2 = 0$,

$$[[\xi_1], [\xi_2]] = (0, \omega_1 \times \mathbf{v}_2)^\wedge \in \mathfrak{n},$$

hence $[\mathfrak{se}(3), \mathfrak{n}] \subseteq \mathfrak{n}$: $\mathfrak{n}$ is an ideal. Taking also $\omega_1 = 0$ gives a zero commutator: $\mathfrak{n}$ is abelian. The isomorphism with $\mathbb{R}^3$ is $\mathbf{v} \mapsto [(0, \mathbf{v})]$. $\square$

Remark 29.3: What a twist “is”. If a rigid body moves according to $T(t) \in SE(3)$, the matrix $[\mathcal{V}] = \dot{T}T^{-1}$ belongs to $\mathfrak{se}(3)$: indeed the curve $s \mapsto T(t+s)T(t)^{-1}$ passes through the identity at $s = 0$ and has derivative $\dot{T}T^{-1}$, and one checks directly that $\dot{T}T^{-1} = \begin{pmatrix} \dot{R}R^\top & \dot{\mathbf{p}} - \dot{R}R^\top \mathbf{p} \\ \mathbf{0}^\top & 0 \end{pmatrix}$ with $\dot{R}R^\top$ skew-symmetric (differentiating $RR^\top = I$). Its coordinates $\mathcal{V} = (\omega, \mathbf{v})$ are the angular velocity of the body and the velocity of the (possibly imaginary) body point that, at that instant, passes through the origin. The component $\mathbf{v}$ is not the velocity of the centre of the tool: it is the velocity of the body-fixed point that occupies the origin of the fixed frame, and this is the first stumbling block for anyone reading a Jacobian table without knowing what it contains.

Lemma 29.3: Conjugation of a skew-symmetric matrix. For every $R \in SO(3)$ and $\omega \in \mathbb{R}^3$,

$$R[\omega]_\times R^\top = [R\omega]_\times.$$

Proof. **Step 1 — equivariance of the cross product.** For $R \in SO(3)$ and $\mathbf{a}, \mathbf{b}, \mathbf{c} \in \mathbb{R}^3$, the scalar triple product is a determinant:

$$((R\mathbf{a}) \times (R\mathbf{b})) \cdot R\mathbf{c} = \det \begin{bmatrix} R\mathbf{a} & R\mathbf{b} & R\mathbf{c} \end{bmatrix} = \det (R[\mathbf{a} \ \mathbf{b} \ \mathbf{c}]) = \det R \cdot \det[\mathbf{a} \ \mathbf{b} \ \mathbf{c}] = (\mathbf{a} \times \mathbf{b}) \cdot \mathbf{c},$$

since $\det R = 1$. On the other hand $(\mathbf{a} \times \mathbf{b}) \cdot \mathbf{c} = (R(\mathbf{a} \times \mathbf{b})) \cdot R\mathbf{c}$, because R preserves the scalar product. Hence $[(R\mathbf{a}) \times (R\mathbf{b}) - R(\mathbf{a} \times \mathbf{b})] \cdot R\mathbf{c} = 0$ for every $\mathbf{c}$; since R is invertible, $R\mathbf{c}$ ranges over all of $\mathbb{R}^3$ and the vector in square brackets vanishes:

$$(R\mathbf{a}) \times (R\mathbf{b}) = R(\mathbf{a} \times \mathbf{b}). \quad (29.4)$$

Step 2 — conclusion. For every $\mathbf{x}$, using $R^\top = R^{-1}$ and (29.4) with $\mathbf{a} = \boldsymbol{\omega}$, $\mathbf{b} = R^\top \mathbf{x}$:

$$R[\boldsymbol{\omega}]_\times R^\top \mathbf{x} = R(\boldsymbol{\omega} \times R^\top \mathbf{x}) = (R\boldsymbol{\omega}) \times (RR^\top \mathbf{x}) = (R\boldsymbol{\omega}) \times \mathbf{x} = [R\boldsymbol{\omega}]_\times \mathbf{x}.$$

□

Lemma 29.4: Exponential of a conjugate. If $S \in GL(n, \mathbb{R})$ and $X \in \mathbb{R}^{n \times n}$, then $e^{SXS^{-1}} = S e^X S^{-1}$.

Proof. By induction, $(SXS^{-1})^k = SX^k S^{-1}$: true for $k = 0, 1$, and $(SXS^{-1})^{k+1} = SX^k S^{-1} \cdot SXS^{-1} = SX^{k+1} S^{-1}$. Since the exponential series converges absolutely and $Y \mapsto SY S^{-1}$ is linear and continuous, it can be exchanged with the sum:

$$e^{SXS^{-1}} = \sum_{k \geq 0} \frac{1}{k!} SX^k S^{-1} = S \left(\sum_{k \geq 0} \frac{X^k}{k!} \right) S^{-1} = S e^X S^{-1}.$$

□

Proposition 29.2: The adjoint Ad_g . For $g = (R, \mathbf{p}) \in SE(3)$ and $\xi = (\boldsymbol{\omega}, \mathbf{v}) \in \mathbb{R}^6$,

$$g[\xi]g^{-1} = [\text{Ad}_g \xi], \quad \text{Ad}_g = \begin{pmatrix} R & 0 \\ [\mathbf{p}]_\times R & R \end{pmatrix} \in \mathbb{R}^{6 \times 6}.$$

Moreover $\text{Ad}_{g_1 g_2} = \text{Ad}_{g_1} \text{Ad}_{g_2}$, $\text{Ad}_I = I_6$ and Ad_g is invertible with $(\text{Ad}_g)^{-1} = \text{Ad}_{g^{-1}}$. Finally

$$g e^{[\xi]\theta} g^{-1} = e^{[\text{Ad}_g \xi]\theta} \quad \text{for every } \theta \in \mathbb{R}.$$

Proof. Step 1 — block computation. With $g^{-1} = (R^\top, -R^\top \mathbf{p})$ (Proposition 29.1):

$$g[\xi] = \begin{pmatrix} R & \mathbf{p} \\ \mathbf{0}^\top & 1 \end{pmatrix} \begin{pmatrix} [\boldsymbol{\omega}]_\times & \mathbf{v} \\ \mathbf{0}^\top & 0 \end{pmatrix} = \begin{pmatrix} R[\boldsymbol{\omega}]_\times & R\mathbf{v} \\ \mathbf{0}^\top & 0 \end{pmatrix},$$

$$g[\xi]g^{-1} = \begin{pmatrix} R[\boldsymbol{\omega}]_\times & R\mathbf{v} \\ \mathbf{0}^\top & 0 \end{pmatrix} \begin{pmatrix} R^\top & -R^\top \mathbf{p} \\ \mathbf{0}^\top & 1 \end{pmatrix} = \begin{pmatrix} R[\boldsymbol{\omega}]_\times R^\top & -R[\boldsymbol{\omega}]_\times R^\top \mathbf{p} + R\mathbf{v} \\ \mathbf{0}^\top & 0 \end{pmatrix}.$$

By Lemma 29.3, $R[\boldsymbol{\omega}]_\times R^\top = [R\boldsymbol{\omega}]_\times$; hence the result is an element of $\mathfrak{se}(3)$ with angular part $R\boldsymbol{\omega}$ and linear part

$$-[R\boldsymbol{\omega}]_\times \mathbf{p} + R\mathbf{v} = -(R\boldsymbol{\omega}) \times \mathbf{p} + R\mathbf{v} = \mathbf{p} \times (R\boldsymbol{\omega}) + R\mathbf{v} = [\mathbf{p}]_\times R\boldsymbol{\omega} + R\mathbf{v},$$

where the antisymmetry of the cross product was used. In coordinates: $\text{Ad}_g \xi = (R\boldsymbol{\omega}, [\mathbf{p}]_\times R\boldsymbol{\omega} + R\mathbf{v})$, that is the block matrix of the statement.

Step 2 — homomorphism. For every ξ ,

$$[\text{Ad}_{g_1 g_2} \xi] = (g_1 g_2)[\xi](g_1 g_2)^{-1} = g_1(g_2[\xi]g_2^{-1})g_1^{-1} = g_1[\text{Ad}_{g_2} \xi]g_1^{-1} = [\text{Ad}_{g_1} \text{Ad}_{g_2} \xi],$$

and since $\eta \mapsto [\eta]$ is injective, one concludes $\text{Ad}_{g_1 g_2} = \text{Ad}_{g_1} \text{Ad}_{g_2}$. With $g_1 = g$, $g_2 = g^{-1}$ and $\text{Ad}_I = I_6$ (evident from the formula, with $R = I$, $\mathbf{p} = \mathbf{0}$), invertibility follows.

Step 3 — exponential. By Lemma 29.4 with $S = g$ and $X = [\xi]\theta$:

$$g e^{[\xi]\theta} g^{-1} = e^{g[\xi]\theta g^{-1}} = e^{[\text{Ad}_g \xi]\theta}.$$

Independent numerical check on 3000 randomly drawn pairs of elements of $SE(3)$:
 $\max |\text{Ad}_{g_1 g_2} - \text{Ad}_{g_1} \text{Ad}_{g_2}| = 5.3 \cdot 10^{-15}$ and $\max |g[\xi]g^{-1} - [\text{Ad}_g \xi]| = 5.6 \cdot 10^{-16}$. ✓ $\square$

29.3. The exponential of a twist in closed form

The series $e^{[\xi]\theta} = \sum_k \frac{\theta^k}{k!} [\xi]^k$ cannot be evaluated by hand term by term, but the powers of $[\omega]_\times$ repeat cyclically (Lemma 29.1), and the series collapses into just three terms. The result is the $SE(3)$ counterpart of Rodrigues' formula.

Theorem 29.4: Exponential of a twist. Let $\xi = (\omega, \mathbf{v}) \in \mathbb{R}^6$ and $\theta \in \mathbb{R}$.

(a) (Purely translational case.) If $\omega = \mathbf{0}$, then

$$e^{[\xi]\theta} = \begin{pmatrix} I & \mathbf{v}\theta \\ \mathbf{0}^\top & 1 \end{pmatrix}.$$

(b) (General case, $\|\omega\| = 1$.) If $\|\omega\| = 1$, then

$$e^{[\xi]\theta} = \begin{pmatrix} e^{[\omega]_\times \theta} & G(\theta)\mathbf{v} \\ \mathbf{0}^\top & 1 \end{pmatrix},$$

where

$$e^{[\omega]_\times \theta} = I + \sin \theta [\omega]_\times + (1 - \cos \theta) [\omega]_\times^2 \quad (\text{Rodrigues}),$$

$$G(\theta) = I\theta + (1 - \cos \theta) [\omega]_\times + (\theta - \sin \theta) [\omega]_\times^2.$$

(c) (Reduction.) If $\omega \neq \mathbf{0}$, setting $\hat{\omega} = \omega/\|\omega\|$, $\hat{\mathbf{v}} = \mathbf{v}/\|\omega\|$ and $\hat{\theta} = \|\omega\|\theta$, one has
 $[\xi]\theta = [\hat{\xi}]\hat{\theta}$ with $\hat{\xi} = (\hat{\omega}, \hat{\mathbf{v}})$, which reduces to (b).

In every case $e^{[\xi]\theta} \in SE(3)$.

Proof. (a). If $\omega = \mathbf{0}$ then $[\xi] = \begin{pmatrix} 0 & \mathbf{v} \\ \mathbf{0}^\top & 0 \end{pmatrix}$ and by (29.2) (with $A = 0$) $[\xi]^2 = 0$, hence $[\xi]^k = 0$ for $k \geq 2$. The series stops at first order: $e^{[\xi]\theta} = I_4 + \theta[\xi]$, which is the matrix of the statement.
(b). Start from (29.3) with $A = [\omega]_\times$ and $t = \theta$:

$$e^{[\xi]\theta} = \begin{pmatrix} e^{[\omega]_\times \theta} & G(\theta)\mathbf{v} \\ \mathbf{0}^\top & 1 \end{pmatrix}, \quad G(\theta) = \sum_{k \geq 1} \frac{\theta^k}{k!} [\omega]_\times^{k-1}.$$

The angular block is Rodrigues' formula, already proved in Chapter 28 (Theorem 28.2); it is rederived here anyway, for completeness, with the same grouping that follows.

Write $K = [\omega]_\times$ and split the terms according to the residue of $k - 1$ modulo 4, using Lemma 29.1 with $\|\omega\| = 1$:

$$K^0 = I, \quad K^1 = K, \quad K^2, \quad K^3 = -K, \quad K^4 = -K^2, \quad K^5 = K, \dots$$

Hence

$$G(\theta) = \underbrace{\theta I}_{k=1} + \underbrace{\left(\frac{\theta^2}{2!} - \frac{\theta^4}{4!} + \frac{\theta^6}{6!} - \dots \right)}_{k=2,4,6,\dots} K + \underbrace{\left(\frac{\theta^3}{3!} - \frac{\theta^5}{5!} + \frac{\theta^7}{7!} - \dots \right)}_{k=3,5,7,\dots} K^2.$$

The two coefficients are well-known power series:

$$\sum_{m \geq 1} (-1)^{m+1} \frac{\theta^{2m}}{(2m)!} = 1 - \left(1 - \frac{\theta^2}{2!} + \frac{\theta^4}{4!} - \cdots\right) = 1 - \cos \theta,$$

$$\sum_{m \geq 1} (-1)^{m+1} \frac{\theta^{2m+1}}{(2m+1)!} = \theta - \left(\theta - \frac{\theta^3}{3!} + \frac{\theta^5}{5!} - \cdots\right) = \theta - \sin \theta.$$

Substituting gives exactly $G(\theta) = I\theta + (1 - \cos \theta)K + (\theta - \sin \theta)K^2$. The rearrangement is legitimate because the exponential series converges absolutely.

With the same grouping applied to $e^{K\theta} = \sum_{k \geq 0} \frac{\theta^k}{k!} K^k$ one finds

$$e^{K\theta} = I + \left(\theta - \frac{\theta^3}{3!} + \cdots\right)K + \left(\frac{\theta^2}{2!} - \frac{\theta^4}{4!} + \cdots\right)K^2 = I + \sin \theta K + (1 - \cos \theta)K^2.$$

(c). $[\xi]\theta$ is a matrix, and one checks directly that

$$[\hat{\xi}]\hat{\theta} = \begin{pmatrix} [\omega/\|\omega\|]_{\times} & \mathbf{v}/\|\omega\| \\ \mathbf{0}^{\top} & 0 \end{pmatrix} \|\omega\|\theta = \begin{pmatrix} [\omega]_{\times}\theta & \mathbf{v}\theta \\ \mathbf{0}^{\top} & 0 \end{pmatrix} = [\xi]\theta,$$

using the linearity of the hat map. The exponentials agree because the matrices agree.

Membership in $SE(3)$. This is Step 2 of the proof of Theorem 29.3. $\square$

Example 29.2: Numerical verification of the closed form. Take

$$\omega = \frac{1}{3}(1, 2, 2)^{\top} \ (\|\omega\| = 1), \quad \mathbf{v} = (1, 0, -1)^{\top}, \quad \theta = 1.2.$$

The closed form of Theorem 29.4(b) gives

$$e^{[\xi]\theta} = \begin{pmatrix} 0.433207 & -0.479661 & 0.763058 & 0.477171 \\ 0.763058 & 0.645754 & -0.027283 & 0.578095 \\ -0.479661 & 0.594076 & 0.645754 & -1.416681 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

First check (independent). The same matrix, computed from the exponential series to 40 decimal digits (`mpmath`), agrees with the above with maximum discrepancy $5.6 \cdot 10^{-17}$: the closed form and the sum of the series give the same result. $\checkmark$

Second check (structural). The 3×3 block must lie in $SO(3)$: $\max |R^{\top}R - I| = 1.1 \cdot 10^{-16}$ and $\det R = 1.000000$. $\checkmark$

Case $\omega = \mathbf{0}$. With $\mathbf{v} = (1, 0, -1)/\sqrt{2}$ and $\theta = 2.5$, part (a) predicts the translation $\mathbf{v}\theta = (1.767767, 0, -1.767767)$; the series to 40 digits gives the same vector with discrepancy 0 (the series has only two terms). $\checkmark$

The matrix $G(\theta)$ is the delicate point of the inverse passage, that is, of the *logarithm*: given a rigid motion, reconstructing the twist that generates it requires inverting $G(\theta)$. The next result states exactly when this is possible and with which formula.

Proposition 29.3: Invertibility of $G(\theta)$ and explicit formula. Let $\|\omega\| = 1$, $K = [\omega]_{\times}$ and $G(\theta) = I\theta + (1 - \cos \theta)K + (\theta - \sin \theta)K^2$. Then

$$\det G(\theta) = 4\theta \sin^2 \frac{\theta}{2},$$

so $G(\theta)$ is invertible if and only if $\theta \neq 0$ and $\theta \notin 2\pi\mathbb{Z}$; in particular for $\theta \in (0, 2\pi)$. In that

case

$$G(\theta)^{-1} = \frac{1}{\theta}I - \frac{1}{2}K + \left(\frac{1}{\theta} - \frac{1}{2}\cot\frac{\theta}{2}\right)K^2.$$

Proof. Step 1 — orthogonal decomposition. Since $\|\omega\| = 1$, Lemma 29.1 gives $K\omega = 0$ and $K^2 = \omega\omega^\top - I$. Decompose $\mathbb{R}^3 = \langle\omega\rangle \oplus \omega^\perp$ (orthogonal sum). On the two summands:

- on $\langle\omega\rangle$: $K\omega = 0$ and $K^2\omega = 0$, hence $G(\theta)\omega = \theta\omega$: G acts as $\theta \text{ id}$;
- on $\omega^\perp$: if $\omega \cdot \mathbf{x} = 0$ then $K^2\mathbf{x} = \omega(\omega \cdot \mathbf{x}) - \mathbf{x} = -\mathbf{x}$, hence $K^2 = -I$ on $\omega^\perp$; moreover K maps $\omega^\perp$ into itself (because $\omega \cdot (\omega \times \mathbf{x}) = 0$). Hence

$$G(\theta)|_{\omega^\perp} = \theta I + (1 - \cos\theta)K - (\theta - \sin\theta)I = \sin\theta I + (1 - \cos\theta)K.$$

Both subspaces are invariant under $G(\theta)$, so the determinant is the product of the determinants of the restrictions.

Step 2 — the determinant. On $\langle\omega\rangle$ (dimension 1) the determinant is θ . On $\omega^\perp$ (dimension 2), $J := K|_{\omega^\perp}$ satisfies $J^2 = -I$: fixing an orthonormal basis $(\mathbf{u}, K\mathbf{u})$ of $\omega^\perp$ — orthonormal because $\|K\mathbf{u}\| = \|\omega \times \mathbf{u}\| = \|\mathbf{u}\|$ and $\mathbf{u} \cdot K\mathbf{u} = 0$ — the matrix of J is $\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$, and

$$\det(\sin\theta I + (1 - \cos\theta)J) = \det\begin{pmatrix} \sin\theta & -(1 - \cos\theta) \\ 1 - \cos\theta & \sin\theta \end{pmatrix},$$

$$\det(\sin\theta I + (1 - \cos\theta)J) = \sin^2\theta + (1 - \cos\theta)^2 = 2 - 2\cos\theta = 4\sin^2\frac{\theta}{2}.$$

Hence $\det G(\theta) = \theta \cdot 4\sin^2(\theta/2)$, which vanishes if and only if $\theta = 0$ or $\sin(\theta/2) = 0$, that is $\theta \in 2\pi\mathbb{Z}$.

Step 3 — the inverse. We look for G^{-1} in the form $aI + bK + cK^2$ (which is legitimate because the space spanned by I, K, K^2 is closed under the product, by Lemma 29.1, and contains the inverse when it exists, as verified a posteriori). We require $aI + bK + cK^2$ to invert G on each of the two subspaces.

- On $\langle\omega\rangle$: $aI + bK + cK^2$ acts as $a \text{ id}$ and G as $\theta \text{ id}$: we need $a\theta = 1$, that is $a = 1/\theta$.
- On $\omega^\perp$: $K^2 = -I$, hence $aI + bK + cK^2$ acts as $(a - c)I + bK$, and we require

$$((a - c)I + bJ)(\sin\theta I + (1 - \cos\theta)J) = I.$$

Using $J^2 = -I$ and expanding:

$$[(a - c)\sin\theta - b(1 - \cos\theta)]I + [(a - c)(1 - \cos\theta) + b\sin\theta]J = I,$$

that is, the system

$$(a - c)\sin\theta - b(1 - \cos\theta) = 1, \quad (a - c)(1 - \cos\theta) + b\sin\theta = 0.$$

The determinant of the system in the unknowns $(a - c, b)$ is $\sin^2\theta + (1 - \cos\theta)^2 = 4\sin^2(\theta/2) \neq 0$; the solution is

$$a - c = \frac{\sin\theta}{4\sin^2(\theta/2)}, \quad b = -\frac{1 - \cos\theta}{4\sin^2(\theta/2)}.$$

With the half-angle formulas $\sin\theta = 2\sin\frac{\theta}{2}\cos\frac{\theta}{2}$ and $1 - \cos\theta = 2\sin^2\frac{\theta}{2}$:

$$a - c = \frac{2\sin\frac{\theta}{2}\cos\frac{\theta}{2}}{4\sin^2\frac{\theta}{2}} = \frac{1}{2}\cot\frac{\theta}{2}, \quad b = -\frac{2\sin^2\frac{\theta}{2}}{4\sin^2\frac{\theta}{2}} = -\frac{1}{2}.$$

From $a = 1/\theta$ it follows that $c = a - \frac{1}{2}\cot\frac{\theta}{2} = \frac{1}{\theta} - \frac{1}{2}\cot\frac{\theta}{2}$. Substituting gives the formula of the statement. Since $aI + bK + cK^2$ and $G(\theta)$ agree, being mutual inverses on two complementary invariant subspaces, the product is the identity on all of $\mathbb{R}^3$.

Independent numerical check. With $\omega = \frac{1}{3}(1, 2, 2)^\top$ we computed $\max |G(\theta)G(\theta)^{-1} - I|$ for $\theta \in \{0.3; 1; \pi/2; 2; 3; 6\}$: the values lie between $7 \cdot 10^{-17}$ and $1.6 \cdot 10^{-15}$. In the same table $\det G(\theta)$ computed by `numpy` agrees with $4\theta \sin^2(\theta/2)$ to ten decimal digits; for instance $\theta = \pi/2$ gives 3.1415926536 both ways (that is π : indeed $4 \cdot \frac{\pi}{2} \sin^2 \frac{\pi}{4} = 2\pi \cdot \frac{1}{2} = \pi$). ✓ $\square$

Remark 29.4: Why $\theta = 2\pi$ is excluded, and why this is not a defect. For $\theta = 2\pi$ the rotation returns to the identity, but the translation accumulated along the axis is not zero: $G(2\pi)\mathbf{v} = 2\pi(\omega \cdot \mathbf{v})\omega$. The matrix $G(2\pi)$ has rank 1 and the equation $G(\theta)\mathbf{v} = \mathbf{p}$ is no longer solvable for arbitrary $\mathbf{p}$: the pair (ω, θ) is no longer sufficient to describe the motion. This is the same phenomenon as the complex logarithm, which is not defined continuously on all of $\mathbb{C}^*$ (Chapter 6); and the construction of Chasles' theorem avoids the problem by always choosing $\theta \in (0, \pi]$, as we shall see in the next section.

29.4. Chasles' theorem

Definition 29.5: Screw motion, axis and pitch. Let $\mathcal{L} = \{\mathbf{q} + \lambda\omega : \lambda \in \mathbb{R}\}$ be an oriented line of $\mathbb{R}^3$ (with $\|\omega\| = 1$), $\theta \in \mathbb{R}$ and $h \in \mathbb{R}$. The **screw motion** of axis $\mathcal{L}$, angle θ and **pitch** h is the map

$$\text{Scr}_{\mathcal{L}, h, \theta}(\mathbf{x}) = \mathbf{q} + e^{[\omega] \times \theta}(\mathbf{x} - \mathbf{q}) + h\theta\omega,$$

that is, the rotation of angle θ about $\mathcal{L}$ composed with the translation of $h\theta$ along $\mathcal{L}$. The case $h = 0$ is *pure rotation* about $\mathcal{L}$; the case $\theta = 0$, with $h\theta$ finite, is understood as *pure translation* (infinite pitch).

Note that the definition does not depend on the point $\mathbf{q}$ chosen on the axis: if $\mathbf{q}' = \mathbf{q} + \mu\omega$ then, since $e^{[\omega] \times \theta}\omega = \omega$ (because $[\omega] \times \omega = 0$, Lemma 29.1),

$$\mathbf{q}' + e^{[\omega] \times \theta}(\mathbf{x} - \mathbf{q}') = \mathbf{q} + \mu\omega + e^{[\omega] \times \theta}(\mathbf{x} - \mathbf{q}) - \mu\omega = \mathbf{q} + e^{[\omega] \times \theta}(\mathbf{x} - \mathbf{q}).$$

Lemma 29.5: Axis and pitch of a twist. Let $\xi = (\omega, \mathbf{v})$ with $\|\omega\| = 1$. Then there exist a unique $h \in \mathbb{R}$ and a unique $\mathbf{q} \in \mathbb{R}^3$ with $\mathbf{q} \perp \omega$ such that

$$\mathbf{v} = h\omega - \omega \times \mathbf{q},$$

and they are given by

$$h = \omega^\top \mathbf{v}, \quad \mathbf{q} = \omega \times \mathbf{v}.$$

The line $\mathcal{L} = \{\mathbf{q} + \lambda\omega\}$ is called the **axis of the twist** and h its **pitch**.

Proof. Existence and formulas. Decompose $\mathbf{v} = \mathbf{v}_\parallel + \mathbf{v}_\perp$ with $\mathbf{v}_\parallel = (\omega^\top \mathbf{v})\omega$ and $\mathbf{v}_\perp = \mathbf{v} - \mathbf{v}_\parallel \perp \omega$. Set $h = \omega^\top \mathbf{v}$ and seek $\mathbf{q} \perp \omega$ with $-\omega \times \mathbf{q} = \mathbf{v}_\perp$. Applying $\omega \times (\cdot)$ to both sides and using Lemma 29.1(i) with $\|\omega\| = 1$:

$$\omega \times \mathbf{v} = \omega \times \mathbf{v}_\perp = -\omega \times (\omega \times \mathbf{q}) = -[\omega]_\times^2 \mathbf{q} = -(\omega\omega^\top - I)\mathbf{q} = \mathbf{q}$$

(the last step because $\omega^\top \mathbf{q} = 0$). Hence necessarily $\mathbf{q} = \omega \times \mathbf{v}$. Conversely, with this choice, $\mathbf{q} \perp \omega$ (because $\omega \cdot (\omega \times \mathbf{v}) = 0$) and

$$-\omega \times \mathbf{q} = -\omega \times (\omega \times \mathbf{v}) = -(\omega(\omega \cdot \mathbf{v}) - \mathbf{v}) = \mathbf{v} - h\omega = \mathbf{v}_\perp,$$

that is $\mathbf{v} = h\omega - \omega \times \mathbf{q}$, as required.

Uniqueness. If $h\omega - \omega \times \mathbf{q} = h'\omega - \omega \times \mathbf{q}'$ with $\mathbf{q}, \mathbf{q}' \perp \omega$, projecting onto ω (the term $\omega \times \mathbf{q}$ is orthogonal to ω) gives $h = h'$; what remains is $\omega \times (\mathbf{q} - \mathbf{q}') = \mathbf{0}$, that is $\mathbf{q} - \mathbf{q}' \parallel \omega$, and since both are orthogonal to ω , $\mathbf{q} = \mathbf{q}'$. $\square$

Theorem 29.5: The exponential of a twist is a screw motion. Let $\xi = (\omega, \mathbf{v})$ with $\|\omega\| = 1$, and let $h = \omega^\top \mathbf{v}$, $\mathcal{L} = \{\mathbf{q} + \lambda\omega\}$ as in Lemma 29.5. Then for every $\theta \in \mathbb{R}$ and every $\mathbf{x} \in \mathbb{R}^3$

$$e^{[\xi]\theta} \mathbf{x} = \mathbf{q} + e^{[\omega] \times \theta} (\mathbf{x} - \mathbf{q}) + h\theta \omega = \text{Scr}_{\mathcal{L}, h, \theta}(\mathbf{x}),$$

that is, $e^{[\xi]\theta}$ is the screw motion of axis $\mathcal{L}$, angle θ and pitch h . In particular the points of $\mathcal{L}$ translate rigidly by $h\theta\omega$, and $\mathcal{L}$ is invariant as a set.

Proof. Write $R = e^{[\omega] \times \theta}$ and $K = [\omega]_\times$. By Theorem 29.4(b), $e^{[\xi]\theta} \mathbf{x} = R\mathbf{x} + G(\theta)\mathbf{v}$; it therefore suffices to prove

$$G(\theta)\mathbf{v} = \mathbf{q} - R\mathbf{q} + h\theta\omega. \quad (29.5)$$

Step 1 — action of G and of R on $\langle \omega \rangle$ and on $\omega^\perp$. As in the proof of Proposition 29.3: $G(\theta)\omega = \theta\omega$, and on $\omega^\perp$ one has $K^2 = -I$, hence $G(\theta)\omega = \theta\omega$, and on $\omega^\perp$ one has $K^2 = -I$, hence

$$G(\theta)|_{\omega^\perp} = \sin \theta I + (1 - \cos \theta)K, \quad R|_{\omega^\perp} = I + \sin \theta K + (1 - \cos \theta)K^2 = \cos \theta I + \sin \theta K.$$

Step 2 — computing $G(\theta)\mathbf{v}$. By Lemma 29.5, $\mathbf{v} = h\omega - K\mathbf{q}$ with $\mathbf{q} \perp \omega$. By linearity,

$$G(\theta)\mathbf{v} = hG(\theta)\omega - G(\theta)K\mathbf{q} = h\theta\omega - G(\theta)K\mathbf{q}.$$

The vector $K\mathbf{q} = \omega \times \mathbf{q}$ belongs to $\omega^\perp$, so by Step 1

$$G(\theta)K\mathbf{q} = \sin \theta K\mathbf{q} + (1 - \cos \theta)K^2\mathbf{q} = \sin \theta K\mathbf{q} - (1 - \cos \theta)\mathbf{q},$$

having used $K^2\mathbf{q} = -\mathbf{q}$ ($\mathbf{q} \in \omega^\perp$). Hence

$$G(\theta)\mathbf{v} = h\theta\omega - \sin \theta K\mathbf{q} + (1 - \cos \theta)\mathbf{q}.$$

Step 3 — computing $\mathbf{q} - R\mathbf{q}$. Again by Step 1, since $\mathbf{q} \in \omega^\perp$,

$$R\mathbf{q} = \cos \theta \mathbf{q} + \sin \theta K\mathbf{q} \implies \mathbf{q} - R\mathbf{q} = (1 - \cos \theta)\mathbf{q} - \sin \theta K\mathbf{q}.$$

Step 4 — comparison. Steps 2 and 3 give

$$G(\theta)\mathbf{v} = h\theta\omega + [(1 - \cos \theta)\mathbf{q} - \sin \theta K\mathbf{q}] = h\theta\omega + \mathbf{q} - R\mathbf{q},$$

which is (29.5). Substituting:

$$e^{[\xi]\theta} \mathbf{x} = R\mathbf{x} + \mathbf{q} - R\mathbf{q} + h\theta\omega = \mathbf{q} + R(\mathbf{x} - \mathbf{q}) + h\theta\omega.$$

Step 5 — points of the axis. If $\mathbf{x} = \mathbf{q} + \lambda\omega$, then $R(\mathbf{x} - \mathbf{q}) = \lambda R\omega = \lambda\omega$ (because $K\omega = 0$ implies $R\omega = \omega$), hence

$$e^{[\xi]\theta} \mathbf{x} = \mathbf{q} + \lambda\omega + h\theta\omega = \mathbf{x} + h\theta\omega :$$

every point of the axis translates by $h\theta\omega$, and the axis maps to itself. $\square$

Theorem 29.6: Chasles' theorem. Let $g = (R, \mathbf{p}) \in SE(3)$. Then there exist $\xi \in \mathbb{R}^6$ and $\theta \in \mathbb{R}$ with $g = e^{[\xi]\theta}$: the exponential map $\exp : \mathfrak{se}(3) \rightarrow SE(3)$ is **surjective**. More precisely, every direct rigid motion of space is a screw motion, and the three alternatives are:

- (i) Identity. If $R = I$ and $\mathbf{p} = \mathbf{0}$, then $g = e^{[\xi]\cdot 0}$ for every ξ : $\theta = 0$, and there is no axis.
- (ii) Pure translation. If $R = I$ and $\mathbf{p} \neq \mathbf{0}$, set $\omega = \mathbf{0}$, $\mathbf{v} = \mathbf{p}/\|\mathbf{p}\|$, $\theta = \|\mathbf{p}\|$; then $g = e^{[\xi]\theta}$. The motion is a translation: infinite pitch, undetermined axis (every line parallel to $\mathbf{p}$ has points that translate along themselves).
- (iii) Generic case $R \neq I$. By Euler's theorem there exist $\theta \in (0, \pi]$ and ω with $\|\omega\| = 1$ such that $R = e^{[\omega]\times\theta}$ (ω is unique if $\theta < \pi$, unique up to sign if $\theta = \pi$). Setting

$$\mathbf{v} = G(\theta)^{-1}\mathbf{p}, \quad h = \omega^\top \mathbf{v}, \quad \mathbf{q} = \omega \times \mathbf{v},$$

one has $g = e^{[\xi]\theta}$ with $\xi = (\omega, \mathbf{v})$, and g is the screw motion of axis $\mathcal{L} = \{\mathbf{q} + \lambda\omega\}$, angle θ and pitch h . If $h = 0$ the motion is a pure rotation about $\mathcal{L}$.

Proof. (i). $e^0 = I_4$.

(ii). This is Theorem 29.4(a): with $\omega = \mathbf{0}$, $e^{[\xi]\theta} = \begin{pmatrix} I & \mathbf{v}\theta \\ \mathbf{0}^\top & 1 \end{pmatrix}$, and $\mathbf{v}\theta = \frac{\mathbf{p}}{\|\mathbf{p}\|}\|\mathbf{p}\| = \mathbf{p}$.

(iii). *Step 1 — existence of (ω, θ) .* By Euler's rotation theorem (Theorem 5.9) there exist a unit vector ω and an angle θ such that R is, in an orthonormal basis $\{\omega, w_1, w_2\}$, the rotation by θ in the plane $\omega^\perp$; replacing, if needed, ω by $-\omega$ and θ by $-\theta$, and then θ by $\theta + 2k\pi$, we can reduce to $\theta \in [0, \pi]$, with $\theta \neq 0$ because $R \neq I$. Rodrigues' formula (Chapter 28, Theorem 28.2) says that this rotation is $e^{[\omega]\times\theta}$, hence $R = e^{[\omega]\times\theta}$. Operationally:

$$\theta = \arccos \frac{\text{tr } R - 1}{2} \in (0, \pi], \quad [\omega]_\times = \frac{R - R^\top}{2 \sin \theta} \text{ if } \theta \in (0, \pi),$$

while for $\theta = \pi$ the axis is read off as the eigenvector of R for the eigenvalue $+1$ (the previous formula degenerates because $\sin \pi = 0$).

Step 2 — existence of $\mathbf{v}$. Since $\theta \in (0, \pi] \subset (0, 2\pi)$, Proposition 29.3 guarantees that $G(\theta)$ is invertible; set $\mathbf{v} = G(\theta)^{-1}\mathbf{p}$, that is, the unique solution of $G(\theta)\mathbf{v} = \mathbf{p}$.

Step 3 — conclusion. By Theorem 29.4(b),

$$e^{[\xi]\theta} = \begin{pmatrix} e^{[\omega]\times\theta} & G(\theta)\mathbf{v} \\ \mathbf{0}^\top & 1 \end{pmatrix} = \begin{pmatrix} R & \mathbf{p} \\ \mathbf{0}^\top & 1 \end{pmatrix} = g.$$

By Theorem 29.5, $e^{[\xi]\theta}$ is the screw motion of axis $\mathcal{L}$, angle θ and pitch h . If $h = \omega^\top \mathbf{v} = 0$, the screw motion formula reduces to $\mathbf{x} \mapsto \mathbf{q} + R(\mathbf{x} - \mathbf{q})$: a pure rotation about $\mathcal{L}$, which has $\mathcal{L}$ as its set of fixed points.

The three cases exhaust $SE(3)$: either $R = I$ (and then (i) or (ii) according to whether $\mathbf{p}$ is zero or not), or $R \neq I$ and (iii) holds. $\square$

Proposition 29.4: Uniqueness of the axis and variational characterisation. Let $g = (R, \mathbf{p})$ with $R \neq I$, and let $\omega, \theta, h, \mathcal{L}$ be as in Theorem 29.6(iii). Then, for every $\mathbf{x} \in \mathbb{R}^3$,

(i) $\omega^\top(g(\mathbf{x}) - \mathbf{x}) = h\theta$: the component of the displacement along the axis is the same for all points (in particular $h\theta = \omega^\top \mathbf{p}$);

(ii) $\|g(\mathbf{x}) - \mathbf{x}\|^2 = (h\theta)^2 + \|(R - I)(\mathbf{x} - \mathbf{q})\|^2 \geq (h\theta)^2$;

(iii) equality holds if and only if $\mathbf{x} \in \mathcal{L}$.

Consequently $\mathcal{L}$ is the set of points of minimal displacement, and depends only on g : the screw axis is unique, and with it the translation vector $h\theta\omega$.

Proof. (i). By Theorem 29.5, $g(\mathbf{x}) - \mathbf{x} = (R - I)(\mathbf{x} - \mathbf{q}) + h\theta\omega$. Since $R\omega = \omega$ and $R^\top = R^{-1}$, one has $R^\top\omega = \omega$, hence for every $\mathbf{y}$

$$\omega^\top(R - I)\mathbf{y} = (R^\top\omega - \omega)^\top\mathbf{y} = 0.$$

Hence $\omega^\top(g(\mathbf{x}) - \mathbf{x}) = h\theta\omega^\top\omega = h\theta$. Setting $\mathbf{x} = \mathbf{0}$ gives $h\theta = \omega^\top\mathbf{p}$.

(ii). The identity just proved shows that $(R - I)(\mathbf{x} - \mathbf{q})$ is orthogonal to ω , so the two terms of $g(\mathbf{x}) - \mathbf{x} = (R - I)(\mathbf{x} - \mathbf{q}) + h\theta\omega$ are orthogonal and the Pythagorean theorem applies.

(iii). Equality in (ii) holds if and only if $(R - I)(\mathbf{x} - \mathbf{q}) = \mathbf{0}$, that is $\mathbf{x} - \mathbf{q} \in \ker(R - I)$. Since $R \neq I$ is a rotation by angle $\theta \in (0, \pi]$ about ω , its eigenspace for eigenvalue 1 is exactly $\langle\omega\rangle$: indeed R acts on $\omega^\perp$ as $\cos\theta I + \sin\theta K$ (Step 1 of the proof of Theorem 29.5), and on a nonzero vector $\mathbf{y} \in \omega^\perp$, $R\mathbf{y} = \mathbf{y}$ would force $(\cos\theta - 1)\mathbf{y} + \sin\theta K\mathbf{y} = \mathbf{0}$; since $\mathbf{y}$ and $K\mathbf{y}$ are orthogonal and nonzero, this would give $\cos\theta = 1$ and $\sin\theta = 0$, that is $\theta \in 2\pi\mathbb{Z}$, which is excluded. Hence $\mathbf{x} \in \mathbf{q} + \langle\omega\rangle = \mathcal{L}$.

Uniqueness. The set $\{\mathbf{x} : \|g(\mathbf{x}) - \mathbf{x}\| \text{ minimal}\}$ is defined from g alone; by (ii)–(iii) it coincides with $\mathcal{L}$. The translation vector is $h\theta\omega = g(\mathbf{x}) - \mathbf{x}$ for $\mathbf{x} \in \mathcal{L}$, likewise a function of g alone. $\square$

Remark 29.5: What remains non-unique. Unique are the axis $\mathcal{L}$ as a line and the vector $h\theta\omega$. Not unique are the pair (ω, θ) , and hence h : the opposite choice $(-\omega, 2\pi - \theta)$ generates the same R , the same line $\mathcal{L}$ and the same total translation, but pitch $h' = -h\theta/(2\pi - \theta)$. The convention $\theta \in (0, \pi]$ of Theorem 29.6 removes the ambiguity except for $\theta = \pi$, where the two possibilities $\pm\omega$ remain (and then h changes sign together with ω , so that $h\theta\omega$ stays the same). There is nothing pathological about this: it is the same non-uniqueness of the logarithm on S^1 (Chapter 12), lifted to $SE(3)$.

Example 29.3: Screw decomposition of a given motion. Consider the rigid motion $g = (R, \mathbf{p})$ with

$$R = \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (\text{rotation by } 90^\circ \text{ about } z), \quad \mathbf{p} = (1, 2, 3)^\top.$$

Axis and angle of the rotation. $\text{tr } R = 1$, hence $\theta = \arccos \frac{1-1}{2} = \frac{\pi}{2}$, and $\omega = \mathbf{e}_3 = (0, 0, 1)^\top$.

The twist. With $K = [\mathbf{e}_3]_\times$ one has $K^2 = \text{diag}(-1, -1, 0)$ and $\cot \frac{\pi}{4} = 1$, so by Proposition 29.3

$$G\left(\frac{\pi}{2}\right)^{-1} = \frac{2}{\pi}I - \frac{1}{2}K + \left(\frac{2}{\pi} - \frac{1}{2}\right)K^2 = \begin{pmatrix} \frac{1}{2} & \frac{1}{2} & 0 \\ -\frac{1}{2} & \frac{1}{2} & 0 \\ 0 & 0 & \frac{2}{\pi} \end{pmatrix},$$

(the diagonal entries (1, 1) and (2, 2) equal $\frac{2}{\pi} - (\frac{2}{\pi} - \frac{1}{2}) = \frac{1}{2}$), and hence

$$\mathbf{v} = G\left(\frac{\pi}{2}\right)^{-1}\mathbf{p} = \left(\frac{3}{2}, \frac{1}{2}, \frac{6}{\pi}\right)^\top = (1.500000, 0.500000, 1.909859)^\top.$$

Pitch and axis.

$$h = \omega^\top\mathbf{v} = \frac{6}{\pi} = 1.909859, \quad \mathbf{q} = \omega \times \mathbf{v} = \left(-\frac{1}{2}, \frac{3}{2}, 0\right)^\top,$$

hence the axis is the vertical line $\mathcal{L} = \{(-\frac{1}{2}, \frac{3}{2}, \lambda)\}$ and the translation along it equals $h\theta = \frac{6}{\pi} \cdot \frac{\pi}{2} = 3$.

First independent check (geometric). The motion leaves the height unchanged and in the xy plane acts as $\mathbf{x} \mapsto R_2\mathbf{x} + (1, 2)$ with $R_2 = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$: its unique fixed point is

$$(I - R_2)^{-1} \begin{pmatrix} 1 \\ 2 \end{pmatrix} = \frac{1}{2} \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} 1 \\ 2 \end{pmatrix} = \begin{pmatrix} -1/2 \\ 3/2 \end{pmatrix},$$

which is exactly the projection of $\mathcal{L}$ onto the xy plane. ✓

Second independent check (algebraic). $h\theta$ must equal $\omega^\top \mathbf{p} = 3$ by Proposition 29.4(i): it coincides. ✓

Third check (numerical). Reconstructing $e^{[\xi]\theta}$ from the closed form and, independently, summing the exponential series to 40 digits, one obtains g with maximum discrepancy $1.1 \cdot 10^{-16}$ and $2.2 \cdot 10^{-16}$ respectively. Moreover the minimal displacement, sought over 200 000 randomly drawn points in a cube, equals 3.000098, against the exact value $|h\theta| = 3$ predicted by Proposition 29.4 (the excess is because no sample point falls exactly on the axis). ✓

Figure 29.1: The screw motion of Theorem 29.5. The point $\mathbf{x}$ rotates by θ about the axis $\mathcal{L}$ (blue arrow, along the ellipse that is the circle of rotation seen in perspective) and then translates by $h\theta\omega$ along the axis (green arrow). The composition, shown as a dotted line, is the total displacement $g(\mathbf{x}) - \mathbf{x}$. Points of the axis undergo translation alone, which is why they are the points of minimal displacement (Proposition 29.4). The ellipses have semi-axes 2 and 0.6; the two points on the lower circle correspond to parameters 200° and 320° , that is $(-1.8794, -0.2052)$ and $(1.5321, -0.3857)$.

Remark 29.6: Chasles, Mozzi and screw theory. The statement was published by Michel Chasles in 1830 in *Férussac's Bulletin des Sciences Mathématiques*, in a six-page note on the “déplacement fini, ou infiniment petit, d’un corps solide libre.” Priority is however disputed: Giulio Mozzi had already described the screw axis (the spontaneous axis of rotation) in 1763, and the historical reconstruction by M. Ceccarelli (*Mechanism and Machine Theory* 35, 2000) documents the Mozzi–Cauchy–Poinsot–Chasles chain; for this reason modern English-language literature often writes “Chasles–Mozzi theorem.” The dual of the theorem, due to Poinsot, states that every system of forces on a rigid body reduces to a force along a line plus a couple about the same line: this is the notion of wrench, which stands to twists as forces stand to velocities. On these two foundations Robert S. Ball built, in 1900, screw theory, of which the present chapter is the modern matrix version.

29.5. The product-of-exponentials formula

Definition 29.6: Open kinematic chain. An **open kinematic chain** with n joints is a sequence of rigid bodies (*links*) $L_0, L_1, \dots, L_n$ such that L_{i-1} and L_i are connected by **joint** i , with L_0 fixed (*base*). Joint i is:

- **revolute** if it allows only rotation of L_i relative to L_{i-1} about a line fixed in L_{i-1} ;
- **prismatic** if it allows only translation of L_i relative to L_{i-1} along a direction fixed in L_{i-1} .

We fix a **base** frame S attached to L_0 and a **tool** frame T attached to L_n ; the **forward kinematics** is the map $\theta = (\theta_1, \dots, \theta_n) \mapsto T(\theta) \in SE(3)$ giving the pose of the tool frame relative to the base frame. The **reference configuration** is $\theta = 0$, and we set $M = T(0)$.

Definition 29.7: Twist of a joint. In the reference configuration, joint i has an axis that, read in the base frame, is the line $\{\mathbf{q}_i + \lambda\omega_i\}$ with $\|\omega_i\| = 1$ (revolute joint), or a direction $\mathbf{v}_i$ with $\|\mathbf{v}_i\| = 1$ (prismatic joint). The **twist of joint** i is

$$\xi_i = (\omega_i, -\omega_i \times \mathbf{q}_i) \quad (\text{revolute}), \quad \xi_i = (\mathbf{0}, \mathbf{v}_i) \quad (\text{prismatic}).$$

The choice of linear part $-\omega_i \times \mathbf{q}_i$ is not arbitrary: by Lemma 29.5 it makes the twist ξ_i have pitch $h = 0$ and axis exactly the joint's line. Indeed $h = \omega_i^\top(-\omega_i \times \mathbf{q}_i) = 0$ and, by the computation in Lemma 29.5, $\omega_i \times (-\omega_i \times \mathbf{q}_i)$ is the component of $\mathbf{q}_i$ orthogonal to ω_i , that is the point of the axis closest to the origin. By Theorem 29.5, $e^{[\xi_i]\theta_i}$ is therefore the *pure rotation* by angle θ_i about the axis of joint i , and for a prismatic joint $e^{[\xi_i]\theta_i}$ is the translation by θ_i along $\mathbf{v}_i$ (Theorem 29.4(a)).

Lemma 29.6: How a pose transforms. Let a rigid body have body-fixed frame B at pose $T \in SE(3)$ relative to the fixed frame S (that is, the S -coordinates of a point with B -coordinates $\mathbf{y}$ are $T\tilde{\mathbf{y}}$). If the rigid displacement $g \in SE(3)$, read in S (that is, every point of space with coordinates $\mathbf{x}$ goes to $g\mathbf{x}$), is applied to the body, the new pose is gT .

Proof. Let P be a point of the body, with coordinates $\mathbf{y}$ in B : before the displacement its coordinates in S are $T\tilde{\mathbf{y}}$. After the displacement, its coordinates in S are $gT\tilde{\mathbf{y}}$. Since the body is rigid, the coordinates of P in the body-fixed frame B do not change, remaining $\mathbf{y}$. The new pose T' is by definition the matrix sending the B -coordinates to the new S -coordinates: $T'\tilde{\mathbf{y}} = gT\tilde{\mathbf{y}}$ for every $\mathbf{y}$, hence $T' = gT$ (two matrices agreeing on all vectors with last component 1 agree, because such vectors span $\mathbb{R}^4$). $\square$

Theorem 29.7: Product-of-exponentials formula. For an open kinematic chain with n joints, with twists $\xi_1, \dots, \xi_n$ read in the reference configuration and $M = T(0)$, the forward kinematics is

$$T(\theta_1, \dots, \theta_n) = e^{[\xi_1]\theta_1} e^{[\xi_2]\theta_2} \dots e^{[\xi_n]\theta_n} M$$

Proof. We prove this by downward induction on the index of the first joint moved. For $k = n+1, n, \dots, 1$ let

$$\mathcal{P}(k) : \quad T(0, \dots, 0, \theta_k, \dots, \theta_n) = e^{[\xi_k]\theta_k} \dots e^{[\xi_n]\theta_n} M \quad \text{for every } \theta_k, \dots, \theta_n.$$

Base case ($k = n+1$). All joints are at zero: $T(0, \dots, 0) = M$, which is the empty product times M . True by the definition of M .

Inductive step ($k+1 \Rightarrow k$). Assume $\mathcal{P}(k+1)$ and fix $\theta_k, \dots, \theta_n$. Consider the subchain $C_k = L_k \cup L_{k+1} \cup \dots \cup L_n$, together with the joints $k+1, \dots, n$ that articulate it. Moving

joint k by θ_k , while keeping $\theta_1 = \dots = \theta_{k-1} = 0$ and the values $\theta_{k+1}, \dots, \theta_n$ fixed, moves C_k *rigidly* (the relative positions inside C_k depend only on $\theta_{k+1}, \dots, \theta_n$, which do not change), and it moves it by the screw motion about the axis of joint k .

That axis, since $\theta_1 = \dots = \theta_{k-1} = 0$, is still in the reference position: joint k is fixed in link L_{k-1} , and L_{k-1} is at the reference pose because all joints preceding it are at zero. Hence the motion is $g = e^{[\xi_k]\theta_k}$, with ξ_k the twist of the joint read in the reference configuration (Definition 29.7); here Theorem 29.5 is used to identify the exponential with the rotation about that axis (or, for a prismatic joint, Theorem 29.4(a) for the translation).

The tool frame T is fixed in $L_n \subset C_k$, so by Lemma 29.6 its pose changes from $T(0, \dots, 0, \theta_{k+1}, \dots, \theta_n)$ to

$$T(0, \dots, 0, \theta_k, \theta_{k+1}, \dots, \theta_n) = e^{[\xi_k]\theta_k} T(0, \dots, 0, \theta_{k+1}, \dots, \theta_n) = e^{[\xi_k]\theta_k} e^{[\xi_{k+1}]\theta_{k+1}} \dots e^{[\xi_n]\theta_n} M,$$

where the last equality is $\mathcal{P}(k+1)$. Hence $\mathcal{P}(k)$ holds.

Conclusion. By induction $\mathcal{P}(1)$ is true, which is the statement. $\square$

The formula, in the form proved here, is due to Roger W. Brockett, who introduced it in 1984 as a systematic tool for the kinematics of open-chain robots; see the source cited at the end of the chapter.

Remark 29.7: Where the difficulty lies. The proof is short, but its delicate point is a single one: the joints are moved from the last to the first, because moving joint k when the preceding ones are at zero leaves its axis in the reference position. If one attempted the induction in the opposite order (first joint 1, then joint 2, ...) the axis of joint 2 would already be displaced by θ_1 , and its twist would no longer be ξ_2 but $\text{Ad}_{\exp([\xi_1]\theta_1)}\xi_2$: one would obtain

$$T(\theta) = e^{[\text{Ad}_{e^{[\xi_1]\theta_1}}\xi_2]\theta_2} e^{[\xi_1]\theta_1} M = e^{[\xi_1]\theta_1} e^{[\xi_2]\theta_2} M$$

for $n = 2$, using Proposition 29.2 — the same formula, but by a longer route. This is exactly why the literature numbers twists “from the base toward the tool” and applies them in that order.

Proposition 29.5: Independence from configuration and frames. Let $T(\theta) = e^{[\xi_1]\theta_1} \dots e^{[\xi_n]\theta_n} M$ be the forward kinematics of an open chain. Then:

- (i) (Change of base frame.) If S is replaced by a new frame S' such that $T'(\theta) = PT(\theta)$ with $P \in SE(3)$ constant, then

$$T'(\theta) = e^{[\xi'_1]\theta_1} \dots e^{[\xi'_n]\theta_n} M', \quad \xi'_i = \text{Ad}_P \xi_i, \quad M' = PM :$$

the formula has the same structure, with the twists carried by the adjoint.

- (ii) (Change of tool frame.) If $T'(\theta) = T(\theta)Q$ with $Q \in SE(3)$ constant, then $T'(\theta) = e^{[\xi_1]\theta_1} \dots e^{[\xi_n]\theta_n} M'$ with $M' = MQ$ and the same twists ξ_i .

- (iii) (Change of reference configuration.) If one chooses as reference configuration $\theta = \bar{\theta}$ instead of $\theta = 0$, setting $\phi_i = \theta_i - \bar{\theta}_i$, one still has $T = e^{[\bar{\xi}_1]\phi_1} \dots e^{[\bar{\xi}_n]\phi_n} \bar{M}$ with $\bar{M} = T(\bar{\theta})$ and $\bar{\xi}_i = \text{Ad}_{e^{[\xi_1]\bar{\theta}_1} \dots e^{[\xi_{i-1}]\bar{\theta}_{i-1}}} \xi_i$.

Proof. (i). By Proposition 29.2, $P e^{[\xi_i]\theta_i} P^{-1} = e^{[\text{Ad}_P \xi_i]\theta_i}$. Inserting $P^{-1}P$ between consecutive factors:

$$P e^{[\xi_1]\theta_1} \dots e^{[\xi_n]\theta_n} M = (P e^{[\xi_1]\theta_1} P^{-1}) \dots (P e^{[\xi_n]\theta_n} P^{-1}) PM = e^{[\xi'_1]\theta_1} \dots e^{[\xi'_n]\theta_n} PM.$$

(ii). Immediate: $T(\theta)Q = e^{[\xi_1]\theta_1} \dots e^{[\xi_n]\theta_n} (MQ)$.

(iii). Write, for every i , $\theta_i = \bar{\theta}_i + \phi_i$; since $[\xi_i]\bar{\theta}_i$ and $[\xi_i]\phi_i$ commute (they are multiples of the

same matrix),

$$e^{[\xi_i]\theta_i} = e^{[\xi_i]\bar{\theta}_i} e^{[\xi_i]\phi_i}.$$

Set $A_i = e^{[\xi_1]\bar{\theta}_1} \dots e^{[\xi_i]\bar{\theta}_i}$ (with $A_0 = I$), so that $A_i = A_{i-1} e^{[\xi_i]\bar{\theta}_i}$, and prove by induction on $m \leq n$ that

$$\prod_{i=1}^m \left(e^{[\xi_i]\bar{\theta}_i} e^{[\xi_i]\phi_i} \right) = \left[\prod_{i=1}^m A_{i-1} e^{[\xi_i]\phi_i} A_{i-1}^{-1} \right] A_m, \quad (29.6)$$

where the products are ordered by increasing index from the left. For $m = 0$ both sides equal I . Assuming it holds for $m - 1$, multiply on the right by $e^{[\xi_m]\bar{\theta}_m} e^{[\xi_m]\phi_m}$ and use the commutativity of the two factors:

$$\Pi_{m-1} A_{m-1} e^{[\xi_m]\phi_m} e^{[\xi_m]\bar{\theta}_m} = \Pi_{m-1} (A_{m-1} e^{[\xi_m]\phi_m} A_{m-1}^{-1}) A_{m-1} e^{[\xi_m]\bar{\theta}_m},$$

having set $\Pi_{m-1} = \prod_{i=1}^{m-1} A_{i-1} e^{[\xi_i]\phi_i} A_{i-1}^{-1}$; and $A_{m-1} e^{[\xi_m]\bar{\theta}_m} = A_m$: this gives (29.6) for m . Applying Proposition 29.2 again, $A_{i-1} e^{[\xi_i]\phi_i} A_{i-1}^{-1} = e^{[\text{Ad}_{A_{i-1}} \xi_i] \phi_i}$, and $A_n M = T(\bar{\theta}) = \bar{M}$: this gives the desired formula. $\square$

Remark 29.8: What “with no intermediate frames” means. The merit of the formula is not brevity but the absence of choices. To apply it one needs only: the tool pose M in some configuration, and for every joint a line (or a direction) in space, read in that same configuration. No intermediate frame needs to be assigned, and Proposition 29.5 says that moving the base, the tool, or the reference configuration breaks nothing: only the data change, not the structure. This is why modern kinematics toolkits adopt this description: modelling errors reduce to errors on measurable lines, not on conventions.

Definition 29.8: Denavit–Hartenberg parameters. In the Denavit–Hartenberg convention, each link is assigned a frame following precise rules (axis z_i along the axis of joint $i + 1$, axis x_i along the common normal between z_{i-1} and z_i), and the transformation between consecutive frames depends on only four parameters $(\theta_i, d_i, a_i, \alpha_i)$:

$$T_{i-1,i} = \text{Rot}_z(\theta_i) \text{Trans}_z(d_i) \text{Trans}_x(a_i) \text{Rot}_x(\alpha_i) \in SE(3),$$

and the forward kinematics is $T_{0,n} = T_{0,1} T_{1,2} \dots T_{n-1,n}$.

Remark 29.9: Denavit–Hartenberg versus product of exponentials. The two descriptions give the same map $T(\theta)$ and are both correct; they differ in modelling cost and in robustness.

- **DH** uses four numbers per joint instead of the twist’s six, but pays for it with the obligation to assign frames according to rigid rules, and with degenerate cases (consecutive parallel or intersecting axes) in which the common normal is not unique and the choice of parameters becomes arbitrary.
- **PoE** uses six numbers per joint (of which one is redundant for a revolute joint, because $\|\omega_i\| = 1$, and three for a prismatic one), but the data are directly measurable physical quantities — lines in space — and there are no degenerate cases.
- Numerically, a calibration error on a line propagates continuously in the PoE; in DH an axis nearly parallel to the previous one makes the parameters a_i, α_i jump even though the geometry changes little. This is the main reason modern kinematic calibration methods are formulated on $\mathfrak{se}(3)$.

Every industrial controller — **KUKA, ABB, FANUC, Yaskawa** — nonetheless computes the tool pose as a product of 4×4 homogeneous transformations; what changes from brand

to brand is the convention by which the orientation is then exposed to the operator (A, B, C angles for KUKA, W, P, R for FANUC, a quaternion in ABB's RAPID *robtarg*et), not the underlying mathematics (Chapter 28).

Example 29.4: Product of exponentials for the planar 3R arm. Consider a planar arm with three revolute joints with axes parallel to $\mathbf{e}_3$ and links of length $\ell_1 = 2$, $\ell_2 = 1.5$, $\ell_3 = 1$. In the reference configuration the arm is stretched out along the x axis, hence

$$\mathbf{q}_1 = (0, 0, 0)^\top, \quad \mathbf{q}_2 = (2, 0, 0)^\top, \quad \mathbf{q}_3 = (3.5, 0, 0)^\top, \quad \omega_i = \mathbf{e}_3,$$

$$M = \begin{pmatrix} I & (4.5, 0, 0)^\top \\ \mathbf{0}^\top & 1 \end{pmatrix}.$$

The twists are $\xi_i = (\mathbf{e}_3, -\mathbf{e}_3 \times \mathbf{q}_i)$, that is

$$\xi_1 = (0, 0, 1, 0, 0, 0), \quad \xi_2 = (0, 0, 1, 0, -2, 0), \quad \xi_3 = (0, 0, 1, 0, -3.5, 0).$$

Comparison with the closed form. Elementary trigonometry gives, for the tool position,

$$x = \ell_1 \cos \theta_1 + \ell_2 \cos(\theta_1 + \theta_2) + \ell_3 \cos(\theta_1 + \theta_2 + \theta_3),$$

$$y = \ell_1 \sin \theta_1 + \ell_2 \sin(\theta_1 + \theta_2) + \ell_3 \sin(\theta_1 + \theta_2 + \theta_3), \quad \varphi = \theta_1 + \theta_2 + \theta_3.$$

Evaluating both expressions at three configurations:

$(\theta_1, \theta_2, \theta_3)$	(x, y) from PoE	(x, y) from closed form
$(30^\circ, 60^\circ, -45^\circ)$	(2.4391576; 3.2071068)	(2.4391576; 3.2071068)
$(30^\circ, 0^\circ, 0^\circ)$	(3.8971143; 2.2500000)	(3.8971143; 2.2500000)
$(0.4; -0.9; 1.3) \text{ rad}$	(3.8552025; 0.7770545)	(3.8552025; 0.7770545)

The rotation block of the PoE agrees with $e^{[\mathbf{e}_3] \times \varphi}$ with maximum discrepancy $1.1 \cdot 10^{-16}$. ✓

Reading. The fact that in the second row $\|(x, y)\| = 4.5 = \ell_1 + \ell_2 + \ell_3$ signals that the arm is fully outstretched: this is the configuration that will turn out to be singular in Section 29.7.

29.6. Geometric Jacobian: spatial and body

Definition 29.9: Spatial twist and body twist. Let $t \mapsto T(t) \in SE(3)$ be a differentiable curve. Set

$$[\mathcal{V}_s] = \dot{T}T^{-1} \in \mathfrak{se}(3) \quad (\text{spatial twist}), \quad [\mathcal{V}_b] = T^{-1}\dot{T} \in \mathfrak{se}(3) \quad (\text{body twist}),$$

and $\mathcal{V}_s, \mathcal{V}_b \in \mathbb{R}^6$ are the corresponding coordinate vectors.

That $\dot{T}T^{-1}$ and $T^{-1}\dot{T}$ lie in $\mathfrak{se}(3)$ is checked at once: if $T = \begin{pmatrix} R & \mathbf{p} \\ \mathbf{0}^\top & 1 \end{pmatrix}$, then $\dot{T} = \begin{pmatrix} \dot{R} & \dot{\mathbf{p}} \\ \mathbf{0}^\top & 0 \end{pmatrix}$ and

$$\dot{T}T^{-1} = \begin{pmatrix} \dot{R} & \dot{\mathbf{p}} \\ \mathbf{0}^\top & 0 \end{pmatrix} \begin{pmatrix} R^\top & -R^\top \mathbf{p} \\ \mathbf{0}^\top & 1 \end{pmatrix} = \begin{pmatrix} \dot{R}R^\top & \dot{\mathbf{p}} - \dot{R}R^\top \mathbf{p} \\ \mathbf{0}^\top & 0 \end{pmatrix},$$

and $\dot{R}R^\top$ is skew-symmetric because differentiating $RR^\top = I$ gives $\dot{R}R^\top + R\dot{R}^\top = 0$, that is $\dot{R}R^\top = -(\dot{R}R^\top)^\top$. Similarly for $T^{-1}\dot{T}$, with $R^\top \dot{R}$ skew-symmetric.

Proposition 29.6: Relation between the two twists. $\mathcal{V}_s = \text{Ad}_T \mathcal{V}_b$ and $\mathcal{V}_b = \text{Ad}_{T^{-1}} \mathcal{V}_s$.

Proof. $[\mathcal{V}_s] = \dot{T}T^{-1} = T(T^{-1}\dot{T})T^{-1} = T[\mathcal{V}_b]T^{-1} = [\text{Ad}_T \mathcal{V}_b]$ by Proposition 29.2; injectivity of the map $\xi \mapsto [\xi]$ gives the first equality, and the second is obtained by applying $\text{Ad}_{T^{-1}} = (\text{Ad}_T)^{-1}$. $\square$

Theorem 29.8: Spatial Jacobian. Let $T(\theta) = e^{[\xi_1]\theta_1} \dots e^{[\xi_n]\theta_n} M$ be the forward kinematics of an open chain (Theorem 29.7) and let $t \mapsto \theta(t)$ be differentiable. Then

$$\mathcal{V}_s = J_s(\theta) \dot{\theta}, \quad J_s(\theta) = [J_{s,1} \ J_{s,2} \ \dots \ J_{s,n}] \in \mathbb{R}^{6 \times n},$$

with

$$J_{s,1} = \xi_1, \quad J_{s,i} = \text{Ad}_{e^{[\xi_1]\theta_1} \dots e^{[\xi_{i-1}]\theta_{i-1}}} \xi_i \quad (i \geq 2).$$

Column i is therefore the twist of joint i carried into the current configuration by the joints preceding it.

Proof. Step 1 — derivative of the product. By the product rule applied to $T(\theta(t))$,

$$\dot{T} = \sum_{i=1}^n \frac{\partial T}{\partial \theta_i} \dot{\theta}_i, \quad \text{hence} \quad [\mathcal{V}_s] = \dot{T}T^{-1} = \sum_{i=1}^n \left(\frac{\partial T}{\partial \theta_i} T^{-1} \right) \dot{\theta}_i.$$

Since $\xi \mapsto [\xi]$ is linear and injective, it suffices to identify $\frac{\partial T}{\partial \theta_i} T^{-1}$ as an element of $\mathfrak{se}(3)$.

Step 2 — the partial derivative. Only the i -th factor depends on θ_i , and $\frac{\partial}{\partial \theta_i} e^{[\xi_i]\theta_i} = [\xi_i] e^{[\xi_i]\theta_i}$ (a prerequisite about the matrix exponential). Hence, setting $A_{i-1} = e^{[\xi_1]\theta_1} \dots e^{[\xi_{i-1}]\theta_{i-1}}$ and $B_i = e^{[\xi_i]\theta_i} \dots e^{[\xi_n]\theta_n} M$ (so that $T = A_{i-1} B_i$),

$$\frac{\partial T}{\partial \theta_i} = A_{i-1} [\xi_i] B_i.$$

Step 3 — simplification. With $T^{-1} = B_i^{-1} A_{i-1}^{-1}$,

$$\frac{\partial T}{\partial \theta_i} T^{-1} = A_{i-1} [\xi_i] B_i B_i^{-1} A_{i-1}^{-1} = A_{i-1} [\xi_i] A_{i-1}^{-1} = [\text{Ad}_{A_{i-1}} \xi_i],$$

by Proposition 29.2. For $i = 1$ one has $A_0 = I$ and the column is ξ_1 .

Step 4 — conclusion. Substituting into Step 1 and passing to coordinates:

$$\mathcal{V}_s = \sum_{i=1}^n (\text{Ad}_{A_{i-1}} \xi_i) \dot{\theta}_i = J_s(\theta) \dot{\theta}.$$

Note that $J_{s,i}$ does not depend on $\theta_i, \dots, \theta_n$: column i is determined by only the upstream joints, which makes the computation recursive ($A_i = A_{i-1} e^{[\xi_i]\theta_i}$). $\square$

Theorem 29.9: Body Jacobian. With the same notation,

$$\mathcal{V}_b = J_b(\theta) \dot{\theta}, \quad J_{b,n} = \text{Ad}_{M^{-1}} \xi_n, \quad J_{b,i} = \text{Ad}_{(e^{[\xi_{i+1}]\theta_{i+1}} \dots e^{[\xi_n]\theta_n} M)^{-1}} \xi_i \quad (i < n),$$

and moreover

$$J_s(\theta) = \text{Ad}_{T(\theta)} J_b(\theta), \quad J_b(\theta) = \text{Ad}_{T(\theta)^{-1}} J_s(\theta).$$

Proof. Step 1. With $B_{i+1} = e^{[\xi_{i+1}]\theta_{i+1}} \dots e^{[\xi_n]\theta_n} M$ one has $T = A_{i-1} e^{[\xi_i]\theta_i} B_{i+1}$, and by Step 2 of the previous proof $\frac{\partial T}{\partial \theta_i} = A_{i-1} [\xi_i] e^{[\xi_i]\theta_i} B_{i+1}$. Since $[\xi_i]$ and $e^{[\xi_i]\theta_i}$ commute, $\frac{\partial T}{\partial \theta_i} =$

$A_{i-1}e^{[\xi_i]\theta_i}[\xi_i]B_{i+1}$, hence

$$T^{-1}\frac{\partial T}{\partial \theta_i} = B_{i+1}^{-1}e^{-[\xi_i]\theta_i}A_{i-1}^{-1} \cdot A_{i-1}e^{[\xi_i]\theta_i}[\xi_i]B_{i+1} = B_{i+1}^{-1}[\xi_i]B_{i+1} = [\text{Ad}_{B_{i+1}^{-1}} \xi_i].$$

For $i = n$ one has $B_{n+1} = M$ and the column is $\text{Ad}_{M^{-1}}\xi_n$.

Step 2. As in the previous theorem, $[\mathcal{V}_b] = T^{-1}\dot{T} = \sum_i (T^{-1}\frac{\partial T}{\partial \theta_i})\dot{\theta}_i$, whence $\mathcal{V}_b = J_b(\theta)\dot{\theta}$.

Step 3 — relation between the two. For every $\dot{\theta}$,

$$J_s\dot{\theta} = \mathcal{V}_s = \text{Ad}_T\mathcal{V}_b = \text{Ad}_T J_b\dot{\theta}$$

by Proposition 29.6; since $\dot{\theta}$ is arbitrary, the matrices agree. The second formula follows by multiplying by $\text{Ad}_{T^{-1}} = (\text{Ad}_T)^{-1}$ (Proposition 29.2). $\square$

Remark 29.10: Which of the two to use. The columns of J_s are twists read in the base frame; those of J_b in the tool frame. For force control and for tracking trajectories expressed relative to the tool, J_b is convenient, because the body twist does not depend on the choice of base frame (Theorem 29.10(i) proves this for the rank, and the same computation proves it for the matrix); for statics and for obstacles described in the world, J_s is convenient. The two descriptions are related by an invertible matrix: any property that depends only on the rank, such as singularity, does not distinguish between them.

Example 29.5: Spatial Jacobian of the planar 3R arm. With the data of Example 29.4 and $\theta = (0.4; -0.9; 1.3)$ radians, the formula of Theorem 29.8 gives

$$J_s(\theta) = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 1 & 1 \\ 0 & 0.778837 & 0.059698 \\ 0 & -1.842122 & -3.158496 \\ 0 & 0 & 0 \end{pmatrix}.$$

Structure. The first three rows (angular part) are $\mathbf{e}_3$ for every column: all axes remain parallel to z , as must hold for a planar arm. The sixth row is zero: no joint produces velocity along z .

Independent check. Approximating $\dot{T}T^{-1}$ with centred finite differences of step 10^{-6} on the forward kinematics computed numerically gives the same matrix with maximum discrepancy $4.2 \cdot 10^{-10}$, of the order of the truncation error expected for a centred difference ($O(\delta^2) = 10^{-12}$ multiplied by the scale of the third derivatives, plus $O(\varepsilon/\delta) \approx 10^{-10}$ of rounding error). $\checkmark$

Rank. $\text{rank } J_s = 3$ and $\text{rank } J_b = 3$: the configuration is not singular, consistently with the fact that $\sin \theta_2 = \sin(-0.9) \neq 0$ (Example 29.6). $\checkmark$

29.7. Kinematic singularities

Definition 29.10: Singular configuration. Let $J(\theta) \in \mathbb{R}^{6 \times n}$ be the Jacobian (spatial or body, per Definition 29.9) of an open chain with n joints (Definition 29.6). The configuration θ is called **singular** if

$$\text{rank } J(\theta) < \min(6, n),$$

that is, if $J(\theta)$ does not have full rank. If the assigned task is not the full pose but only part

of it (for instance, position alone, or motion in a plane), J is replaced with the corresponding **task Jacobian matrix** and the same definition is applied.

Proposition 29.7: *The rank does not depend on the choice of Jacobian. For every θ , $\text{rank } J_s(\theta) = \text{rank } J_b(\theta)$.*

Proof. By Theorem 29.9, $J_s = \text{Ad}_T J_b$; by Proposition 29.2 the matrix $\text{Ad}_T \in \mathbb{R}^{6 \times 6}$ is invertible. Multiplying on the left by an invertible matrix does not change the rank: $\text{rank}(\text{Ad}_T J_b) = \text{rank } J_b$, because Ad_T is an isomorphism of $\mathbb{R}^6$ and sends the image of J_b to a subspace of the same dimension. $\square$

Theorem 29.10: *Singularities do not depend on the frames. Let $T(\theta)$ be the forward kinematics of an open chain.*

- (i) *If the base frame is changed, that is T is replaced with $T'(\theta) = P T(\theta)$ with $P \in SE(3)$ constant, then $J'_b(\theta) = J_b(\theta)$.*
- (ii) *If the tool frame is changed, that is $T'(\theta) = T(\theta)Q$ with $Q \in SE(3)$ constant, then $J'_s(\theta) = J_s(\theta)$.*

In both cases the set of singular configurations remains the same.

Proof. (i). $T' = PT$ with P constant gives $\dot{T}' = P\dot{T}$, hence

$$(T')^{-1}\dot{T}' = T^{-1}P^{-1}P\dot{T} = T^{-1}\dot{T},$$

that is $\mathcal{V}'_b = \mathcal{V}_b$ for every $\dot{\theta}$; since $\mathcal{V}_b = J_b\dot{\theta}$ and $\mathcal{V}'_b = J'_b\dot{\theta}$ for every $\dot{\theta}$, one concludes $J'_b = J_b$.

(ii). $T' = TQ$ with Q constant gives $\dot{T}' = \dot{T}Q$, hence

$$\dot{T}'(T')^{-1} = \dot{T}Q Q^{-1}T^{-1} = \dot{T}T^{-1},$$

that is $J'_s = J_s$ by the same argument.

Conclusion. In (i) the rank of J_b is unchanged and, by Proposition 29.7, so is that of J_s ; in (ii) that of J_s is unchanged, and hence so is that of J_b . The condition in Definition 29.10 does not change. $\square$

Remark 29.11: *Why singularity is a property of the mechanism. Theorem 29.10 says that moving the robot within the cell (change of base) or mounting a different tool (change of tool frame) neither creates nor removes singularities. This is a fact that is not intuitive to programmers: the temptation to “escape a singularity by redefining the TCP” is understandable and wrong. What can be done is to change the task — for instance, giving up control of orientation about one axis — and then the task Jacobian matrix is a different matrix, with different singularities.*

Theorem 29.11: *Two collinear revolute axes give a singularity. Let there be an open chain with $n \leq 6$ joints, of which two — joint i and joint j , $i \neq j$ — are revolute, and suppose that in configuration θ their axes, read in the base frame, are the same line (same direction up to sign and same support). Then θ is singular.*

Proof. Step 1 — the columns are the twists of the current axes. By Theorem 29.8, $J_{s,k} = \text{Ad}_{A_{k-1}} \xi_k$. By Proposition 29.2, $\text{Ad}_{A_{k-1}}$ sends the twist of a line to the twist of the transformed line: if $\xi_k = (\omega_k, -\omega_k \times \mathbf{q}_k)$ and $A_{k-1} = (R, \mathbf{p})$, then

$$\text{Ad}_{A_{k-1}} \xi_k = (R\omega_k, [\mathbf{p}]_{\times} R\omega_k + R(-\omega_k \times \mathbf{q}_k)) = (\tilde{\omega}_k, -\tilde{\omega}_k \times \tilde{\mathbf{q}}_k),$$

with $\tilde{\omega}_k = R\omega_k$ and $\tilde{\mathbf{q}}_k = R\mathbf{q}_k + \mathbf{p}$. Checking the last equality is a direct computation:

$$-\tilde{\omega}_k \times \tilde{\mathbf{q}}_k = -(R\omega_k) \times (R\mathbf{q}_k + \mathbf{p}) = -R(\omega_k \times \mathbf{q}_k) - (R\omega_k) \times \mathbf{p} = R(-\omega_k \times \mathbf{q}_k) + [\mathbf{p}]_{\times} R\omega_k,$$

where the equivariance (29.4) and the antisymmetry of the cross product were used. Hence column k is the twist of the axis of joint k in the current position, with zero pitch.

Step 2 — collinearity. Let $\tilde{\omega}_i, \tilde{\mathbf{q}}_i$ and $\tilde{\omega}_j, \tilde{\mathbf{q}}_j$ be the data of the two current axes. By hypothesis the two lines coincide, hence $\tilde{\omega}_j = \varepsilon \tilde{\omega}_i$ with $\varepsilon \in \{+1, -1\}$ and $\tilde{\mathbf{q}}_j = \tilde{\mathbf{q}}_i + \mu \tilde{\omega}_i$ for some $\mu \in \mathbb{R}$. Then

$$J_{s,j} = (\varepsilon \tilde{\omega}_i, -\varepsilon \tilde{\omega}_i \times (\tilde{\mathbf{q}}_i + \mu \tilde{\omega}_i)) = \varepsilon (\tilde{\omega}_i, -\tilde{\omega}_i \times \tilde{\mathbf{q}}_i) = \varepsilon J_{s,i},$$

because $\tilde{\omega}_i \times \tilde{\omega}_i = \mathbf{0}$.

Step 3 — conclusion. Two columns of J_s are proportional, hence linearly dependent, and $\text{rank } J_s \leq n - 1$. Since $n \leq 6$, $\min(6, n) = n$, and hence $\text{rank } J_s < \min(6, n)$: the configuration is singular by Definition 29.10. $\square$

***Remark 29.12: Why the hypothesis $n \leq 6$.** The hypothesis is not a technicality. In a redundant robot ($n > 6$) the loss of one independent column does not necessarily bring the rank below 6: two aligned axes remove one internal degree of freedom without preventing any motion of the tool, and the loss shows up in the null space of J , not in its rank. For industrial six-axis manipulators, which are by far the most frequent case, J is square and the condition $\det J(\theta) = 0$ is equivalent to Definition 29.10: this is what controllers monitor.*

First worked example: the three-joint planar arm

Example 29.6: Singularity of the planar 3R arm. We return to the arm of Example 29.4: three revolute joints parallel to $\mathbf{e}_3$, links $\ell_1 = 2$, $\ell_2 = 1.5$, $\ell_3 = 1$. The task is the pose planar pose (x, y, φ) , so the task Jacobian matrix is 3×3 .

Step 1 — the matrix. Differentiating the formulas of Example 29.4, with $s_1 = \sin \theta_1$, $s_{12} = \sin(\theta_1 + \theta_2)$, $s_{123} = \sin(\theta_1 + \theta_2 + \theta_3)$ and analogously for the cosines:

$$J = \begin{pmatrix} -\ell_1 s_1 - \ell_2 s_{12} - \ell_3 s_{123} & -\ell_2 s_{12} - \ell_3 s_{123} & -\ell_3 s_{123} \\ \ell_1 c_1 + \ell_2 c_{12} + \ell_3 c_{123} & \ell_2 c_{12} + \ell_3 c_{123} & \ell_3 c_{123} \\ 1 & 1 & 1 \end{pmatrix}.$$

Step 2 — the determinant. Subtract the second column from the first and the third from the second (operations that do not change the determinant):

$$\det J = \det \begin{pmatrix} -\ell_1 s_1 & -\ell_2 s_{12} & -\ell_3 s_{123} \\ \ell_1 c_1 & \ell_2 c_{12} & \ell_3 c_{123} \\ 0 & 0 & 1 \end{pmatrix} = \det \begin{pmatrix} -\ell_1 s_1 & -\ell_2 s_{12} \\ \ell_1 c_1 & \ell_2 c_{12} \end{pmatrix} = \ell_1 \ell_2 (c_1 s_{12} - s_1 c_{12}),$$

having expanded along the last row. By the subtraction formula, $c_1 s_{12} - s_1 c_{12} = \sin((\theta_1 + \theta_2) - \theta_1) = \sin \theta_2$, hence

$$\boxed{\det J = \ell_1 \ell_2 \sin \theta_2}$$

Step 3 — the singular set. $\det J = 0$ if and only if $\sin \theta_2 = 0$, that is $\theta_2 \in \{0, \pi\}$ (modulo 2π): a fully outstretched arm ($\theta_2 = 0$, *elbow singularity*) or a fully folded one ($\theta_2 = \pi$). The result depends neither on θ_1 nor on θ_3 nor on ℓ_3 : the last is a structural fact, because the last link contributes to the position but its contribution is identical in the three columns and disappears in the subtractions of Step 2.

Step 4 — what is lost. In the outstretched configuration $\theta = (30^\circ, 0, 0)$ the tool is located at $(3.8971143; 2.2500000)$, at distance $\|P\| = 4.5 = \ell_1 + \ell_2 + \ell_3$ from the origin — the maximum reachable. The left singular vector associated with the zero singular value, computed with the singular value decomposition, is

$$\mathbf{u} = (0.8660254; 0.5000000; 0) = (\cos 30^\circ, \sin 30^\circ, 0),$$

that is, the direction of the outstretched arm: no combination of joint velocities can produce a tool velocity with a component along the arm (at constant orientation φ). This is geometrically obvious in hindsight — the distance from the origin is maximal, hence its derivative is zero — but it is the rank computation that produces it without need of intuition.

Step 5 — independent numerical check. For four configurations we computed the determinant with `numpy` and the singular values of J ; the product of the singular values must equal $|\det J|$.

$(\theta_1, \theta_2, \theta_3)$	$\det J$	$\ell_1 \ell_2 \sin \theta_2$	singular values
$(30^\circ, 60^\circ, -45^\circ)$	2.5980762	2.5980762	4.952994; 0.807799; 0.649353
$(30^\circ, 5.73^\circ, -45^\circ)$	0.2995002	0.2995002	5.181025; 0.981248; 0.058912
$(30^\circ, 0^\circ, 0^\circ)$	0	0	5.466340; 0.786845; 0
$(30^\circ, 180^\circ, 22.9^\circ)$	0	0	3.091766; 0.884932; 0

(the second row corresponds to $\theta_2 = 0.1$ rad, the fourth to $\theta_3 = 0.4$ rad). In the first two rows the product of the singular values reproduces $|\det J|$ to ten digits ($4.952994 \cdot 0.807799 \cdot 0.649353 = 2.5980762114$ and $5.181025 \cdot 0.981248 \cdot 0.058912 = 0.2995002499$); in the last two the rank computed with tolerance 10^{-9} equals 2. ✓ Moreover J obtained by centred finite differences ($\delta = 10^{-6}$) from the forward kinematics agrees with the analytic one to within $2.9 \cdot 10^{-10}$. ✓

Figure 29.2: The planar 3R arm with lengths $\ell_1 = 2$, $\ell_2 = 1.5$, $\ell_3 = 1$. The first link (dark grey) is common to both configurations, which share $\theta_1 = 30^\circ$. In blue the configuration $(30^\circ, 60^\circ, -45^\circ)$, with vertices $(0, 0)$, $(1.7321; 1)$, $(1.7321; 2.5)$, $(2.4392; 3.2071)$ and $\det J = 2.598076$. In red the outstretched configuration $(30^\circ, 0, 0)$, with vertices $(0, 0)$, $(1.7321; 1)$, $(3.0311; 1.75)$, $(3.8971; 2.25)$: here $\det J = \ell_1 \ell_2 \sin 0 = 0$ and the tool, located at the maximum distance 4.5 from the origin, cannot move instantaneously along the direction $(\cos 30^\circ, \sin 30^\circ)$ of the outstretched arm (double orange arrow).

Second worked example: the spherical wrist

Example 29.7: Singularity of the spherical wrist. A **spherical wrist** is formed by three revolute joints whose axes meet at a point $\mathbf{c}$ (the *wrist centre*). Consider the reference configuration in which the axes are, in order, $\mathbf{e}_3, \mathbf{e}_2, \mathbf{e}_3$ (a “ZYZ” wrist, by far the most common form in six-axis industrial robots, where the three joints are J4, J5, J6).

Step 1 — reduction to 3×3 . Take $\mathbf{c}$ as the origin of the base frame. Then every joint twist has the form $\xi_k = (\omega_k, -\omega_k \times \mathbf{0}) = (\omega_k, \mathbf{0})$. It follows that every $e^{[\xi_k]\theta_k}$ is a rotation about a line through the origin, that is, of the form $(R, \mathbf{0})$ (Theorem 29.5 with $h = 0$ and $\mathbf{q} = \mathbf{0}$); hence also $A_{k-1} = e^{[\xi_1]\theta_1} \dots e^{[\xi_{k-1}]\theta_{k-1}}$ has the form $(R_{k-1}, \mathbf{0})$, and by Proposition 29.2

$$J_{s,k} = \text{Ad}_{A_{k-1}} \xi_k = (R_{k-1}\omega_k, [\mathbf{0}]_{\times} R_{k-1}\omega_k + R_{k-1}\mathbf{0}) = (R_{k-1}\omega_k, \mathbf{0}).$$

All columns have zero linear part: geometrically, no wrist joint moves the centre $\mathbf{c}$. Hence

$$J_s(\theta) = \begin{pmatrix} J_\omega(\theta) \\ 0 \end{pmatrix}, \quad \text{rank } J_s = \text{rank } J_\omega, \quad J_\omega = \begin{bmatrix} \omega_1 & R_1\omega_2 & R_1R_2\omega_3 \end{bmatrix} \in \mathbb{R}^{3 \times 3},$$

with $R_1 = e^{[\mathbf{e}_3] \times \theta_1}$ and $R_2 = e^{[\mathbf{e}_2] \times \theta_2}$.

Step 2 — the three columns. With $c_k = \cos \theta_k$, $s_k = \sin \theta_k$:

$$\mathbf{c}_1 = \mathbf{e}_3 = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, \quad \mathbf{c}_2 = R_1\mathbf{e}_2 = \begin{pmatrix} -s_1 \\ c_1 \\ 0 \end{pmatrix}, \quad \mathbf{c}_3 = R_1R_2\mathbf{e}_3 = R_1 \begin{pmatrix} s_2 \\ 0 \\ c_2 \end{pmatrix} = \begin{pmatrix} c_1s_2 \\ s_1s_2 \\ c_2 \end{pmatrix}.$$

Step 3 — the determinant. Expanding along the first column (whose only nonzero entry is in position $(3, 1)$):

$$\det J_\omega = (+1) \cdot \det \begin{pmatrix} -s_1 & c_1s_2 \\ c_1 & s_1s_2 \end{pmatrix} = -s_1^2s_2 - c_1^2s_2 = -s_2,$$

hence

$$\boxed{\det J_\omega = -\sin \theta_2}$$

and the wrist is singular if and only if $\theta_2 \in \{0, \pi\}$: the fifth axis (J5) at 0° or 180° , that is, axes J4 and J6 aligned. This is the **wrist singularity**.

Step 4 — singular values in closed form. The three columns are unit vectors, and

$$\mathbf{c}_1 \cdot \mathbf{c}_2 = 0, \quad \mathbf{c}_2 \cdot \mathbf{c}_3 = -s_1c_1s_2 + c_1s_1s_2 = 0, \quad \mathbf{c}_1 \cdot \mathbf{c}_3 = c_2.$$

The Gram matrix is therefore

$$J_\omega^\top J_\omega = \begin{pmatrix} 1 & 0 & c_2 \\ 0 & 1 & 0 \\ c_2 & 0 & 1 \end{pmatrix},$$

whose eigenvalues are read off by inspection: 1 (eigenvector $(0, 1, 0)$) and $1 \pm c_2$ (eigenvectors $(1, 0, \pm 1)$). The singular values of J_ω are the square roots:

$$\sigma = \left\{ \sqrt{1 + \cos \theta_2}, 1, \sqrt{1 - \cos \theta_2} \right\} = \left\{ \sqrt{2} \left| \cos \frac{\theta_2}{2} \right|, 1, \sqrt{2} \left| \sin \frac{\theta_2}{2} \right| \right\}.$$

The product equals $\sqrt{(1 + c_2)(1 - c_2)} = \sqrt{1 - c_2^2} = |\sin \theta_2| = |\det J_\omega|$: consistent with Step 3. ✓

Step 5 — independent numerical check. The singular value decomposition of J_ω computed with `numpy` (with $\theta_1 = 0.7$ and $\theta_3 = -1.1$, which do not matter) gives:

θ_2 (rad)	$\det J_\omega$	$-\sin \theta_2$	singular values (numerical)
$\pi/3$	-0.8660254	-0.8660254	1.2247449; 1; 0.7071068
0.3	-0.2955202	-0.2955202	1.3983335; 1; 0.2113374
0.01	-0.0099998	-0.0099998	1.4141959; 1; 0.0070710
0.001	-0.0010000	-0.0010000	1.4142134; 1; 0.0007071
0	0	0	1.4142136; 1; 0
π	0	0	1.4142136; 1; 0

The maximum discrepancy between the numerical singular values and those of Step 4 is $5.5 \cdot 10^{-15}$. ✓ Note the behaviour $\sigma_{\min} \approx |\theta_2|/\sqrt{2}$ as $\theta_2 \rightarrow 0$, which is also read off from the closed form: $\sqrt{2} |\sin(\theta_2/2)| \approx |\theta_2|/\sqrt{2}$.

Step 6 — what is lost. At $\theta_2 = 0$ one has $\mathbf{c}_3 = \mathbf{c}_1 = \mathbf{e}_3$, hence the image of J_ω is $\langle \mathbf{e}_3, R_1 \mathbf{e}_2 \rangle$ and the lost direction is $R_1 \mathbf{e}_1 = (\cos \theta_1, \sin \theta_1, 0)$. For $\theta_1 = 0.7$ the singular value decomposition gives, as the left singular vector of the zero singular value, $\pm(0.7648422; 0.6442177; 0)$, and indeed $(\cos 0.7; \sin 0.7; 0) = (0.7648422; 0.6442177; 0)$. ✓ The wrist cannot rotate instantaneously about the direction orthogonal to the plane of the first two axes: this is the *gimbal lock* of Chapter 28 (Theorem 28.5) in its mechanical incarnation, with the — essential — difference that here it is not an artefact of the parametrisation but a property of the mechanism: two physical axes are truly aligned.

Figure 29.3: The ZYZ spherical wrist, seen in the xz plane of the page with $\theta_1 = 0$; axis J5, which points along y , that is out of the page, is drawn obliquely. On the left the regular configuration $\theta_2 = 60^\circ$: the three axes meet at the centre $\mathbf{c}$ and are linearly independent; J6 makes the angle θ_2 with J4 and is directed along $(\sin 60^\circ, \cos 60^\circ) = (0.8660; 0.5000)$. On the right the singular configuration $\theta_2 = 0$: J6 returns to coincide with J4 (dashed red line, shifted slightly for legibility), the independent columns drop to two and the wrist cannot rotate about the direction $R_1 \mathbf{e}_1$, orthogonal to the plane of J4 and J5 (double orange arrow). This is the wrist singularity, the one controllers flag when the fifth axis crosses zero.

Remark 29.13: What controllers do: damped least squares. Near a singularity the exact solution $\dot{\theta} = J^{-1}\mathcal{V}$ blows up like $1/\sigma_{\min}$. The standard countermeasure is the damped least squares (DLS) inverse

$$\dot{\theta}_\lambda = J^\top (JJ^\top + \lambda^2 I)^{-1} \mathcal{V},$$

which, in terms of singular values, replaces the factor $1/\sigma_i$ with $\sigma_i/(\sigma_i^2 + \lambda^2)$: the latter is bounded by $1/(2\lambda)$ and tends to 0 as $\sigma_i \rightarrow 0$, instead of diverging. On the planar 3R arm of Example 29.6, requesting the twist $\mathcal{V} = (\cos 30^\circ, \sin 30^\circ, 0)$ — precisely the direction that is lost — with $\lambda = 0.05$:

θ_2 (rad)	$\ J^{-1}\mathcal{V}\ $	$\ \dot{\theta}_\lambda\ $	error $\ J\dot{\theta}_\lambda - \mathcal{V}\ $
0.2	7.1584	6.3164	0.11531
0.05	28.6718	9.3688	0.67239
0.01	143.3716	2.7364	0.98086
0.001	1433.7208	0.2789	0.99980

One reads the trade-off: the joint velocity stays bounded, but the tracking error grows until the requested motion is given up entirely. Industrial controllers implement this strategy or variants (**FANUC** Singular Avoidance, **ABB** SingArea, **KUKA** \$SINGULARITY_HANDLING); none of them “eliminates” the singularity, which by Theorem 29.10 is a property of the mechanism, but all of them make passing through it numerically harmless.

Remark 29.14: Panorama: the Baker–Campbell–Hausdorff formula. The chapter has repeatedly used the fact that $e^A e^B \neq e^{A+B}$ when A and B do not commute: this is why the order of the factors in the product of exponentials matters, and why there are no “coordinates” in which composing two rigid motions reduces to adding. The quantitative measure of the discrepancy is the **Baker–Campbell–Hausdorff** formula, reported here as a panorama, without proof:

$$e^A e^B = \exp \left(A + B + \frac{1}{2}[A, B] + \frac{1}{12}([A, [A, B]] - [B, [A, B]]) + \cdots \right),$$

where the subsequent terms are rational combinations of nested commutators and the series converges for $\|A\|, \|B\|$ sufficiently small. The first correction term $\frac{1}{2}[A, B]$ is, for two twists, the commutator computed in Theorem 29.3(ii): to first order, reversing the order of two infinitesimal screw motions produces a net screw motion with twist $[\xi_1, \xi_2]$. This is the principle behind nonholonomic manoeuvring — think of parallel parking, where alternating steering and forward motion generates a lateral displacement that neither command possesses on its own.

What is missing to prove it here: the construction of the Dynkin series and the convergence estimate, which require the free Lie algebra and the Poincaré–Birkhoff–Witt theorem. Sources: Murray, Li, Sastry, *A Mathematical Introduction to Robotic Manipulation*, Theorem 8.5, p. 381 (stated in the form reported here); B. C. Hall, *An Elementary Introduction to Groups and Representations*, arXiv:math-ph/0005032, Chapter 4 (in particular §4.3, series form), for the complete proof.

29.8. Assigned exercises

Answers are in the Teacher’s key (Section 29.11).

Exercise 29.1: Axis and pitch, and how they are transported. *Objective:* handle the correspondence between twist and screw (axis + pitch) and understand how the adjoint transports it. *Estimated time:* 30 minutes. *Type:* symbolic/proof-based.

Let $\xi = (\omega, \mathbf{v})$ with $\|\omega\| = 1$, and let $h = \omega^\top \mathbf{v}$ and $\mathcal{L} = \{\omega \times \mathbf{v} + \lambda \omega\}$ be its pitch and its axis.

- Compute the pitch and axis of $\xi = (\mathbf{e}_3, (1, 0, 2)^\top)$ and describe in words the motion $e^{[\xi]\theta}$.
- Prove that for every $g \in SE(3)$ the twist $\text{Ad}_g \xi$ has the same pitch h and axis the line $g(\mathcal{L})$.
- Deduce that the pitch is an invariant of the screw motion under changes of frame, and relate the result to Theorem 29.10.
- Verify (b) numerically with $g = (e^{[\mathbf{e}_2] \times 0.8}, (1, -2, \frac{1}{2})^\top)$ and the twist of (a): compute $\text{Ad}_g \xi$, its pitch and axis point, and check that the latter differs from $g(\omega \times \mathbf{v})$ by a multiple of the new ω .

Exercise 29.2: Screw decomposition of a given motion. *Objective:* carry out the full algorithm of Theorem 29.6 and check it by two independent routes. *Estimated time:* 40 minutes. *Type:* numerical/computational.

Consider $g = (R, \mathbf{p})$ with

$$R = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}, \quad \mathbf{p} = (2, 1, -1)^\top.$$

- (a) Determine θ and ω .
- (b) Write $G(\theta)^{-1}$ explicitly and compute $\mathbf{v} = G(\theta)^{-1}\mathbf{p}$.
- (c) Compute the pitch h , the axis point $\mathbf{q}$ and the translation along the axis $h\theta$; verify that $h\theta = \omega^\top \mathbf{p}$.
- (d) *Independent geometric check:* the motion acts on the yz plane as a planar rotation composed with a translation; compute its fixed point and compare it with $\mathbf{q}$.
- (e) *Numerical check:* verify $e^{[\xi]\theta} = g$ and estimate $\min_{\mathbf{x}} \|g(\mathbf{x}) - \mathbf{x}\|$ on a random sample, comparing it with $|h\theta|$.

Exercise 29.3: The RPY wrist and gimbal lock. *Objective:* transfer the method of Example 29.7 to a different wrist architecture and recognise that the singularity changes position but not nature. *Estimated time:* 40 minutes. *Type:* computational with a proof-based part.

Consider a spherical wrist whose three axes, in the reference configuration, are $\omega_1 = \mathbf{e}_3$, $\omega_2 = \mathbf{e}_2$, $\omega_3 = \mathbf{e}_1$ (a “ZYX” wrist, that is, the *roll-pitch-yaw* convention).

- (a) Write the three columns of $J_\omega(\theta)$.
- (b) Compute $\det J_\omega$ and determine the singular set.
- (c) Compute the Gram matrix $J_\omega^\top J_\omega$ and derive from it the singular values in closed form; verify that their product equals $|\det J_\omega|$.
- (d) Identify the lost rotation direction at the singular configuration and verify it numerically with the singular value decomposition for $\theta_1 = 0.9$.
- (e) Compare the result with Theorem 28.5 of Chapter 28 and explain in what sense the singularity here is *not* an artefact of the parametrisation.

29.9. Worked exercises

Exercise 29.4: Composing two rotations: intersecting axes and skew axes. *Type:* symbolic/geometric with numerical check. Let

- g_1 be the rotation by 90° about the z axis (line $\{(0, 0, \lambda)\}$);
- g_2 be the rotation by 90° about the line $\{(t, 0, 1)\}$, parallel to the x axis and passing through $(0, 0, 1)$.

Determine the screw axis and pitch of $g = g_2 \circ g_1$. Repeat replacing g_2 with the rotation by 90° about the line $\{(t, 1, 0)\}$, which is *skew* to the z axis, and comment on the difference.

Solution. Strategy. We write g_1 and g_2 as pairs $(R, \mathbf{p})$ using the form $\mathbf{x} \mapsto \mathbf{c} + R(\mathbf{x} - \mathbf{c})$ for a rotation about a line through $\mathbf{c}$; compose with Proposition 29.1; apply the algorithm of Theorem 29.6(iii).

Step 1 — the two matrices. $g_1 = (R_1, \mathbf{0})$ with $R_1 = e^{[\mathbf{e}_3] \times \pi/2} = \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}$ (the axis passes through the origin, so $\mathbf{p}_1 = \mathbf{0}$). For g_2 , with $\mathbf{c} = (0, 0, 1)^\top$ and $R_2 = e^{[\mathbf{e}_1] \times \pi/2} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}$, one has $\mathbf{x} \mapsto R_2\mathbf{x} + (\mathbf{c} - R_2\mathbf{c})$, that is

$$\mathbf{p}_2 = \mathbf{c} - R_2\mathbf{c} = (0, 0, 1)^\top - (0, -1, 0)^\top = (0, 1, 1)^\top.$$

Step 2 — the composition. By Proposition 29.1, $g = g_2 g_1 = (R_2 R_1, R_2 \mathbf{0} + \mathbf{p}_2) = (R, \mathbf{p})$ with

$$R = R_2 R_1 = \begin{pmatrix} 0 & -1 & 0 \\ 0 & 0 & -1 \\ 1 & 0 & 0 \end{pmatrix}, \quad \mathbf{p} = (0, 1, 1)^\top.$$

(The matrix R cyclically permutes the axes: $\mathbf{e}_1 \mapsto \mathbf{e}_3 \mapsto -\mathbf{e}_2 \mapsto \dots$; read off column by column.)

Step 3 — angle and axis of the rotation. $\text{tr } R = 0$, hence

$$\theta = \arccos \frac{0 - 1}{2} = \frac{2\pi}{3} = 120^\circ.$$

Since $\sin \theta = \frac{\sqrt{3}}{2}$,

$$[\omega]_\times = \frac{R - R^\top}{2 \sin \theta} = \frac{1}{\sqrt{3}} \begin{pmatrix} 0 & -1 & -1 \\ 1 & 0 & -1 \\ 1 & 1 & 0 \end{pmatrix} \implies \omega = \frac{1}{\sqrt{3}}(1, -1, 1)^\top.$$

Check: $R(1, -1, 1)^\top = (1, -1, 1)^\top$, so ω is indeed the axis. ✓

Step 4 — pitch. By Proposition 29.4(i),

$$h\theta = \omega^\top \mathbf{p} = \frac{1}{\sqrt{3}}(1 \cdot 0 + (-1) \cdot 1 + 1 \cdot 1) = 0,$$

so $h = 0$: the composition is a *pure rotation* by 120° .

Step 5 — the axis. With $\theta = \frac{2\pi}{3}$ one has $\cot \frac{\theta}{2} = \cot \frac{\pi}{3} = \frac{1}{\sqrt{3}}$, and Proposition 29.3 gives $\mathbf{v} = G(\theta)^{-1} \mathbf{p} = \frac{1}{\sqrt{3}}(1, 1, 0)^\top = (0.577350; 0.577350; 0)$. Hence

$$\mathbf{q} = \omega \times \mathbf{v} = \left(-\frac{1}{3}, \frac{1}{3}, \frac{2}{3}\right)^\top.$$

Independent check (geometric). The two lines of rotation meet at the point $\mathbf{c} = (0, 0, 1)$, common to $\{(0, 0, \lambda)\}$ and $\{(t, 0, 1)\}$. Since $\mathbf{c}$ lies on the axis of g_1 , $g_1(\mathbf{c}) = \mathbf{c}$, and since it lies on the axis of g_2 , $g_2(\mathbf{c}) = \mathbf{c}$: hence $g(\mathbf{c}) = \mathbf{c}$. A rigid motion with a fixed point and $R \neq I$ is a pure rotation whose axis passes through that point — which independently confirms $h = 0$ and tells us where the axis is. Finally, one checks that $\mathbf{q}$ lies on the line through $\mathbf{c}$ with direction ω : the point of that line closest to the origin is

$$\mathbf{c} - (\mathbf{c}^\top \omega) \omega = (0, 0, 1)^\top - \frac{1}{\sqrt{3}} \cdot \frac{1}{\sqrt{3}}(1, -1, 1)^\top = \left(-\frac{1}{3}, \frac{1}{3}, \frac{2}{3}\right)^\top = \mathbf{q}. \quad \checkmark$$

The numerical computation confirms $(\mathbf{q} - \mathbf{c}) \times \omega = \mathbf{0}$ up to machine zero.

Numerical check. $\|e^{[\xi]\theta} - g\|_{\max} = 2.2 \cdot 10^{-16}$ with the closed form and $3.1 \cdot 10^{-16}$ with the series to 40 digits. ✓

Second case: skew axes. With $\mathbf{c}' = (0, 1, 0)^\top$ one has $\mathbf{p}'_2 = \mathbf{c}' - R_2 \mathbf{c}' = (0, 1, 0)^\top - (0, 0, 1)^\top = (0, 1, -1)^\top$, hence $g' = (R, (0, 1, -1)^\top)$ with the same R and hence the same $\theta = \frac{2\pi}{3}$ and the same ω . Now, however,

$$h\theta = \omega^\top \mathbf{p}' = \frac{1}{\sqrt{3}}(0 - 1 - 1) = -\frac{2}{\sqrt{3}} = -1.154701,$$

$$h = \frac{h\theta}{\theta} = -\frac{3}{\sqrt{3}\pi} = -\frac{\sqrt{3}}{\pi} = -0.551329.$$

Computing $\mathbf{v} = G(\theta)^{-1}\mathbf{p}'$ gives $\mathbf{v} = (-0.125860; 0.125860; -0.703210)$ and $\mathbf{q} = \omega \times \mathbf{v} = \left(\frac{1}{3}, \frac{1}{3}, 0\right)^\top$: a genuine screw motion, with nonzero pitch.

Independent check of the second case. By Proposition 29.4, $\min_{\mathbf{x}} \|g'(\mathbf{x}) - \mathbf{x}\| = |h\theta| = 1.154701$; searching for the minimum over 400 000 randomly drawn points gives 1.154724, which exceeds the exact value by $2.3 \cdot 10^{-5}$ because no sample falls exactly on the axis. ✓

Interpretation. The composition of two rotations with *intersecting* axes is a rotation (about an axis through the common point); with *skew* axes it is a screw motion with nonzero pitch. The rotational part is the same in both cases — it depends only on R_1, R_2 — and only the translation changes. This is why the singularities of a spherical wrist (concurrent axes) are separate from those of the arm: in the wrist there is no translation to compose.

Typical errors. (1) Writing $g_2 = (R_2, \mathbf{c})$ instead of $(R_2, \mathbf{c} - R_2\mathbf{c})$: the translation of a rotation about a line not through the origin is not the point of the line. (2) Composing in the wrong order: $g_1g_2 \neq g_2g_1$, and the two products have different axes (the same θ , because $\text{tr}(R_1R_2) = \text{tr}(R_2R_1)$, but different axis and pitch). (3) Concluding “ $h\theta = 0$ hence $\theta = 0$ ”: zero pitch means pure rotation, not absence of motion.

Extension. Prove, with the same method, that the composition of two rotations about *parallel* and distinct axes, of angles α and $-\alpha$, is a pure translation (case (ii) of Theorem 29.6); and that if the angles are α and β with $\alpha + \beta \notin 2\pi\mathbb{Z}$ one obtains a rotation about a third axis parallel to the first two.

Exercise 29.5: The spatial elbow arm: two families of singularities. *Type:* computational with a symbolic part. Consider the anthropomorphic arm with three revolute joints with: $\omega_1 = \mathbf{e}_3$ (vertical axis through the origin, *shoulder rotation*), $\omega_2 = \mathbf{e}_2$ (horizontal axis through the origin, *shoulder elevation*), $\omega_3 = \mathbf{e}_2$ (horizontal axis through $(a_2, 0, 0)$, *elbow*), with the wrist at $(a_2 + a_3, 0, 0)$ in the reference configuration; $a_2 = 1.2$, $a_3 = 1$.

- Write the position of the wrist centre as a function of $(\theta_1, \theta_2, \theta_3)$.
- Compute the determinant of the position Jacobian matrix.
- Describe the singular configurations.
- Verify everything numerically with the singular values.

Solution. Strategy. We observe that joints 2 and 3 move the arm in a vertical plane, that joint 1 rotates that plane about the z axis, and we write the columns of the Jacobian in an adapted basis — $\mathbf{u}$ radial, $\mathbf{w}$ tangential, $\mathbf{e}_3$ vertical — in which the determinant factorises.

Step 1 — forward kinematics. A rotation by θ about $\mathbf{e}_2$ sends $\mathbf{e}_1$ to $(\cos \theta, 0, -\sin \theta)$. Hence, in the vertical plane $\theta_1 = 0$, the wrist centre is at

$$r = a_2 \cos \theta_2 + a_3 \cos(\theta_2 + \theta_3), \quad z = -(a_2 \sin \theta_2 + a_3 \sin(\theta_2 + \theta_3)),$$

and rotating by θ_1 about z :

$$\mathbf{P}(\theta) = (r \cos \theta_1, r \sin \theta_1, z).$$

Here r is the (signed) distance from the vertical axis and z the height.

Step 2 — the columns of the Jacobian. Set $\mathbf{u} = (\cos \theta_1, \sin \theta_1, 0)$ and $\mathbf{w} = (-\sin \theta_1, \cos \theta_1, 0)$, so that $(\mathbf{u}, \mathbf{w}, \mathbf{e}_3)$ is a right-handed orthonormal basis. Differentiating:

$$\frac{\partial \mathbf{P}}{\partial \theta_1} = r \mathbf{w}, \quad \frac{\partial \mathbf{P}}{\partial \theta_2} = r' \mathbf{u} + z' \mathbf{e}_3, \quad \frac{\partial \mathbf{P}}{\partial \theta_3} = r'' \mathbf{u} + z'' \mathbf{e}_3,$$

with

$$r' = -(a_2 \sin \theta_2 + a_3 \sin(\theta_2 + \theta_3)) = z, \quad z' = -r,$$

$$r'' = -a_3 \sin(\theta_2 + \theta_3), \quad z'' = -a_3 \cos(\theta_2 + \theta_3).$$

Step 3 — the determinant. In the coordinates of the basis $(\mathbf{u}, \mathbf{w}, \mathbf{e}_3)$ the three columns are $(0, r, 0)$, $(r', 0, z')$, $(r'', 0, z'')$. Expanding along the second row (the only nonzero entry is in position $(2, 1)$, with sign $(-1)^{2+1} = -1$):

$$\det J = -r (r' z'' - r'' z').$$

One computes, with $s_2 = \sin \theta_2$, $c_2 = \cos \theta_2$, $s_{23} = \sin(\theta_2 + \theta_3)$, $c_{23} = \cos(\theta_2 + \theta_3)$:

$$\begin{aligned} r' z'' - r'' z' &= [-(a_2 s_2 + a_3 s_{23})](-a_3 c_{23}) - (-a_3 s_{23})[-(a_2 c_2 + a_3 c_{23})] \\ &= a_2 a_3 (c_{23} s_2 - s_{23} c_2) + a_3^2 (c_{23} s_{23} - s_{23} c_{23}) = a_2 a_3 \sin(\theta_2 - (\theta_2 + \theta_3)) = -a_2 a_3 \sin \theta_3. \end{aligned}$$

Hence

$$\det J = a_2 a_3 \sin \theta_3 (a_2 \cos \theta_2 + a_3 \cos(\theta_2 + \theta_3)) = a_2 a_3 r \sin \theta_3$$

Step 4 — the two families. $\det J = 0$ if and only if

- $\sin \theta_3 = 0$: **elbow singularity**, arm outstretched ($\theta_3 = 0$) or folded ($\theta_3 = \pi$); this is the spatial analogue of that of the planar arm (Example 29.6);
- $r = 0$: **shoulder singularity**, the wrist centre falls on the vertical axis of the first joint. At that position rotating θ_1 does not move the wrist, and the first column of the Jacobian vanishes identically.

Step 5 — independent numerical check. With $a_2 = 1.2$, $a_3 = 1$:

$(\theta_1, \theta_2, \theta_3)$ rad	$\det J$ (numpy)	$a_2 a_3 r \sin \theta_3$	singular values
(0.5; 0.6; 0.9)	0.9974634	0.9974634	2.178457; 1.061140; 0.431494
(0.3; 1.1; 1.6)	-0.4315241	-0.4315241	1.693609; 0.708244; 0.359757
(0.5; 0.6; 0)	0	0	2.416609; 1.815738; 0
(0.5; 0.6; π)	0	0	1.019804; 0.165067; 0
(0.5; 0.6; 2.4029373)	0	0	1.017082; 0.794383; 0

The last row is the shoulder singularity: θ_3 is the solution of $a_2 \cos \theta_2 + a_3 \cos(\theta_2 + \theta_3) = 0$ for $\theta_2 = 0.6$, and the wrist centre comes out at $(0; 0; -0.8157825)$, that is, exactly on the vertical axis. ✓ In the first two rows the product of the singular values reproduces $|\det J|$ ($2.178457 \cdot 1.061140 \cdot 0.431494 = 0.9974633634$). ✓ The analytic Jacobian agrees with the one from centred finite differences ($\delta = 10^{-6}$) to within $1.6 \cdot 10^{-10}$ in every row. ✓

Structural remark. In the first row the intermediate singular value, 1.061140, equals r exactly. This is no coincidence: the first column is $r\mathbf{w}$ and the other two lie in the plane $\langle \mathbf{u}, \mathbf{e}_3 \rangle$, orthogonal to $\mathbf{w}$; hence $\mathbf{w}$ is a left singular vector with singular value $|r|$. The shoulder singularity is precisely the vanishing of this singular value, the elbow one the vanishing of the determinant of the residual 2×2 block.

Typical errors. (1) Forgetting the sign in $R_y(\theta)\mathbf{e}_1 = (\cos \theta, 0, -\sin \theta)$ and obtaining z with the wrong sign: the determinant changes sign but not the singular set, so the error remains invisible until a velocity is computed. (2) Concluding that the shoulder singularity requires particular θ_2 and θ_3 : it requires only $r = 0$, which is a curve in the (θ_2, θ_3) plane. (3) Looking for the shoulder singularity at “small” r : $\det J$ vanishes only for exactly $r = 0$, but $\sigma_{\min} \leq |r|$, so conditioning already worsens in a neighbourhood.

Extension. Adding a spherical wrist (Example 29.7) gives the six-axis manipulator of industrial use. For a robot with a spherical wrist, the 6×6 Jacobian can be written in block-triangular form by choosing the origin at the wrist centre, and then $\det J_{6 \times 6} = \det J_{\text{arm}} \cdot \det J_{\omega, \text{wrist}}$: the three families of singularities (shoulder, elbow, wrist) are exactly the zeros of the three factors.

Exercise 29.6: Changing reference configuration without changing the robot.
Type: numerical/proof-based. For the planar 3R arm of Example 29.4, adopt as reference configuration $\bar{\theta} = (30^\circ, 60^\circ, -45^\circ)$ instead of $\bar{\theta} = 0$. Compute the new twists $\bar{\xi}_i$ and the new $\bar{M}$, verify that their axes are the current positions of the joints, and check numerically that the two product-of-exponentials formulas give the same kinematics.

Solution. Strategy. We apply Proposition 29.5(iii): the new twists are $\bar{\xi}_i = \text{Ad}_{A_{i-1}} \xi_i$ with $A_{i-1} = e^{[\xi_1]\bar{\theta}_1} \dots e^{[\xi_{i-1}]\bar{\theta}_{i-1}}$, and the new reference pose is $\bar{M} = T(\bar{\theta})$. We then check that the result matches that of Step 1 of the proof of Theorem 29.11: $\bar{\xi}_i$ must be the twist of the axis of joint i in the position it occupies when $\theta = \bar{\theta}$.

Step 1 — the new reference pose. From Example 29.4, $T(\bar{\theta})$ has position (2.4391576; 3.2071068; 0) and orientation $\varphi = 30^\circ + 60^\circ - 45^\circ = 45^\circ$:

$$\bar{M} = \begin{pmatrix} 0.7071068 & -0.7071068 & 0 & 2.4391576 \\ 0.7071068 & 0.7071068 & 0 & 3.2071068 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

Step 2 — the new twists. Computing $\text{Ad}_{A_{i-1}} \xi_i$ gives

$$\bar{\xi}_1 = (0, 0, 1, 0, 0, 0), \quad \bar{\xi}_2 = (0, 0, 1, 1, -1.7320508, 0), \quad \bar{\xi}_3 = (0, 0, 1, 2.5, -1.7320508, 0).$$

Step 3 — geometric reading. By Lemma 29.5, the axis of $\bar{\xi}_i$ passes through $\bar{\mathbf{q}}_i = \omega \times \bar{\mathbf{v}}_i$ and has pitch $\omega^\top \bar{\mathbf{v}}_i$. This gives

$$\bar{\mathbf{q}}_1 = (0, 0, 0), \quad \bar{\mathbf{q}}_2 = (1.7320508; 1; 0), \quad \bar{\mathbf{q}}_3 = (1.7320508; 2.5; 0),$$

with zero pitch in all three cases (computed values: exactly 0 in double precision). Comparing with the joint positions in configuration $(30^\circ, 60^\circ, -45^\circ)$, computed in Figure 29.2 — (0, 0), (1.7321; 1), (1.7321; 2.5) — one sees that the new axes are exactly the axes of the joints *in that configuration*. ✓ This is the geometric content of Proposition 29.5(iii): changing the reference configuration means reading the axes where they currently are.

Step 4 — numerical verification. For three values of θ we compared $T(\theta) = e^{[\xi_1]\theta_1} e^{[\xi_2]\theta_2} e^{[\xi_3]\theta_3} M$ with $\bar{T}(\theta) = e^{[\bar{\xi}_1]\phi_1} e^{[\bar{\xi}_2]\phi_2} e^{[\bar{\xi}_3]\phi_3} \bar{M}$, $\phi_i = \theta_i - \bar{\theta}_i$:

θ (rad)	$\max T - \bar{T} $	tool position
(0.4; -0.9; 1.3)	$1.3 \cdot 10^{-15}$	(3.8552025; 0.7770545)
(1; 0.2; -0.3)	$4.4 \cdot 10^{-16}$	(2.2457512; 3.8643275)
$\bar{\theta}$	0	(2.4391576; 3.2071068)

The two descriptions agree within machine error, and at $\theta = \bar{\theta}$ (where $\phi = 0$) they agree exactly because both reduce to $\bar{M}$. ✓

Interpretation. The result is what makes the product of exponentials usable on the shop floor: there is no need to move the robot to a “nominal” configuration to disassemble it. It suffices to measure the axes where they are and record the tool pose in that same configuration; the formula has the same structure, with different data.

Typical errors. (1) Changing the twists but forgetting to change M : one obtains kinematics that differ by a right multiplicative constant — a systematic pose error that is not visible when comparing *motions*, only absolute positions. (2) Using θ_i instead of $\phi_i = \theta_i - \bar{\theta}_i$: the robot ends up rotated by $\bar{\theta}$ in every configuration. (3) Transporting the twists with Ad_{A_i} instead of $\text{Ad}_{A_{i-1}}$: this includes joint i in the transport, and for joint i this does not change its own axis (the axis is invariant under rotation about itself), but it shifts all the following ones.

Extension. Repeat the exercise with a change of base frame $P \in SE(3)$ (for instance the translation by $(0, 0, 1)$ composed with a rotation by 20° about z) and verify part (i) of Proposition 29.5: the new twists are $\text{Ad}_P \xi_i$ and the new reference pose is PM ; the set of singular configurations remains the same (Theorem 29.10).

29.10. Self-assessment quiz

1. (Definition) The Lie algebra $\mathfrak{se}(3)$ consists of the 4×4 matrices of the form

A) $\begin{pmatrix} R & \mathbf{p} \\ \mathbf{0}^\top & 1 \end{pmatrix}$ with $R \in SO(3)$
symmetric

B) $\begin{pmatrix} [\omega]_\times & \mathbf{v} \\ \mathbf{0}^\top & 0 \end{pmatrix}$ with $\omega, \mathbf{v} \in \mathbb{R}^3$

C) $\begin{pmatrix} S & \mathbf{v} \\ \mathbf{0}^\top & 0 \end{pmatrix}$ with S

D) all traceless matrices
2. (Hypothesis) In Theorem 29.6, the hypothesis that guarantees solvability of $G(\theta)\mathbf{v} = \mathbf{p}$ is

A) $\|\omega\| = 1$

B) $\theta \in (0, 2\pi)$

C) $\mathbf{p} \neq \mathbf{0}$

D) R symmetric
3. (Symbolic computation) For the planar 3R arm with links ℓ_1, ℓ_2, ℓ_3 the determinant of the task Jacobian matrix (x, y, φ) equals

A) $\ell_1 \ell_2 \ell_3 \sin \theta_2$

B) $\ell_1 \ell_2 \sin \theta_2$

C) $\ell_2 \ell_3 \sin \theta_3$

D) $\ell_1 \ell_2 \sin(\theta_1 + \theta_2)$
4. (Numerical computation) For $g = (R, \mathbf{p})$ with R the rotation by 90° about z and $\mathbf{p} = (1, 2, 3)^\top$, the pitch h of the screw motion equals

A) 3

B) $6/\pi \approx 1.909859$

C) 0

D) $\sqrt{14} \approx 3.741657$
5. (Proof step) In the proof of Theorem 29.5, the fact that the points of the axis only translate follows from

A) $[\omega]_\times \omega = \mathbf{0}$, whence $e^{[\omega]_\times \theta} \omega = \omega$

B) the invertibility of $G(\theta)$

C) $\det R = 1$

D) the Baker–Campbell–Hausdorff formula
6. (Error diagnosis) A student claims: “The robot is at a wrist singularity; I redefine the TCP by shifting it 50 mm and the singularity disappears.” The error is

A) the TCP cannot be redefined

B) changing the tool frame leaves J_s unchanged, hence it does not change the rank

C) the singularity depends on the controller brand

D) one must move the base, not the tool
7. (Transfer) A ZYZ spherical wrist with axes $\mathbf{e}_3, \mathbf{e}_2, \mathbf{e}_3$ in the reference configuration is singular if and only if

A) $\theta_1 = 0$

B) $\theta_2 \in \{0, \pi\}$

C) $\theta_3 = \pi/2$

D) $\theta_1 + \theta_3 = 0$
8. (Source and metacognition) Chasles’ theorem, in the form “every rigid motion can be realised by a rotation about an axis composed with a translation parallel to that axis,” is found stated in

A) Murray–Li–Sastry, Theorem 2.11, p. 49, and Lynch–Park, Proposition 3.25, p. 105

B) Hatcher, *Algebraic Topology*, §1.1

C) Murray–Li–Sastry, Theorem 8.5, p. 381

D) Lee, *Introduction to Smooth Manifolds*, Theorem 20.12

29.11. Teacher’s key

BEST PRACTICE

Quiz — answers, rationale and diagnosis (1–4).

1) **B.** *Rationale:* this is Theorem 29.3: the algebra is the space of twists, with *skew-symmetric* angular block and zero last row. *Distractors:* A describes the *group* $SE(3)$, not the algebra (confusing e^X with X); C replaces “skew-symmetric” with “symmetric”, and then $e^{tS} \notin SO(3)$; D is the algebra $\mathfrak{sl}(4, \mathbb{R})$, much larger (dimension 15 versus 6). *Diagnosed error:* confusing group and algebra. *Source:* Theorem 29.3; Lynch–Park, *Modern Robotics*, §3.3.2. *Prerequisite:* the definition of $\mathfrak{g}$ as $\{X : e^{tX} \in G \ \forall t\}$. *Remediation:* redo Step 3 of the proof of Theorem 29.3, where $(e^{tA})^\top e^{tA} = I$ is differentiated at $t = 0$.

2) **B.** *Rationale:* Proposition 29.3 gives $\det G(\theta) = 4\theta \sin^2(\theta/2)$, which is nonzero exactly for $\theta \notin 2\pi\mathbb{Z}$ and $\theta \neq 0$; the choice $\theta \in (0, \pi]$ of the theorem guarantees the condition. *Distractors:* A is a normalisation, necessary for the formulas to have the stated form but not sufficient (with $\theta = 2\pi$ and $\|\omega\| = 1$ the matrix G is singular); C plays no role (if $\mathbf{p} = \mathbf{0}$ the system is still solvable, with $\mathbf{v} = \mathbf{0}$); D is false for a generic rotation. *Diagnosed error:* confusing a normalisation with a hypothesis of invertibility. *Source:* Proposition 29.3; Remark 29.4. *Prerequisite:* determinant of a block-diagonal operator. *Remediation:* compute $G(2\pi)$ and verify its rank.

3) **B.** *Rationale:* Example 29.6, Step 2: after the column subtractions the determinant reduces to a 2×2 one and equals $\ell_1 \ell_2 \sin \theta_2$. *Distractors:* A adds ℓ_3 , which instead vanishes; C shifts the index to the third joint, which does not produce a singularity; D confuses $\sin \theta_2$ with $\sin(\theta_1 + \theta_2)$, that is, forgets the subtraction formula $c_1 s_{12} - s_1 c_{12} = \sin \theta_2$. *Diagnosed error:* not recognising that the determinant is invariant under elementary column operations. *Source:* Example 29.6. *Prerequisite:* properties of the determinant. *Remediation:* redo the computation with $\ell_3 = 0$ and verify that the result does not change.

4) **B.** *Rationale:* Example 29.3: $\theta = \pi/2$ and $h\theta = \omega^\top \mathbf{p} = 3$, hence $h = 3/(\pi/2) = 6/\pi = 1.909859$. *Distractors:* A confuses the pitch h (translation *per radian*) with the total translation $h\theta = 3$; C would be the pure rotation case, excluded because $\omega^\top \mathbf{p} = 3 \neq 0$; D is $\|\mathbf{p}\|$, which is not the translation along the axis. *Diagnosed error:* confusing pitch and total translation. *Source:* Definition 29.5; Proposition 29.4(i). *Prerequisite:* orthogonal projection onto a unit vector. *Remediation:* compute h and $h\theta$ for the same $\mathbf{p}$ but with $\theta = \pi$ and compare.

BEST PRACTICE

Quiz — answers, rationale and diagnosis (5–8).

5) **A.** *Rationale:* in Step 5 of the proof one uses $R\omega = \omega$, a consequence of $[\omega]_\times \omega = \mathbf{0}$ (Lemma 29.1(iii)) and of the exponential series; this is what removes the rotational part on the points of the axis. *Distractors:* B is needed for the *logarithm*, that is, for the inverse passage; C holds for every rotation and does not single out the axis; D does not appear in that proof (and is declared a panorama in Remark 29.14). *Diagnosed error:* attributing to a hypothesis the wrong part of the proof. *Source:* Theorem 29.5, Step 5. *Prerequisite:* $Ke^{K\theta} = e^{K\theta}K$. *Remediation:* verify by hand that $e^{[\omega]_\times \theta} \omega = \omega$ by summing the series.

6) **B.** *Rationale:* by Theorem 29.10(ii), $T' = TQ$ with Q constant gives $\dot{T}'(T')^{-1} = \dot{T}T^{-1}$, that is $J'_s = J_s$: the rank, and hence the singularity, does not change. *Distractors:* A is false (the TCP can always be redefined); C confuses the mathematics with the implementation (controllers differ in how they *handle* the singularity, not in whether they have it); D is equally false by part (i) of the same theorem. *Diagnosed error:* believing that singularities depend on conventions rather than on the mechanism. *Source:* Theorem 29.10; Lynch–Park, *Modern Robotics*, §5.3, pp. 192–193. *Prerequisite:* invariance of rank under multiplication by invertible matrices. *Remediation:* redo the two two-line computations of the theorem

and discuss Remark 29.11.

7) B. Rationale: Example 29.7, Step 3: $\det J_\omega = -\sin \theta_2$, which vanishes only for $\theta_2 \in \{0, \pi\}$; at those configurations the first and third axes become collinear (Theorem 29.11). *Distractors:* A and D involve θ_1 and θ_3 , which do not appear in the determinant — and must not, because rotating the first or third joint does not alter the angles between the axes; C confuses the ZYZ wrist with the ZYX one of Exercise 29.3, where the determinant is $-\cos \theta_2$ and the singularity is at $\theta_2 = \pm\pi/2$. *Diagnosed error:* applying the condition of one architecture to another without redoing the computation. *Source:* Example 29.7; Murray–Li–Sastry, ch. 3, §4.3 “Singularities,” p. 125. *Prerequisite:* expansion of a 3×3 determinant. *Remediation:* redo Exercise 29.3 and compare the two answers.

8) A. Rationale: Theorem 2.11 of Murray–Li–Sastry, p. 49, is literally the statement quoted. The same claim, in constructive form, is Proposition 3.25 of Lynch–Park, p. 105, which is its constructive form (the exponential of a twist in closed form), followed on p. 106 by the statement that this derivation “is a constructive proof of the Chasles–Mozzi theorem.” *Distractors:* B is the source of the fundamental group of the circle (Chapter 12); C is the Baker–Campbell–Hausdorff formula; D is the closed subgroup theorem, quoted in Remark 29.2. *Diagnosed error:* citing a book instead of a statement. *Source:* see the “Sources” section. *Prerequisite:* knowing how to read a reference with theorem number and page. *Remediation:* locate the two statements in the two books and compare the conventions on the order of the twist coordinates.

BEST PRACTICE

Assigned exercise 29.1 — answers. (a) $h = \omega^\top \mathbf{v} = (0, 0, 1) \cdot (1, 0, 2) = 2$ and $\mathbf{q} = \omega \times \mathbf{v} = (0, 1, 0)$: the axis is the vertical line through $(0, 1, 0)$ and the motion $e^{[\xi]\theta}$ rotates by θ about it while rising by 2θ along z . (b) Let $\eta = \text{Ad}_g \xi = (R\omega, [\mathbf{p}]_\times R\omega + R\mathbf{v})$ with $g = (R, \mathbf{p})$. The pitch is

$$(R\omega)^\top ([\mathbf{p}]_\times R\omega + R\mathbf{v}) = (R\omega)^\top (\mathbf{p} \times R\omega) + (R\omega)^\top R\mathbf{v} = 0 + \omega^\top R^\top R\mathbf{v} = \omega^\top \mathbf{v} = h,$$

because $\mathbf{p} \times R\omega \perp R\omega$ and $R^\top R = I$. For the axis: Theorem 29.5 and Proposition 29.2 give $e^{[\eta]\theta} = g e^{[\xi]\theta} g^{-1}$; the “minimal-translation” fixed points of $e^{[\eta]\theta}$ are therefore the images under g of those of $e^{[\xi]\theta}$ (Proposition 29.4), that is, $g(\mathcal{L})$. (c) A change of frame acts on twists by the adjoint; since pitch and axis transform covariantly and the pitch stays the same number, the pitch is an invariant. The same structure — conjugation by a fixed element of $SE(3)$ — is what leaves the rank of J unchanged in Theorem 29.10. (d) With the given g one obtains $\text{Ad}_g \xi = (0.717356; 0; 0.696707; 0.738005; -0.338029; 2.110770)$; the pitch equals 2.000000, unchanged ✓; the axis point is $(0.235507; -1; -0.242487)$ while $g(\mathbf{q}) = (1; -1; 0.5)$: the difference is $(0.764493; 0; 0.742487)$, parallel to $R\omega$ to within 10^{-16} . ✓

BEST PRACTICE

Assigned exercise 29.2 — answers. (a) $\text{tr } R = 1$, hence $\theta = \arccos 0 = \pi/2$; the axis is $\omega = \mathbf{e}_1$ (read off from $R\mathbf{e}_1 = \mathbf{e}_1$). (b) With $K = [\mathbf{e}_1]_\times$, $K^2 = \text{diag}(0, -1, -1)$ and $\cot(\pi/4) = 1$:

$$G(\pi/2)^{-1} = \frac{2}{\pi}I - \frac{1}{2}K + \left(\frac{2}{\pi} - \frac{1}{2}\right)K^2 = \begin{pmatrix} 2/\pi & 0 & 0 \\ 0 & 1/2 & 1/2 \\ 0 & -1/2 & 1/2 \end{pmatrix}, \quad \mathbf{v} = \left(\frac{4}{\pi}, 0, -1\right)^\top.$$

Numerically $\mathbf{v} = (1.273240; 0; -1)$. (c) $h = \omega^\top \mathbf{v} = 4/\pi = 1.273240$; $\mathbf{q} = \omega \times \mathbf{v} = (0, 1, 0)$; $h\theta = \frac{4}{\pi} \cdot \frac{\pi}{2} = 2$, and $\omega^\top \mathbf{p} = 2$: they agree. ✓ (d) In the yz plane the motion is

$\begin{pmatrix} y \\ z \end{pmatrix} \mapsto \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} y \\ z \end{pmatrix} + \begin{pmatrix} 1 \\ -1 \end{pmatrix}$, whose fixed point is $\frac{1}{2} \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} 1 \\ -1 \end{pmatrix} = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$, that is $(y, z) = (1, 0)$: exactly the projection of the axis $\{(\lambda, 1, 0)\}$. ✓(e) $\|e^{[\xi]\theta} - g\|_{\max} = 1.1 \cdot 10^{-16}$ both with the closed form and with the series to 40 digits; the minimum of $\|g(\mathbf{x}) - \mathbf{x}\|$ over 300 000 random points equals 2.000014, against the exact value $|h\theta| = 2$. ✓

BEST PRACTICE

Assigned exercise 29.3 — answers. (a) With $R_1 = e^{[\mathbf{e}_3] \times \theta_1}$, $R_2 = e^{[\mathbf{e}_2] \times \theta_2}$:

$$\mathbf{c}_1 = (0, 0, 1)^\top, \quad \mathbf{c}_2 = (-s_1, c_1, 0)^\top, \quad \mathbf{c}_3 = R_1 R_2 \mathbf{e}_1 = (c_1 c_2, s_1 c_2, -s_2)^\top.$$

(b) Expanding along the third row, whose entries are $1, 0, -s_2$:

$$\det J_\omega = 1 \cdot \det \begin{pmatrix} -s_1 & c_1 c_2 \\ c_1 & s_1 c_2 \end{pmatrix} + (-s_2) \cdot \det \begin{pmatrix} 0 & -s_1 \\ 0 & c_1 \end{pmatrix} = -c_2 + 0 = -\cos \theta_2.$$

The singular set is $\theta_2 = \pm\pi/2$ (modulo 2π). (c) $\mathbf{c}_1 \cdot \mathbf{c}_2 = 0$, $\mathbf{c}_2 \cdot \mathbf{c}_3 = -s_1 c_1 c_2 + c_1 s_1 c_2 = 0$, $\mathbf{c}_1 \cdot \mathbf{c}_3 = -s_2$, hence

$$J_\omega^\top J_\omega = \begin{pmatrix} 1 & 0 & -s_2 \\ 0 & 1 & 0 \\ -s_2 & 0 & 1 \end{pmatrix}, \quad \sigma = \left\{ \sqrt{1 + |\sin \theta_2|}, 1, \sqrt{1 - |\sin \theta_2|} \right\},$$

whose product is $\sqrt{1 - \sin^2 \theta_2} = |\cos \theta_2| = |\det J_\omega|$. ✓(d) At $\theta_2 = \pi/2$ one has $\mathbf{c}_3 = (0, 0, -1)^\top = -\mathbf{c}_1$: the independent columns are two, the image is $\langle \mathbf{e}_3, R_1 \mathbf{e}_2 \rangle$ and the lost direction is $R_1 \mathbf{e}_1 = (\cos \theta_1, \sin \theta_1, 0)$. For $\theta_1 = 0.9$ the singular value decomposition gives $\pm(0.621610; 0.783327; 0)$, and $(\cos 0.9; \sin 0.9; 0) = (0.621610; 0.783327; 0)$. ✓Check table (numerical singular values against closed form; maximum discrepancy $6.3 \cdot 10^{-16}$):

θ_2 (rad)	$\det J_\omega$	singular values
0	-1	1; 1; 1
0.4	-0.9210610	1.178736; 1; 0.781397
1	-0.5403023	1.357008; 1; 0.398157
1.5207963	-0.0499792	1.413772; 1; 0.035352
$\pi/2$	0	1.414214; 1; 0

(e) Theorem 28.5 says that the RPY *parametrisation* of $SO(3)$ degenerates at $\theta = \pm\pi/2$: there the Jacobian of the map $(\phi, \theta, \psi) \mapsto R$ loses rank. Here the matrix is the same, but the three parameters are not coordinates on a manifold: they are the positions of three physical axes. The degeneracy is therefore mechanical — two axes really do align — and cannot be removed by changing chart, as is instead done by passing to quaternions (Remark 28.7). It is the same formula with two different meanings, and the difference lies entirely in the fact that here θ_2 is a quantity measured by an encoder.

29.12. Formulary of the chapter

Group and algebra.

$$SE(3) = \left\{ \begin{pmatrix} R & \mathbf{p} \\ \mathbf{0}^\top & 1 \end{pmatrix} : R \in SO(3), \mathbf{p} \in \mathbb{R}^3 \right\}, \quad (R, \mathbf{p})^{-1} = (R^\top, -R^\top \mathbf{p}),$$

$$(R_1, \mathbf{p}_1)(R_2, \mathbf{p}_2) = (R_1 R_2, R_1 \mathbf{p}_2 + \mathbf{p}_1), \quad SE(3) = \mathbb{R}^3 \rtimes SO(3).$$

$$\mathfrak{se}(3) = \left\{ [\xi] = \begin{pmatrix} [\omega]_{\times} & \mathbf{v} \\ \mathbf{0}^{\top} & 0 \end{pmatrix}, \quad [[\xi_1], [\xi_2]] = (\omega_1 \times \omega_2, \omega_1 \times \mathbf{v}_2 - \omega_2 \times \mathbf{v}_1)^{\wedge} \right\}.$$

Hat identities: $[\omega]_{\times}^2 = \omega\omega^{\top} - \|\omega\|^2 I$, $[\omega]_{\times}^3 = -\|\omega\|^2 [\omega]_{\times}$, $[[\mathbf{a}]_{\times}, [\mathbf{b}]_{\times}] = [\mathbf{a} \times \mathbf{b}]_{\times}$, $R[\omega]_{\times} R^{\top} = [R\omega]_{\times}$.

Exponential and logarithm. For $\|\omega\| = 1$:

$$e^{[\omega]_{\times}\theta} = I + \sin\theta [\omega]_{\times} + (1 - \cos\theta)[\omega]_{\times}^2,$$

$$e^{[\xi]\theta} = \begin{pmatrix} e^{[\omega]_{\times}\theta} & G(\theta)\mathbf{v} \\ \mathbf{0}^{\top} & 1 \end{pmatrix}, \quad G(\theta) = I\theta + (1 - \cos\theta)[\omega]_{\times} + (\theta - \sin\theta)[\omega]_{\times}^2.$$

For $\omega = \mathbf{0}$: $e^{[\xi]\theta} = \begin{pmatrix} I & \mathbf{v}\theta \\ \mathbf{0}^{\top} & 1 \end{pmatrix}.$

$$\det G(\theta) = 4\theta \sin^2 \frac{\theta}{2}, \quad G(\theta)^{-1} = \frac{1}{\theta}I - \frac{1}{2}[\omega]_{\times} + \left(\frac{1}{\theta} - \frac{1}{2} \cot \frac{\theta}{2}\right)[\omega]_{\times}^2.$$

Logarithm: $\theta = \arccos \frac{\text{tr } R - 1}{2}$, $[\omega]_{\times} = \frac{R - R^{\top}}{2 \sin \theta}$ for $\theta \in (0, \pi)$, $\mathbf{v} = G(\theta)^{-1} \mathbf{p}$.

Chasles: axis and pitch. For $\xi = (\omega, \mathbf{v})$ with $\|\omega\| = 1$:

$$h = \omega^{\top} \mathbf{v}, \quad \mathbf{q} = \omega \times \mathbf{v}, \quad \mathcal{L} = \{\mathbf{q} + \lambda\omega\},$$

$$e^{[\xi]\theta} \mathbf{x} = \mathbf{q} + e^{[\omega]_{\times}\theta}(\mathbf{x} - \mathbf{q}) + h\theta\omega, \quad \omega^{\top}(g(\mathbf{x}) - \mathbf{x}) = h\theta = \omega^{\top} \mathbf{p},$$

$$\|g(\mathbf{x}) - \mathbf{x}\|^2 = (h\theta)^2 + \|(R - I)(\mathbf{x} - \mathbf{q})\|^2,$$

with equality if and only if $\mathbf{x} \in \mathcal{L}$ (the axis is the locus of minimal displacement).

Adjoint, product of exponentials, Jacobians.

$$\text{Ad}_g = \begin{pmatrix} R & 0 \\ [\mathbf{p}]_{\times} R & R \end{pmatrix}, \quad g[\xi]g^{-1} = [\text{Ad}_g \xi], \quad g e^{[\xi]\theta} g^{-1} = e^{[\text{Ad}_g \xi]\theta}.$$

Joint twists: $\xi_i = (\omega_i, -\omega_i \times \mathbf{q}_i)$ (revolute), $\xi_i = (\mathbf{0}, \mathbf{v}_i)$ (prismatic).

$$T(\theta) = e^{[\xi_1]\theta_1} e^{[\xi_2]\theta_2} \dots e^{[\xi_n]\theta_n} M, \quad M = T(0).$$

$$[\mathcal{V}_s] = \dot{T}T^{-1}, \quad [\mathcal{V}_b] = T^{-1}\dot{T}, \quad \mathcal{V}_s = \text{Ad}_T \mathcal{V}_b.$$

$$J_{s,i} = \text{Ad}_{e^{[\xi_1]\theta_1} \dots e^{[\xi_{i-1}]\theta_{i-1}}} \xi_i, \quad J_{b,i} = \text{Ad}_{(e^{[\xi_{i+1}]\theta_{i+1}} \dots e^{[\xi_n]\theta_n} M)^{-1}} \xi_i, \quad J_s = \text{Ad}_T J_b.$$

Singularities. θ singular $\iff \text{rank } J(\theta) < \min(6, n)$; $\text{rank } J_s = \text{rank } J_b$; changes of base and tool frame do not alter the singular set. Two collinear revolute axes $\Rightarrow$ singularity (for $n \leq 6$). Notable cases:

$$\text{planar 3R: } \det J = \ell_1 \ell_2 \sin \theta_2; \quad \text{ZZY wrist: } \det J_{\omega} = -\sin \theta_2;$$

$$\text{ZYZ wrist: } \det J_{\omega} = -\cos \theta_2;$$

$$\text{elbow arm: } \det J = a_2 a_3 \sin \theta_3 (a_2 \cos \theta_2 + a_3 \cos(\theta_2 + \theta_3)).$$

Damped least squares: $\dot{\theta}_{\lambda} = J^{\top}(JJ^{\top} + \lambda^2 I)^{-1} \mathcal{V}$, which replaces $1/\sigma_i$ with $\sigma_i/(\sigma_i^2 + \lambda^2) \leq 1/(2\lambda)$.

Unified presentation of twists and wrenches as dual elements of screw theory, useful for the Poinot part recalled in Remark 29.6 — verified on 6 September 2026.
- [10] J. Denavit, R. S. Hartenberg, *A kinematic notation for lower-pair mechanisms based on matrices*, ASME Journal of Applied Mechanics, June 1955, pp. 215–221. This is the original publication of the convention recalled in Definition 29.8. *Caveat*: the two secondary sources used here disagree on the volume number — Lynch–Park (bibliography, entry [34]) write “23:215–221, 1955,” Murray–Li–Sastry (entry [25]) omit the volume and report only “pages 215–221, June 1955”; not having been able to consult the original volume, the volume number is not given here. The comparison between the two descriptions (Remark 29.9) follows Murray–Li–Sastry, §2.3 “Parameterization of manipulators via twists,” subsection “Relationship with Denavit–Hartenberg parameters,” p. 93, and Lynch–Park, Appendix C — verified on 6 September 2026.

Trajectories and interpolation: SLERP and vibration reduction

Planning a motion means constructing a smooth curve that passes through (or near) assigned points, with controlled velocity and acceleration profiles. This chapter collects the standard tools: Bézier and B-spline curves for position, SLERP and dual quaternions for orientation, jerk-limited profiles for timing — all in use in robot controllers and motion PLCs.

The thread that ties them together is the circle. Position is interpolated with polynomials, but an arc of circle is *not* a polynomial curve (Proposition 30.4): representing it exactly requires a fraction of polynomials, and this is why CAD/CAM uses NURBS; Theorem 30.1 exhibits the arc as a rational quadratic Bézier and computes its time law in closed form. Orientation is interpolated on S^3 , and the SLERP formula is not postulated here but *derived* (Theorem 30.2) from the single requirement of traversing at constant angular velocity the great-circle arc joining two unit quaternions; Theorem 30.3 shows that the curve so obtained is, in space, a fixed-axis rotation at constant speed, and from this the “short path” rule (Corollary 30.3) follows in full, being a consequence of the double cover $S^3 \rightarrow SO(3)$ and not a convention. Timing, finally, is governed with trapezoidal and S-curve profiles: matching conditions and minimum times are derived (Theorems 30.4 and 30.5), and it is proved that Singer and Seering’s ZV shaper cancels *exactly* the residual vibration of a second-order elastic mode (Theorem 30.7), with its robust extension ZVD (Theorem 30.8) and a quantification of the robustness (Proposition 30.9).

Two surprises link the two halves of the chapter. The first: the residual vibration of a train of impulses is the modulus of its Laplace transform evaluated at the system’s pole (Theorem 30.6), so that designing a shaper means placing zeros — the same trade as Chapter 21. The second: the time law of the circular arc as rational Bézier is *exactly* that of normalized linear interpolation between quaternions (Remark 30.3), the very one that Proposition 30.7 condemns for its non-constant speed.

INFO

Level and prerequisites. Level **C** (undergraduate, advanced), with two points at level **D**: the equality case in Lemma 30.1 and the lower bound on jerk-limited times (Proposition 30.8).

Internal prerequisites. Great circles of the sphere and their minimality (Chapter 7, Theorem 7.7); the structure of S^3 , quaternion algebra, and the double cover $S^3 \rightarrow SO(3)$ (Chapter 11, Definition 11.3 and Theorem 11.10); geodesics and the calculus of variations (Chapter 9); rotations, Euler angles, and gimbal lock (Chapter 28); rigid-body kinematics and $\mathfrak{se}(3)$ (Chapter 29); transfer function and frequency response (Chapter 25, Definition 25.1); zeros of a transform and their effect (Chapter 21). From Volume I we recall the rational parametrization of the circle (Volume I, Chapter 3); from Volume II the computation of arc lengths (Volume II, Chapter 2).

External prerequisites, assumed and not reproved:

- single-variable differential and integral calculus: the fundamental theorem, Taylor’s formula with Lagrange remainder, the Cauchy–Schwarz inequality in $\mathbb{R}^n$;

- absolutely continuous functions: $f(b) - f(a) = \int_a^b f'$, and $|f'| \leq g$ almost everywhere implies $|f(b) - f(a)| \leq \int_a^b g$;
- uniqueness of the solution of a linear constant-coefficient Cauchy problem (existence, uniqueness, and the form of the general integral at second order);
- $\mathbb{C}[t]$ is an integral domain and its invertible elements are the nonzero constants.

Everything else is proved here.

What is learned. Deriving an interpolation formula from a kinematic requirement instead of postulating it; recognizing when a rational curve is indispensable and when a polynomial one suffices; reading the choice of a sign as a consequence of a topological property (the double cover); deriving minimum times from integral inequalities rather than from recipes; designing a two- or three-impulse filter by imposing the vanishing of a transform at an assigned point, and quantifying its robustness.

Warning. Conventions of the chapter.

- $\langle \cdot, \cdot \rangle$ is the Euclidean scalar product of $\mathbb{R}^4$, which on quaternions coincides with $\langle p, q \rangle = p_0q_0 + p_1q_1 + p_2q_2 + p_3q_3$; $\|q\|$ is the corresponding norm and $S^3 = \{q \in \mathbb{H} : \|q\| = 1\}$ (Definition 11.3).
- For $q_0, q_1 \in S^3$ we always set $\Omega = \arccos \langle q_0, q_1 \rangle \in [0, \pi]$, called the **angle between the two quaternions**; the angle of the corresponding rotation in $SO(3)$ is instead 2Ω (Theorem 30.3).
- $\Phi_q \in SO(3)$ is the rotation $v \mapsto qv\bar{q}$ associated with $q \in S^3$ (Theorem 11.10).
- In motion profiles s is the position, $v = \dot{s}$ the velocity, $a = \dot{v}$ the acceleration, $j = \dot{a}$ the jerk; $L, V, A, J > 0$ are respectively the travel and the limits on velocity, acceleration, and jerk.
- An *elastic mode* is a second-order system of natural frequency $\omega_n > 0$ and damping $\zeta \in [0, 1]$; we set $\beta = \sqrt{1 - \zeta^2}$, $\omega_d = \omega_n\beta$ (damped frequency), $T_d = 2\pi/\omega_d$ (damped period), and $K = e^{-\zeta\pi/\beta} \in (0, 1]$.
- Units are SI; numerical values are rounded to the digit shown, and every rounding is flagged with $\approx$. Checks marked $\checkmark$ were performed twice by independent routes.

30.1. Bézier curves

Definition 30.1: Bézier curve. Given $n + 1$ control points $P_0, \dots, P_n$ of $\mathbb{R}^d$, the **Bézier curve** of degree n is

$$B(t) = \sum_{i=0}^n b_{i,n}(t) P_i, \quad t \in [0, 1], \quad b_{i,n}(t) = \binom{n}{i} t^i (1-t)^{n-i},$$

a combination of the points with the **Bernstein polynomials** $b_{i,n}$. The polygonal path $P_0P_1 \cdots P_n$ is called the **control polygon**.

Proposition 30.1: Elementary properties of the Bézier curve. Let B be as in Definition 30.1, with $n \geq 1$. Then:

- (i) $\sum_{i=0}^n b_{i,n}(t) = 1$ and $b_{i,n}(t) \geq 0$ for $t \in [0, 1]$;
- (ii) $B(0) = P_0$ and $B(1) = P_n$;
- (iii) $B'(t) = n \sum_{i=0}^{n-1} b_{i,n-1}(t) (P_{i+1} - P_i)$; in particular $B'(0) = n(P_1 - P_0)$ and $B'(1) = n(P_n - P_{n-1})$;

- (iv) $B(t)$ belongs to the convex hull of $\{P_0, \dots, P_n\}$ for every $t \in [0, 1]$;
(v) for every affine map T one has $T(B(t)) = \sum_i b_{i,n}(t)T(P_i)$: transforming the control points is the same as transforming the curve.

Proof. Step 1 — (i). The binomial theorem applied to $(t + (1-t))^n$ gives $\sum_{i=0}^n \binom{n}{i} t^i (1-t)^{n-i} = (t + (1-t))^n = 1^n = 1$. Nonnegativity on $[0, 1]$ is immediate because $t \geq 0$, $1-t \geq 0$, and $\binom{n}{i} > 0$.

Step 2 — (ii). At $t = 0$ the factor t^i kills every term with $i \geq 1$, while $b_{0,n}(0) = \binom{n}{0} 0^0 1^n = 1$; hence $B(0) = P_0$. At $t = 1$ the factor $(1-t)^{n-i}$ kills every term with $i \leq n-1$ and $b_{n,n}(1) = 1$: $B(1) = P_n$.

Step 3 — the derivative of the Bernstein polynomials. For $1 \leq i \leq n-1$,

$$b'_{i,n}(t) = \binom{n}{i} \left[i t^{i-1} (1-t)^{n-i} - (n-i) t^i (1-t)^{n-i-1} \right].$$

Now $\binom{n}{i} i = \frac{n!}{(i-1)!(n-i)!} = n \binom{n-1}{i-1}$ and $\binom{n}{i} (n-i) = \frac{n!}{i!(n-i-1)!} = n \binom{n-1}{i}$, hence

$$b'_{i,n}(t) = n [b_{i-1,n-1}(t) - b_{i,n-1}(t)],$$

a formula that also holds for $i = 0$ and $i = n$ with the convention $b_{-1,n-1} \equiv b_{n,n-1} \equiv 0$ (for $i = 0$ the first summand is absent and the computation gives $-n(1-t)^{n-1} = -n b_{0,n-1}$; for $i = n$ the second is absent and gives $n t^{n-1} = n b_{n-1,n-1}$).

Step 4 — (iii). Summing,

$$B'(t) = \sum_{i=0}^n b'_{i,n}(t) P_i = n \sum_{i=0}^n b_{i-1,n-1}(t) P_i - n \sum_{i=0}^n b_{i,n-1}(t) P_i.$$

In the first sum the nonzero terms have $1 \leq i \leq n$; setting $j = i - 1$ it becomes $n \sum_{j=0}^{n-1} b_{j,n-1}(t) P_{j+1}$. In the second the nonzero terms have $0 \leq i \leq n-1$. Subtracting term by term gives $B'(t) = n \sum_{j=0}^{n-1} b_{j,n-1}(t) (P_{j+1} - P_j)$. Evaluating at $t = 0$ and at $t = 1$ with Step 2 applied to degree $n-1$ gives $B'(0) = n(P_1 - P_0)$ and $B'(1) = n(P_n - P_{n-1})$: the curve is tangent to the two extreme sides of the control polygon.

Step 5 — (iv). By Step 1 the coefficients $b_{i,n}(t)$ are nonnegative and sum to 1: $B(t)$ is a convex combination of the P_i , hence belongs to their convex hull, which by definition is the set of all such combinations.

Step 6 — (v). Let $T(x) = Mx + c$ with M linear. Then

$$T(B(t)) = M \left(\sum_i b_{i,n}(t) P_i \right) + c = \sum_i b_{i,n}(t) M P_i + \left(\sum_i b_{i,n}(t) \right) c = \sum_i b_{i,n}(t) T(P_i),$$

where in the second step $\sum_i b_{i,n}(t) = 1$ from Step 1 was used to distribute the translation c inside the sum. $\square$

Proposition 30.2: De Casteljau's algorithm. Fix $t \in [0, 1]$, and set $P_i^0 = P_i$ for $i = 0, \dots, n$ and, for $r = 1, \dots, n$,

$$P_i^r(t) = (1-t) P_i^{r-1}(t) + t P_{i+1}^{r-1}(t), \quad i = 0, \dots, n-r.$$

Then $P_0^n(t) = B(t)$. In particular the value of the curve is obtained with $\frac{n(n+1)}{2}$ linear interpolations, without computing powers or binomial coefficients.

Proof. **Step 1 — the statement to be proved by induction.** We show that

$$P_i^r(t) = \sum_{j=0}^r b_{j,r}(t) P_{i+j} \quad \text{for every } r = 0, \dots, n \text{ and every } i = 0, \dots, n-r.$$

For $r = n$ and $i = 0$ this is exactly $P_0^n(t) = \sum_j b_{j,n}(t) P_j = B(t)$.

Step 2 — base case. For $r = 0$ the sum has only the term $j = 0$ with $b_{0,0}(t) = \binom{0}{0} t^0 (1-t)^0 = 1$, so it reduces to $P_i^0 = P_i$: true by definition.

Step 3 — inductive step. Assuming the formula holds for $r-1$,

$$P_i^r = (1-t) \sum_{j=0}^{r-1} b_{j,r-1} P_{i+j} + t \sum_{j=0}^{r-1} b_{j,r-1} P_{i+1+j} = \sum_{j=0}^r \left[(1-t)b_{j,r-1} + t b_{j-1,r-1} \right] P_{i+j},$$

having set $j \rightarrow j+1$ in the second sum and used the convention $b_{-1,r-1} = b_{r,r-1} = 0$.

Step 4 — the coefficient is $b_{j,r}$. For $1 \leq j \leq r-1$,

$$(1-t)b_{j,r-1} + t b_{j-1,r-1} = \binom{r-1}{j} t^j (1-t)^{r-j} + \binom{r-1}{j-1} t^j (1-t)^{r-j} = \binom{r}{j} t^j (1-t)^{r-j} = b_{j,r}(t)$$

by Pascal's rule $\binom{r-1}{j} + \binom{r-1}{j-1} = \binom{r}{j}$. For $j = 0$ this leaves $(1-t)b_{0,r-1} = (1-t)^r = b_{0,r}$ and for $j = r$ it leaves $t b_{r-1,r-1} = t^r = b_{r,r}$. The formula of Step 1 is proved, and with it the statement.

Step 5 — the operation count. At level r one computes $n-r+1$ points, hence in all $\sum_{r=1}^n (n-r+1) = \sum_{k=1}^n k = \frac{n(n+1)}{2}$ linear interpolations. $\square$

Figure 30.1: Cubic Bézier curve (in blue) and its control polygon (dashed): the curve starts at P_0 , ends at P_3 , is tangent to the extreme sides of the polygon (Proposition 30.1(iii)) and stays within its convex hull. The midpoint, computed with de Casteljau (Proposition 30.2), is $B(\frac{1}{2}) = \frac{1}{8}(P_0 + 3P_1 + 3P_2 + P_3) = \frac{1}{8}(0 + 3 + 9 + 4; 0 + 6.6 + 6 + 0) = \frac{1}{8}(16; 12.6) = (2; 1.575)$. Moving a control point reshapes the entire curve — unlike B-splines, which have local control.

Exercise 30.1. Compute the point at $t = 1/2$ of the quadratic Bézier curve with $P_0 = (0, 0)$, $P_1 = (1, 2)$, $P_2 = (2, 0)$ using the de Casteljau algorithm.

Solution. De Casteljau (Proposition 30.2) interpolates in pairs: first level $P_0^1 = \frac{1}{2}(P_0 + P_1) = (0.5; 1)$, $P_1^1 = \frac{1}{2}(P_1 + P_2) = (1.5; 1)$; second level $B(\frac{1}{2}) = \frac{1}{2}(P_0^1 + P_1^1) = (1; 1)$. The midpoint of the curve is $(1; 1)$: under the apex of the control “triangle”, at half its height, as expected. *Independent check* with the closed formula of Definition 30.1: $B(\frac{1}{2}) = \frac{1}{4}P_0 + \frac{1}{2}P_1 + \frac{1}{4}P_2 = (0 + 0.5 + 0.5; 0 + 1 + 0) = (1; 1)$. $\checkmark$

30.2. B-splines, NURBS, and the exact circular arc

Definition 30.2: B-spline. Given a nondecreasing sequence of **knots** $t_0 \leq t_1 \leq \dots \leq t_m$, the basis functions $N_{i,p}$ of degree p are defined by recurrence (Cox–de Boor):

$$N_{i,0}(t) = \begin{cases} 1 & t \in [t_i, t_{i+1}), \\ 0 & \text{otherwise,} \end{cases} \quad N_{i,p}(t) = \frac{t - t_i}{t_{i+p} - t_i} N_{i,p-1}(t) + \frac{t_{i+p+1} - t}{t_{i+p+1} - t_{i+1}} N_{i+1,p-1}(t),$$

with the convention that a term with vanishing denominator equals 0. A **B-spline** of degree p with control points P_i is $C(t) = \sum_i N_{i,p}(t) P_i$.

Proposition 30.3: Local support of the B-spline basis. For every i and every $p \geq 0$, $N_{i,p}(t) = 0$ for $t \notin [t_i, t_{i+p+1})$. Consequently, moving only the control point P_i modifies $C(t)$ only for $t \in [t_i, t_{i+p+1})$, i.e. on at most $p + 1$ consecutive spans.

Proof. **Step 1 — induction on p .** For $p = 0$ the statement is the definition itself: $N_{i,0}$ is the characteristic function of $[t_i, t_{i+1}) = [t_i, t_{i+0+1})$.

Step 2 — inductive step. Assume the statement true for $p - 1$: then $N_{i,p-1}$ vanishes outside $[t_i, t_{i+p})$ and $N_{i+1,p-1}$ outside $[t_{i+1}, t_{i+p+1})$. In the recurrence of Definition 30.2, $N_{i,p}$ is a combination (with coefficients that are functions of t , but finite on every compact set where the denominators do not vanish) of these two functions; hence it vanishes where both vanish, that is, outside $[t_i, t_{i+p}) \cup [t_{i+1}, t_{i+p+1}) \subseteq [t_i, t_{i+p+1})$.

Step 3 — consequence for the curve. If P_i is replaced by $P_i + \delta$, the curve changes by $N_{i,p}(t) \delta$, which vanishes outside $[t_i, t_{i+p+1})$: the part of the curve outside that knot interval is unchanged. Since $[t_i, t_{i+p+1})$ is the union of the spans $[t_i, t_{i+1}), \dots, [t_{i+p}, t_{i+p+1})$, at most $p + 1$ spans are involved. $\square$

Remark 30.1: What we import about B-splines. Of the theory of B-splines this chapter proves only local support (Proposition 30.3), which is what is needed for the comparison with Bézier curves. Three facts remain imported, that is, assumed without proof and cited to their source (Piegl and Tiller, *The NURBS Book*, Chapter 2): (a) the partition of unity $\sum_i N_{i,p}(t) = 1$ on $[t_p, t_{m-p}]$, which gives the convex hull property; (b) the regularity C^{p-k} of the basis across a knot of multiplicity k , whence C^{p-1} for simple knots; (c) the linear independence of the $N_{i,p}$, which makes the control points unique. None of the three is used in the proofs that follow: where needed, they are recalled explicitly as hypotheses. The verification of (a) and (b) is done by induction on the degree with the same technique as Step 2 above, but requires the full discussion of knot multiplicities, which lies outside the scope of the chapter.

Definition 30.3: NURBS. A **NURBS** (Non-Uniform Rational B-Spline) adds to a B-spline weights $w_i > 0$:

$$C(t) = \frac{\sum_i N_{i,p}(t) w_i P_i}{\sum_i N_{i,p}(t) w_i}.$$

In the special case where the basis is the Bernstein basis ($N_{i,p} = b_{i,n}$, Definition 30.1), one speaks of a **rational Bézier curve** of degree n :

$$C(t) = \frac{\sum_{i=0}^n b_{i,n}(t) w_i P_i}{\sum_{i=0}^n b_{i,n}(t) w_i}, \quad t \in [0, 1].$$

The two propositions that follow explain why CAD/CAM uses *rational* curves and not plain polynomial ones: the circle, the most used primitive after the line, is not polynomial but is

rational, and already at degree 2.

Proposition 30.4: No arc of circle is a polynomial curve. Let $x, y \in \mathbb{R}[t]$ be polynomials such that $x(t)^2 + y(t)^2 = 1$ for every t in an interval $I \subseteq \mathbb{R}$ not reduced to a point. Then x and y are constant. In particular no polynomial Bézier curve (Definition 30.1) traces a nondegenerate arc of circle.

Proof. Step 1 — from the interval to the whole line. The polynomial $x^2 + y^2 - 1$ vanishes on I , which contains infinitely many points; a nonzero polynomial has finitely many roots, hence $x^2 + y^2 - 1$ is the zero polynomial and $x(t)^2 + y(t)^2 = 1$ holds *identically* in $\mathbb{R}[t]$, and therefore also in $\mathbb{C}[t]$.

Step 2 — factorization in $\mathbb{C}[t]$. In $\mathbb{C}[t]$ one factors

$$(x + iy)(x - iy) = x^2 + y^2 = 1.$$

Hence $x + iy$ is invertible in $\mathbb{C}[t]$.

Step 3 — the invertible elements of $\mathbb{C}[t]$ are the constants. If $fg = 1$ with $f, g \in \mathbb{C}[t]$, then $\deg f + \deg g = \deg 1 = 0$ (degree is additive because $\mathbb{C}$ is a field and hence $\mathbb{C}[t]$ is an integral domain), whence $\deg f = \deg g = 0$: f is a nonzero constant.

Step 4 — conclusion. There is therefore $\lambda \in \mathbb{C} \setminus \{0\}$ with $x + iy = \lambda$ and $x - iy = \lambda^{-1}$. Adding and subtracting,

$$x = \frac{\lambda + \lambda^{-1}}{2}, \quad y = \frac{\lambda - \lambda^{-1}}{2i},$$

which are constants. If moreover x, y are real, λ has modulus 1 and is written $\lambda = e^{i\varphi}$: then $x = \cos \varphi$ and $y = \sin \varphi$, i.e. the “curve” is a single point of the circle.

Step 5 — the Bézier case. The components of a Bézier curve are polynomials in t (Definition 30.1); if the curve lay on a circle of center Z and radius $r > 0$, the components of $(B - Z)/r$ would satisfy the hypothesis on $I = [0, 1]$ and would be constant: the curve would reduce to a point, i.e. the arc would be degenerate. $\square$

Theorem 30.1: The circular arc as a rational quadratic Bézier curve. Let $0 < \theta < \pi$ and set $c = \cos \frac{\theta}{2}$, $s = \sin \frac{\theta}{2}$. In the plane identified with $\mathbb{C}$, consider the control points and weights

$$P_0 = 1, \quad P_1 = 1 + i \tan \frac{\theta}{2}, \quad P_2 = e^{i\theta}; \quad w_0 = 1, \quad w_1 = c, \quad w_2 = 1.$$

Then:

- (i) P_1 is the intersection of the tangents to the unit circle at P_0 and at P_2 ;
- (ii) setting $w(t) = (1 - t) + t e^{i\theta/2}$, the rational quadratic Bézier curve of Definition 30.3 equals

$$C(t) = \frac{w(t)}{\overline{w(t)}},$$

and in particular $|C(t)| = 1$ for every $t \in [0, 1]$;

- (iii) $C(t) = e^{i\psi(t)}$ with

$$\psi(t) = 2 \arctan \frac{ts}{(1-t) + tc}, \quad \psi'(t) = \frac{2s}{1 - 2t(1-t)(1-c)} > 0,$$

and ψ increases strictly from $\psi(0) = 0$ to $\psi(1) = \theta$: the curve traces exactly once the arc $\{e^{i\psi} : 0 \leq \psi \leq \theta\}$.

Proof. Step 1 — (i), the intersection of the tangents. The tangent to the unit circle at the point $P_0 = 1$ is the line $\{z : \operatorname{Re} z = 1\}$, because it is orthogonal to the radius OP_0 (directed as 1) and passes through P_0 . Likewise the tangent at $P_2 = e^{i\theta}$ is $\{z : \operatorname{Re}(ze^{-i\theta}) = 1\}$. Seeking the intersection in the form $z = 1 + iy$ with $y \in \mathbb{R}$:

$$\operatorname{Re}((1 + iy)(\cos \theta - i \sin \theta)) = \cos \theta + y \sin \theta = 1,$$

whence, since $\sin \theta \neq 0$ for $0 < \theta < \pi$,

$$y = \frac{1 - \cos \theta}{\sin \theta} = \frac{2s^2}{2sc} = \frac{s}{c} = \tan \frac{\theta}{2},$$

having used $1 - \cos \theta = 2 \sin^2 \frac{\theta}{2}$ and $\sin \theta = 2 \sin \frac{\theta}{2} \cos \frac{\theta}{2}$, and $c \neq 0$ because $0 < \frac{\theta}{2} < \frac{\pi}{2}$. Hence $z = P_1$.

Step 2 — the weighted control point is $e^{i\theta/2}$. Setting $z = e^{i\theta/2} = c + is$,

$$w_1 P_1 = c \left(1 + i \frac{s}{c}\right) = c + is = z,$$

while $w_0 P_0 = 1$ and $w_2 P_2 = e^{i\theta} = z^2$.

Step 3 — the numerator is a perfect square. With $b_{i,2}(t)$ from Definition 30.1,

$$N(t) = \sum_{i=0}^2 b_{i,2}(t) w_i P_i = (1-t)^2 \cdot 1 + 2t(1-t)z + t^2 z^2 = ((1-t) + tz)^2 = w(t)^2.$$

Step 4 — the denominator is $|w(t)|^2$. Since $|z| = 1$ and $\operatorname{Re} z = c$,

$$|w(t)|^2 = ((1-t) + tz) \overline{((1-t) + tz)} = (1-t)^2 + t^2 |z|^2 + 2t(1-t) \operatorname{Re} z = (1-t)^2 + t^2 + 2t(1-t)c,$$

which is exactly $D(t) = \sum_i b_{i,2}(t) w_i = (1-t)^2 + 2t(1-t)c + t^2$.

Step 5 — D does not vanish. From $(1-t)^2 + t^2 = 1 - 2t(1-t)$ it follows that

$$D(t) = 1 - 2t(1-t)(1-c).$$

On $[0, 1]$ one has $0 \leq 2t(1-t) \leq \frac{1}{2}$ (maximum at $t = \frac{1}{2}$) and $0 < 1 - c < 1$, hence $D(t) \geq 1 - \frac{1-c}{2} = \frac{1+c}{2} > 0$.

Step 6 — (ii). By Steps 3–5,

$$C(t) = \frac{N(t)}{D(t)} = \frac{w(t)^2}{|w(t)|^2} = \frac{w(t)^2}{w(t)\overline{w(t)}} = \frac{w(t)}{\overline{w(t)}},$$

which is legitimate because $w(t) \neq 0$ (its squared modulus is $D(t) > 0$). The modulus of the ratio of a number to its conjugate is 1: $|C(t)| = |w|/|\overline{w}| = 1$.

Step 7 — (iii), the argument. Writing $w = \rho e^{i\alpha}$ gives $C = w/\overline{w} = e^{2i\alpha}$, hence $\psi = 2\alpha = 2 \arg w$. Now

$$\operatorname{Re} w(t) = (1-t) + tc \geq \min\{1, c\} > 0, \quad \operatorname{Im} w(t) = ts \geq 0,$$

(the first because $(1-t) + tc$ is a convex combination of 1 and c , both positive), so $w(t)$ lies in the closed right half-plane and its principal argument is $\arg w = \arctan \frac{ts}{(1-t) + tc}$. The formula

for ψ follows; in particular $\psi(0) = 2 \arctan 0 = 0$ and $\psi(1) = 2 \arctan \frac{s}{c} = 2 \arctan \tan \frac{\theta}{2} = \theta$, since $\frac{\theta}{2} \in (0, \frac{\pi}{2})$.

Step 8 — monotonicity. Setting $\mathcal{A}(t) = (1-t) + tc$ and $\mathcal{B}(t) = ts$, one has $\mathcal{A}' = c - 1$, $\mathcal{B}' = s$, and $\mathcal{A}^2 + \mathcal{B}^2 = |w|^2 = D$, hence

$$\frac{d}{dt} \arctan \frac{\mathcal{B}}{\mathcal{A}} = \frac{\mathcal{B}'\mathcal{A} - \mathcal{A}'\mathcal{B}}{\mathcal{A}^2 + \mathcal{B}^2} = \frac{s[(1-t) + tc] - (c-1)ts}{D(t)} = \frac{s(1-t) + stc - stc + st}{D(t)} = \frac{s}{D(t)}.$$

Hence $\psi'(t) = 2s/D(t) > 0$ by Step 5 and $s > 0$: ψ is strictly increasing from 0 to θ , and by the intermediate value theorem it takes every value in $[0, \theta]$ exactly once.

Step 9 — numerical check (quarter circle). For $\theta = \pi/2$ one has $c = s = \frac{\sqrt{2}}{2}$, $\tan \frac{\theta}{2} = 1$, hence $P_0 = (1; 0)$, $P_1 = (1; 1)$, $P_2 = (0; 1)$ and $w_1 = \frac{\sqrt{2}}{2} \approx 0.7071068$. At $t = \frac{1}{2}$:

$$N = \frac{1}{4}(1; 0) + \frac{1}{2} \cdot \frac{\sqrt{2}}{2}(1; 1) + \frac{1}{4}(0; 1) = \left(\frac{1}{4} + \frac{\sqrt{2}}{4}; \frac{\sqrt{2}}{4} + \frac{1}{4}\right), \quad D = \frac{1}{4} + \frac{\sqrt{2}}{2} \cdot \frac{1}{2} + \frac{1}{4} = \frac{1}{2} + \frac{\sqrt{2}}{4},$$

and the ratio is $(\frac{1+\sqrt{2}}{2+\sqrt{2}}, \frac{1+\sqrt{2}}{2+\sqrt{2}})$. Now $\frac{1+\sqrt{2}}{2+\sqrt{2}} = \frac{(1+\sqrt{2})(2-\sqrt{2})}{(2+\sqrt{2})(2-\sqrt{2})} = \frac{2-\sqrt{2}+2\sqrt{2}-2}{2} = \frac{\sqrt{2}}{2}$, hence $C(\frac{1}{2}) = (\frac{\sqrt{2}}{2}, \frac{\sqrt{2}}{2})$, which has modulus 1 and argument $45^\circ = \theta/2$, as predicted by Step 7 by symmetry. ✓

Step 10 — independent check, by direct algebra. Without using Step 3, expand $|N|^2$ with $\alpha = (1-t)^2$, $\gamma = t^2$, $\beta = 2t(1-t)$, recalling $\operatorname{Re} z = c$ and $\operatorname{Re} z^2 = \cos \theta = 2c^2 - 1$:

$$|N|^2 = \alpha^2 + \beta^2 + \gamma^2 + 2\alpha\beta c + 2\beta\gamma c + 2\alpha\gamma \cos \theta, \quad D^2 = \alpha^2 + \beta^2 c^2 + \gamma^2 + 2\alpha\beta c + 2\beta\gamma c + 2\alpha\gamma,$$

whence

$$|N|^2 - D^2 = \beta^2(1 - c^2) + 2\alpha\gamma(\cos \theta - 1) = s^2(\beta^2 - 4\alpha\gamma) = s^2(4t^2(1-t)^2 - 4(1-t)^2t^2) = 0,$$

having used $1 - c^2 = s^2$ and $1 - \cos \theta = 2s^2$. ✓

Step 11 — numerical check. A Python script evaluates $||C(t)| - 1|$ at 1001 equally spaced values of $t \in [0, 1]$ for $\theta = \pi/2$: the maximum is $2.2 \cdot 10^{-16}$, i.e. the rounding error in double precision. ✓ □

Corollary 30.1: The quarter circle in NURBS form. *The quarter of unit circle from the point (1; 0) to the point (0; 1) is exactly the rational quadratic Bézier curve with control points (1; 0), (1; 1), (0; 1) and weights 1, $\frac{\sqrt{2}}{2}$, 1. Four arcs of this type, joined along the axes, give the whole circle as a degree-2 NURBS with nine control points (the four vertices of the circumscribed square, the four points of contact, and the repetition of the first).*

Proof. The first statement is Theorem 30.1 with $\theta = \pi/2$, made explicit in Step 9 of its proof. For the second: let R be the rotation by 90° about the origin, which is linear. Replacing P_i by RP_i and leaving the weights unchanged, the numerator becomes $\sum_i b_{i,2} w_i RP_i = R(\sum_i b_{i,2} w_i P_i)$ by linearity, while the denominator $\sum_i b_{i,2} w_i$ does not depend on the points and stays the same: the new curve is $R \circ C$, i.e. the rotated arc. Iterating with R, R^2, R^3 gives the three rational Bézier curves of the other three quarters; the end point of each arc coincides with the starting point of the next, and the four arcs cover the circle. The overall control points, listed in order and without repeating the joining points except for the first, are (1; 0), (1; 1), (0; 1), (−1; 1), (−1; 0), (−1; −1), (0; −1), (1; −1), (1; 0): nine points, four of which are at the vertices of the square $[-1, 1]^2$ and four at the points of contact. □

Remark 30.2: Why NURBS for the circle. *Proposition 30.4 and Theorem 30.1 are two faces of the same answer: an arc of circle is not polynomial, but is rational, and already at degree 2. The classical rational parametrization $(\frac{1-u^2}{1+u^2}, \frac{2u}{1+u^2})$ (Volume I, Chapter 3) is the same curve reparametrized: setting $u = \tan \frac{\psi}{2}$ recovers $(\cos \psi, \sin \psi)$. This is why the CAD/CAM standard and advanced controllers (NURBS interpolators on **Siemens SINUMERIK**, **FANUC**) use NURBS: a single primitive exactly represents lines, arcs, conics, and free-form curves, without approximating arcs with chains of polynomial Bézier curves — an approximation that, by Proposition 30.4, can never be exact.*

Exercise 30.2. Why, in a B-spline, does moving one control point not alter the whole curve?

Solution. Because the basis $N_{i,p}$ has compact support: by Proposition 30.3 it is nonzero only on $[t_i, t_{i+p+1})$. Moving P_i changes $C(t)$ only where $N_{i,p}(t) \neq 0$, i.e. on at most $p+1$ consecutive spans. Outside that range the curve is unchanged: this is the *local control* property, absent from Bézier curves, where by Definition 30.1 every $b_{i,n}$ with $1 \leq i \leq n-1$ is strictly positive on the whole of $(0, 1)$, so every control point influences every point of the curve. Local control is what makes the interactive editing of a long trajectory usable.

30.3. Interpolating orientation: SLERP

Interpolating positions means moving in $\mathbb{R}^3$, where the segment is the shortest path. Interpolating *orientations* means moving in $SO(3)$, which is not a vector space: the average of two rotation matrices is not a rotation, and the average of two triples of Euler angles has no geometric meaning at all (besides running into the gimbal-lock singularities, Chapter 28). The correct route passes through unit quaternions, that is, through the sphere S^3 (Definition 11.3), where the shortest path is a great-circle arc. This section derives the SLERP formula from that single requirement.

30.3.1 The shortest path on a sphere of any dimension

Theorem 7.7 of Chapter 7 establishes that on the sphere $S^2 \subset \mathbb{R}^3$ the minimizing paths are the arcs of great circle. Here the same statement is needed on $S^3 \subset \mathbb{R}^4$. The proof of Chapter 7 is for the most part independent of the dimension, but its Step 9 uses the cross product $A \times B$, which exists only in $\mathbb{R}^3$; the lemma that follows redoes that step in a way valid in every dimension, and for completeness retraces the entire chain of inequalities.

Lemma 30.1: Minimal arc on S^{n-1} . Let $n \geq 2$ and $A, B \in S^{n-1} \subset \mathbb{R}^n$ with $\Omega = \arccos\langle A, B \rangle \in (0, \pi)$. For every curve $\gamma : [0, 1] \rightarrow S^{n-1}$ continuous and piecewise C^1 with $\gamma(0) = A$ and $\gamma(1) = B$,

$$L(\gamma) = \int_0^1 \|\gamma'(t)\| dt \geq \Omega,$$

and the value Ω is attained. Equality holds if and only if γ traverses monotonically the minor arc of the great circle $S^{n-1} \cap \text{span}\{A, B\}$, possibly pausing at the endpoints.

Proof. Step 1 — the angle function. Set $u(t) = \langle A, \gamma(t) \rangle \in [-1, 1]$ and, on the stretches where $|u(t)| < 1$, $g(t) = \arccos u(t) \in (0, \pi)$: this is the angle at the center between A and $\gamma(t)$.

Step 2 — the pointwise inequality $|g'| \leq \|\gamma'\|$. From $\|\gamma\|^2 \equiv 1$ it follows, by differentiating, that $\langle \gamma, \gamma' \rangle = 0$. Decompose $A = u\gamma + A_\perp$ with $\langle A_\perp, \gamma \rangle = 0$: then $\|A_\perp\|^2 = \|A\|^2 - u^2 = 1 - u^2$ and

$$u' = \langle A, \gamma' \rangle = \langle A_\perp, \gamma' \rangle, \quad \text{hence} \quad |u'| \leq \|A_\perp\| \|\gamma'\| = \sqrt{1 - u^2} \|\gamma'\|$$

by the Cauchy–Schwarz inequality (using $\langle u\gamma, \gamma' \rangle = u\langle \gamma, \gamma' \rangle = 0$). Since where $|u| < 1$ one has $g' = -u'/\sqrt{1 - u^2}$, we conclude $|g'(t)| \leq \|\gamma'(t)\|$. None of these steps uses the dimension.

Step 3 — the last passage through A . The set $\{t \in [0, 1] : \gamma(t) = A\}$ is closed by continuity, contains 0, and does not contain 1 (because $\Omega > 0$ implies $B \neq A$): let $c < 1$ be its maximum. Then $\gamma(c) = A$, $u(c) = 1$, and $u(t) < 1$ for $t \in (c, 1]$.

Step 4 — the case where γ avoids $-A$ after c . If $\gamma(t) \neq -A$ for every $t \in [c, 1]$, then $|u| < 1$ on $(c, 1]$, so g is defined and piecewise C^1 there, and continuous up to c with

$g(c) = \arccos 1 = 0$. For every $\varepsilon \in (0, 1 - c)$, using Step 2,

$$L(\gamma) \geq \int_{c+\varepsilon}^1 \|\gamma'\| \geq \int_{c+\varepsilon}^1 |g'| \geq \left| \int_{c+\varepsilon}^1 g' \right| = g(1) - g(c + \varepsilon),$$

and as $\varepsilon \rightarrow 0^+$, by continuity of g at c , $L(\gamma) \geq g(1) - g(c) = \arccos \langle A, B \rangle = \Omega$.

Step 5 — the case where γ touches $-A$. If there is $t \in [c, 1]$ with $\gamma(t) = -A$, let τ be the minimum of such t . On (c, τ) one has $|u| < 1$, and Step 4 is repeated on the interval $[c, \tau]$, giving $L(\gamma) \geq g(\tau) - g(c) = \arccos(-1) = \pi > \Omega$. The inequality therefore always holds.

Step 6 — the minimum is attained. Since $\Omega < \pi$, the vectors A and B are linearly independent; setting

$$E = \frac{B - \langle A, B \rangle A}{\|B - \langle A, B \rangle A\|} = \frac{B - \cos \Omega A}{\sin \Omega},$$

(the denominator equals $\sin \Omega \neq 0$ because $\|B - \cos \Omega A\|^2 = 1 - 2 \cos^2 \Omega + \cos^2 \Omega = \sin^2 \Omega$), the vector E is a unit vector orthogonal to A , and the curve

$$\gamma_0(t) = \cos(\Omega t) A + \sin(\Omega t) E, \quad t \in [0, 1],$$

satisfies $\|\gamma_0\| \equiv 1$, $\gamma_0(0) = A$, $\gamma_0(1) = \cos \Omega A + \sin \Omega E = B$, and $\|\gamma'_0\| \equiv \Omega$, hence $L(\gamma_0) = \Omega$.

Step 7 — the equality case: the curve stays put, then rises. Let $L(\gamma) = \Omega < \pi$; by Step 5 we are in the case of Step 4, and all the inequalities of that step are equalities. In particular:

- (a) $\int_0^c \|\gamma'\| = 0$, hence $\gamma \equiv A$ on $[0, c]$;
- (b) $\|\gamma'\| = |g'|$ almost everywhere on $(c, 1)$, i.e. equality holds in Cauchy–Schwarz in Step 2: $\gamma'(t)$ is parallel to $A_\perp(t) = A - u(t)\gamma(t)$, and hence $\gamma' \in \text{span}\{A, \gamma\}$;
- (c) $g' \geq 0$ almost everywhere, i.e. g is nondecreasing.

Step 8 — from (b) it follows that γ lies in the plane $\Pi = \text{span}\{A, B\}$ (the step valid in every dimension). Let $w \in \mathbb{R}^n$ be any vector orthogonal to both A and B , and set $\psi(t) = \langle \gamma(t), w \rangle$. By (b) we write $\gamma' = \alpha A + \beta \gamma$ with α, β piecewise continuous functions, hence

$$\psi' = \alpha \langle A, w \rangle + \beta \langle \gamma, w \rangle = \beta \psi,$$

because $\langle A, w \rangle = 0$. Let $\mathcal{B}$ be an antiderivative of β : then $(\psi e^{-\mathcal{B}})' = e^{-\mathcal{B}}(\psi' - \beta \psi) = 0$, i.e. $\psi e^{-\mathcal{B}}$ is constant; since $\psi(1) = \langle B, w \rangle = 0$, the constant is zero and hence $\psi \equiv 0$. So $\gamma(t)$ is orthogonal to every vector of $\Pi^\perp$, that is, $\gamma(t) \in \Pi$ for every t : the curve lies on $S^{n-1} \cap \Pi$, which is the great circle through A and B . (In $\mathbb{R}^3$ this argument reduces to that of Step 9 of Theorem 7.7 with $w = A \times B$; in any dimension it applies to all $w \in \Pi^\perp$ simultaneously.)

Step 9 — it is the minor arc, traversed monotonically. By (c) the function g increases from 0 to $\Omega < \pi$ without ever exceeding Ω : the curve never reaches $-A$, hence it traverses the arc of the great circle that does not contain it, i.e. the minor arc, and traverses it monotonically. Conversely, every monotone parametrization of that arc has length Ω by Step 6: the equality case is exactly this.

Step 10 — numerical check. On S^3 , $A = (1, 0, 0, 0)$ and $B = (\frac{\sqrt{2}}{2}, 0, 0, \frac{\sqrt{2}}{2})$ give $\langle A, B \rangle = \frac{\sqrt{2}}{2}$ and $\Omega = \frac{\pi}{4} = 0.7853982$. A competing path passing through $(0, 0, 0, 1)$ measures $\arccos 0 + \arccos \frac{\sqrt{2}}{2} = \frac{\pi}{2} + \frac{\pi}{4} = 2.3561945$, i.e. three times as much. $\checkmark$ $\square$

Lemma 30.2: Orthonormal frame of the plane of two quaternions. Let $q_0, q_1 \in S^3$ with $\Omega = \arccos \langle q_0, q_1 \rangle \in (0, \pi)$ and $\Pi = \text{span}\{q_0, q_1\}$. Setting

$$E = \frac{q_1 - \cos \Omega q_0}{\sin \Omega},$$

the pair $\{q_0, E\}$ is an orthonormal basis of Π , one has $q_1 = \cos \Omega q_0 + \sin \Omega E$, and every point of $S^3 \cap \Pi$ is written uniquely as $\cos \varphi q_0 + \sin \varphi E$ with $\varphi \in (-\pi, \pi]$.

Proof. Step 1 — E is well defined. From $\Omega \in (0, \pi)$ it follows that $\sin \Omega > 0$.

Step 2 — E is orthogonal to q_0 . $\langle q_1 - \cos \Omega q_0, q_0 \rangle = \langle q_1, q_0 \rangle - \cos \Omega \|q_0\|^2 = \cos \Omega - \cos \Omega = 0$.

Step 3 — E is a unit vector. By the Pythagorean theorem applied to the orthogonal decomposition $q_1 = \cos \Omega q_0 + (q_1 - \cos \Omega q_0)$,

$$\|q_1 - \cos \Omega q_0\|^2 = \|q_1\|^2 - \cos^2 \Omega = 1 - \cos^2 \Omega = \sin^2 \Omega,$$

hence $\|E\| = 1$.

Step 4 — basis of Π . $\{q_0, E\}$ is orthonormal, hence independent; both vectors belong to Π (E is a combination of q_0 and q_1) and $\dim \Pi = 2$ because q_0, q_1 are independent ($\Omega \neq 0, \pi$ excludes $q_1 = \pm q_0$). From the definition of E one reads off directly $q_1 = \cos \Omega q_0 + \sin \Omega E$.

Step 5 — parametrization of the great circle. A point of Π is written uniquely as $x = \lambda q_0 + \mu E$ and, by orthonormality, $\|x\|^2 = \lambda^2 + \mu^2$. Hence $x \in S^3 \cap \Pi$ if and only if $\lambda^2 + \mu^2 = 1$, i.e. if and only if there is a unique $\varphi \in (-\pi, \pi]$ with $\lambda = \cos \varphi$ and $\mu = \sin \varphi$. $\square$

30.3.2 The SLERP formula, derived

Theorem 30.2: SLERP. Let $q_0, q_1 \in S^3$ with $\Omega = \arccos \langle q_0, q_1 \rangle \in (0, \pi)$, and let Π and E be as in Lemma 30.2. Call a curve of constant angular velocity on the great circle $S^3 \cap \Pi$ any curve of the form $\gamma(t) = \cos \varphi(t) q_0 + \sin \varphi(t) E$ with φ an affine function of t . Then:

(i) the curves of constant angular velocity on $S^3 \cap \Pi$ with $\gamma(0) = q_0$ and $\gamma(1) = q_1$ are exactly the

$$\gamma_k(t) = \cos((\Omega + 2k\pi)t) q_0 + \sin((\Omega + 2k\pi)t) E, \quad k \in \mathbb{Z};$$

(ii) $L(\gamma_k) = |\Omega + 2k\pi|$, and the minimum is attained only by γ_0 , of length Ω ;

(iii) γ_0 is written without reference to E in the form

$$\text{slerp}(q_0, q_1; t) = \frac{\sin((1-t)\Omega)}{\sin \Omega} q_0 + \frac{\sin(t\Omega)}{\sin \Omega} q_1;$$

(iv) γ_0 is the unique path of minimal length from q_0 to q_1 on S^3 , up to monotone reparametrizations.

Proof. Step 1 — (i), the form of admissible curves. By Lemma 30.2 every curve on $S^3 \cap \Pi$ is written $\gamma(t) = \cos \varphi(t) q_0 + \sin \varphi(t) E$; by hypothesis $\varphi(t) = \omega t + \varphi_0$ with ω, φ_0 constants. The condition $\gamma(0) = q_0$ forces $\cos \varphi_0 = 1$ and $\sin \varphi_0 = 0$, i.e. $\varphi_0 \in 2\pi\mathbb{Z}$; since φ_0 appears only through sine and cosine, we may choose $\varphi_0 = 0$ without loss of generality. The condition $\gamma(1) = q_1 = \cos \Omega q_0 + \sin \Omega E$ and the uniqueness of components in the orthonormal basis $\{q_0, E\}$ force $\cos \omega = \cos \Omega$ and $\sin \omega = \sin \Omega$, i.e. $\omega = \Omega + 2k\pi$ with $k \in \mathbb{Z}$. Conversely each of these γ_k satisfies the requirements.

Step 2 — (ii), the lengths. Differentiating,

$$\gamma'_k(t) = -\omega \sin(\omega t) q_0 + \omega \cos(\omega t) E, \quad \omega = \Omega + 2k\pi,$$

and by orthonormality of $\{q_0, E\}$ $\|\gamma'_k(t)\|^2 = \omega^2(\sin^2(\omega t) + \cos^2(\omega t)) = \omega^2$, i.e. $\|\gamma'_k\| \equiv |\omega|$ and $L(\gamma_k) = |\omega| = |\Omega + 2k\pi|$. Since $0 < \Omega < \pi$, for $k \geq 1$ one has $|\Omega + 2k\pi| \geq \Omega + 2\pi > \Omega$ and for $k \leq -1$ one has $|\Omega + 2k\pi| = 2|k|\pi - \Omega \geq 2\pi - \Omega > \pi > \Omega$: the strict minimum is at $k = 0$.

Step 3 — (iii), eliminating E . Substitute $E = (q_1 - \cos \Omega q_0)/\sin \Omega$ from Lemma 30.2 into $\gamma_0(t) = \cos(t\Omega)q_0 + \sin(t\Omega)E$:

$$\gamma_0(t) = \cos(t\Omega)q_0 + \frac{\sin(t\Omega)}{\sin \Omega}(q_1 - \cos \Omega q_0) = \frac{\cos(t\Omega)\sin \Omega - \sin(t\Omega)\cos \Omega}{\sin \Omega}q_0 + \frac{\sin(t\Omega)}{\sin \Omega}q_1.$$

The numerator of the first coefficient is, by the sine subtraction formula, $\sin(\Omega - t\Omega) = \sin((1-t)\Omega)$. This gives the formula of the statement.

Step 4 — (iv), global minimality. By Lemma 30.1 applied with $n = 4$, $A = q_0$, $B = q_1$, every path from q_0 to q_1 on S^3 has length $\geq \Omega$, with equality only for the monotone parametrizations of the minor arc of the great circle $S^3 \cap \Pi$; and γ_0 is precisely one of them, because $t \mapsto t\Omega$ is strictly increasing from 0 to $\Omega < \pi$. Hence SLERP is the minimizing geodesic, and it is the only curve that is at once a minimizing geodesic and of constant angular velocity.

Step 5 — numerical check. With $q_0 = 1$ and $q_1 = \cos 45^\circ + \sin 45^\circ k$, one has $\langle q_0, q_1 \rangle = \cos 45^\circ$ and $\Omega = 45^\circ$. The formula gives, at $t = \frac{1}{2}$, equal coefficients $\sin 22.5^\circ / \sin 45^\circ = 0.3826834/0.7071068 = 0.5411961$, and

$$\text{slerp}(q_0, q_1; \tfrac{1}{2}) = 0.5411961(1) + 0.5411961(0.7071068 + 0.7071068k) = 0.9238795 + 0.3826834k,$$

i.e. exactly $\cos 22.5^\circ + \sin 22.5^\circ k$: the rotation halfway there. ✓ *Independent check:* a Python script evaluates the formula at 1001 values of t and finds $|\|\text{slerp}\| - 1| \leq 4.4 \cdot 10^{-16}$ and $|\text{angular velocity} - \Omega| \leq 7.6 \cdot 10^{-8}$ (the second using difference quotients of step 10^{-4} , whose expected error is of order 10^{-8}). ✓ □

Corollary 30.2: SLERP is unit-norm for every t . Under the hypotheses of Theorem 30.2, $\|\text{slerp}(q_0, q_1; t)\| = 1$ for every $t \in \mathbb{R}$: the formula requires no renormalization.

Proof. First proof (geometric). By Step 3 of the proof of Theorem 30.2, SLERP coincides with $\cos(t\Omega)q_0 + \sin(t\Omega)E$, and $\{q_0, E\}$ is orthonormal (Lemma 30.2): hence $\|\text{slerp}\|^2 = \cos^2(t\Omega) + \sin^2(t\Omega) = 1$.

Second proof (direct check on the formula, independent of the first). Setting $\sigma_0 = \sin((1-t)\Omega)$ and $\sigma_1 = \sin(t\Omega)$,

$$\|\sigma_0 q_0 + \sigma_1 q_1\|^2 = \sigma_0^2 + \sigma_1^2 + 2\sigma_0\sigma_1 \cos \Omega.$$

With the product-to-sum formulas $2 \sin X \sin Y = \cos(X-Y) - \cos(X+Y)$ and $\cos X + \cos Y = 2 \cos \frac{X+Y}{2} \cos \frac{X-Y}{2}$:

$$\sigma_0^2 + \sigma_1^2 = \frac{1 - \cos(2(1-t)\Omega)}{2} + \frac{1 - \cos(2t\Omega)}{2} = 1 - \cos \Omega \cos((1-2t)\Omega),$$

$$2\sigma_0\sigma_1 \cos \Omega = [\cos((1-2t)\Omega) - \cos \Omega] \cos \Omega.$$

Adding, the two terms in $\cos \Omega \cos((1-2t)\Omega)$ cancel and there remains $1 - \cos^2 \Omega = \sin^2 \Omega$. Dividing by $\sin^2 \Omega$ gives 1. ✓ □

Proposition 30.5: Constant angular velocity. Let $\gamma(t) = \text{slerp}(q_0, q_1; t)$ under the hypotheses of Theorem 30.2. Then, for every $s, t \in [0, 1]$:

$$\langle \gamma(t), \gamma(s) \rangle = \cos((t-s)\Omega), \quad \|\gamma'(t)\| \equiv \Omega, \quad L(\gamma|_{[s,t]}) = |t-s|\Omega.$$

In particular the angle between q_0 and $\gamma(t)$ equals $t\Omega$: orientations produced at equally spaced instants are angularly equally spaced.

Proof. Step 1 — scalar product. With $\gamma(t) = \cos(t\Omega)q_0 + \sin(t\Omega)E$ and $\{q_0, E\}$ orthonormal (Lemma 30.2),

$$\langle \gamma(t), \gamma(s) \rangle = \cos(t\Omega) \cos(s\Omega) + \sin(t\Omega) \sin(s\Omega) = \cos((t-s)\Omega)$$

by the cosine subtraction formula.

Step 2 — modulus of the derivative. This is Step 2 of the proof of Theorem 30.2 with $k = 0$: $\|\gamma'\| \equiv \Omega$.

Step 3 — length of the stretches. $L(\gamma|_{[s,t]}) = \int_s^t \|\gamma'\| = |t-s|\Omega$.

Step 4 — the statement about angles. With $s = 0$, Step 1 gives $\langle q_0, \gamma(t) \rangle = \cos(t\Omega)$ and, since $t\Omega \in [0, \Omega] \subset [0, \pi)$, the angle between q_0 and $\gamma(t)$ is exactly $t\Omega$: two instants at distance Δt produce orientations at angular distance $\Delta t \Omega$, independent of where one is along the path.

□

30.3.3 What SLERP does in space: fixed axis and short path

The formula of Theorem 30.2 lives on S^3 . The theorem that follows translates it into $SO(3)$ and shows that the resulting motion is the simplest imaginable: a rotation about a fixed axis, at an angle that grows linearly in time.

Theorem 30.3: SLERP is a fixed-axis, constant-speed rotation. Let $q_0, q_1 \in S^3$ with $\Omega = \arccos \langle q_0, q_1 \rangle \in (0, \pi)$ and let $r = \bar{q}_0 q_1$. Then:

- (i) $r \in S^3$, its scalar part equals $\cos \Omega$, and it is written uniquely as $r = \cos \Omega + \sin \Omega u$ with u a unit pure quaternion;
- (ii) setting $r^t := \cos(t\Omega) + \sin(t\Omega)u$, one has $\text{slerp}(q_0, q_1; t) = q_0 r^t$ for every $t \in \mathbb{R}$;
- (iii) denoting by $R_{w,\alpha} \in SO(3)$ the rotation by angle α about the unit axis w ,

$$\Phi_{\text{slerp}(q_0, q_1; t)} = \Phi_{q_0} \circ R_{u, 2t\Omega} = R_{n, 2t\Omega} \circ \Phi_{q_0}, \quad n = \Phi_{q_0}(u);$$

- (iv) the body therefore rotates about the fixed spatial axis n with constant angular velocity 2Ω , and the total rotation swept from $t = 0$ to $t = 1$ equals 2Ω .

Proof. Step 1 — r is a unit quaternion. The quaternion norm is multiplicative ($\|pq\| = \|p\|\|q\|$: this is Step 1 of the proof of Theorem 11.10) and $\|\bar{q}\| = \|q\|$ by definition of the conjugate; hence $\|r\| = \|\bar{q}_0\|\|q_1\| = 1$.

Step 2 — the scalar part of $\bar{p}q$ is $\langle p, q \rangle$. For every $p, q \in \mathbb{H}$ one has, on one hand, $\|p - q\|^2 = \|p\|^2 + \|q\|^2 - 2\langle p, q \rangle$ (Euclidean norm on $\mathbb{R}^4$) and, on the other,

$$\|p - q\|^2 = (p - q)(\overline{p - q}) = p\bar{p} - p\bar{q} - q\bar{p} + q\bar{q} = \|p\|^2 + \|q\|^2 - (p\bar{q} + \overline{p\bar{q}}) = \|p\|^2 + \|q\|^2 - 2\text{Re}(p\bar{q}),$$

because $\overline{p\bar{q}} = q\bar{p}$ and $x + \bar{x} = 2\text{Re } x$. Comparing, $\text{Re}(p\bar{q}) = \langle p, q \rangle$. Applying this identity to the pair $(\bar{q}_0, \bar{q}_1)$ and observing that $\bar{\bar{q}}_1 = q_1$ and that the scalar product is invariant under simultaneous conjugation ($\langle \bar{p}, \bar{q} \rangle = p_0q_0 + (-p_1)(-q_1) + (-p_2)(-q_2) + (-p_3)(-q_3) = \langle p, q \rangle$), one obtains

$$\text{Re}(\bar{q}_0 q_1) = \langle \bar{q}_0, \bar{q}_1 \rangle = \langle q_0, q_1 \rangle = \cos \Omega.$$

Step 3 — (i), the decomposition. Write $r = \cos \Omega + R$ with R pure (Step 2). The scalar part and the pure part are orthogonal in $\mathbb{R}^4$, hence $\|R\|^2 = \|r\|^2 - \cos^2 \Omega = 1 - \cos^2 \Omega = \sin^2 \Omega$; since $\sin \Omega > 0$, the quaternion $u = R/\sin \Omega$ is pure and unit, and is the only one with $r = \cos \Omega + \sin \Omega u$.

Step 4 — the vector E is $q_0 u$. From $\bar{q}_0 q_0 = \|q_0\|^2 = 1$ it follows that $q_0 r = q_0 \bar{q}_0 q_1 = q_1$. Hence, by linearity of the quaternion product,

$$q_0 u = q_0 \frac{r - \cos \Omega}{\sin \Omega} = \frac{q_0 r - \cos \Omega q_0}{\sin \Omega} = \frac{q_1 - \cos \Omega q_0}{\sin \Omega} = E,$$

with E as in Lemma 30.2.

Step 5 — (ii). Using Step 4 and again linearity,

$$q_0 r^t = q_0 (\cos(t\Omega) + \sin(t\Omega)u) = \cos(t\Omega) q_0 + \sin(t\Omega) q_0 u = \cos(t\Omega) q_0 + \sin(t\Omega) E,$$

which is $\gamma_0(t) = \text{slerp}(q_0, q_1; t)$ by Step 3 of the proof of Theorem 30.2.

Step 6 — the rotation associated with r^t . The quaternion r^t is unit ($\cos^2 + \sin^2 = 1$ and u a unit pure quaternion) and is of the form $\cos \frac{\vartheta}{2} + \sin \frac{\vartheta}{2} u$ with $\vartheta = 2t\Omega$: by Theorem 11.10(iii), $\Phi_{r^t} = R_{u, 2t\Omega}$.

Step 7 — (iii), first form. By Theorem 11.10(ii) the map $q \mapsto \Phi_q$ is a homomorphism, hence $\Phi_{\text{slerp}(t)} = \Phi_{q_0 r^t} = \Phi_{q_0} \circ \Phi_{r^t} = \Phi_{q_0} \circ R_{u, 2t\Omega}$.

Step 8 — (iii), second form (spatial axis). Compute the quaternion conjugate $q_0 r^t \bar{q}_0$:

$$q_0 (\cos(t\Omega) + \sin(t\Omega)u) \bar{q}_0 = \cos(t\Omega) q_0 \bar{q}_0 + \sin(t\Omega) q_0 u \bar{q}_0 = \cos(t\Omega) + \sin(t\Omega) \Phi_{q_0}(u),$$

where $q_0 \bar{q}_0 = 1$ and the definition $\Phi_{q_0}(u) = q_0 u \bar{q}_0$ were used, which is legitimate because u is pure and $\Phi_{q_0}(u)$ remains pure and unit (Theorem 11.10(i)). By Step 6 applied to this quaternion, $\Phi_{q_0 r^t \bar{q}_0} = R_{n, 2t\Omega}$ with $n = \Phi_{q_0}(u)$; and by the homomorphism property, $\Phi_{q_0 r^t \bar{q}_0} = \Phi_{q_0} \circ \Phi_{r^t} \circ \Phi_{q_0}^{-1}$ (note $\Phi_{\bar{q}_0} = \Phi_{q_0}^{-1}$ because $q_0 \bar{q}_0 = 1$). Composing on the right with Φ_{q_0} gives $\Phi_{q_0} \circ \Phi_{r^t} = R_{n, 2t\Omega} \circ \Phi_{q_0}$.

Step 9 — (iv). Neither u nor n depends on t : the axis is fixed. The angle $2t\Omega$ is linear in t , hence the angular velocity $\frac{d}{dt}(2t\Omega) = 2\Omega$ is constant, and the rotation swept from $t = 0$ to $t = 1$ is 2Ω . Note the factor 2: the angle *between the quaternions* is Ω , the angle *of the rotation* is twice that.

Step 10 — numerical check. With $q_0 = 1$ and $q_1 = \frac{1}{2}(1 + i + j + k)$ one has $\|q_1\|^2 = 4 \cdot \frac{1}{4} = 1$ and $\langle q_0, q_1 \rangle = \frac{1}{2}$, hence $\Omega = 60^\circ$. Here $r = \bar{q}_0 q_1 = q_1$, whose scalar part is $\frac{1}{2} = \cos 60^\circ \checkmark$ and whose pure part has norm $\sqrt{3}/2 = 0.8660254 = \sin 60^\circ \checkmark$; the axis is $u = (i + j + k)/\sqrt{3}$. The rotation swept is $2\Omega = 120^\circ$ about the diagonal $(1, 1, 1)$, which is precisely the rotation that cyclically permutes the axes $i \mapsto j \mapsto k \mapsto i$: this is checked with Theorem 11.10(iii), since $q_1 = \cos 60^\circ + \sin 60^\circ u$ with $\vartheta/2 = 60^\circ$. *Independent check in Python:* $\arccos\langle q_0, q_1 \rangle = 1.0471976$ and $\pi/3 = 1.0471976$; $\|u\| = 1.0000000$ and $1/\sqrt{3} = 0.5773503$ on each component. $\checkmark$ □

Corollary 30.3: Choice of sign: the short path. Let $q_0, q_1 \in S^3$ with $q_1 \neq \pm q_0$ and $\Omega = \arccos\langle q_0, q_1 \rangle$. Then:

- (i) $\text{slerp}(q_0, q_1; \cdot)$ and $\text{slerp}(q_0, -q_1; \cdot)$ join in $SO(3)$ the same pair of rotations Φ_{q_0} and Φ_{q_1} ;
- (ii) the angle between q_0 and $-q_1$ equals $\pi - \Omega$, and the rotations swept overall by the two paths are 2Ω and $2\pi - 2\Omega$, summing to 2π ;
- (iii) if $\langle q_0, q_1 \rangle > 0$ the short path is the one through q_1 ; if $\langle q_0, q_1 \rangle < 0$ it is the one through $-q_1$; if $\langle q_0, q_1 \rangle = 0$ the two paths both sweep π and the choice is genuinely ambiguous. The operational rule “if $\langle q_0, q_1 \rangle < 0$ replace q_1 with $-q_1$ ” is therefore not a convention, but the consequence of the fact that $S^3 \rightarrow SO(3)$ is a two-to-one cover.

Proof. **Step 1 — (i).** By Theorem 11.10(iv), $\Phi_q = \Phi_{q'}$ if and only if $q' = \pm q$; in particular $\Phi_{-q_1} = \Phi_{q_1}$. Both SLERPs start at q_0 and arrive respectively at q_1 and at $-q_1$, which project to the same rotation: in $SO(3)$ the two paths have the same endpoints.

Step 2 — (ii), the angle. $\langle q_0, -q_1 \rangle = -\langle q_0, q_1 \rangle = -\cos \Omega = \cos(\pi - \Omega)$, and $\pi - \Omega \in (0, \pi)$ because $\Omega \in (0, \pi)$ (the hypothesis $q_1 \neq \pm q_0$ excludes $\Omega \in \{0, \pi\}$): hence the angle is $\pi - \Omega$. By Theorem 30.3(iv) the rotations swept are 2Ω and $2(\pi - \Omega) = 2\pi - 2\Omega$, whose sum is 2π .

Step 3 — (iii). From $2\Omega + (2\pi - 2\Omega) = 2\pi$ it follows that one of the two values is less than π and the other greater, except when they are both equal to π . Precisely $2\Omega < \pi \iff \Omega <$

$\frac{\pi}{2} \iff \cos \Omega > 0 \iff \langle q_0, q_1 \rangle > 0$; $2\Omega > \pi \iff \langle q_0, q_1 \rangle < 0$; and $2\Omega = \pi$ if and only if $\langle q_0, q_1 \rangle = 0$, in which case the other path also sweeps $2\pi - \pi = \pi$.

Step 4 — why the double cover is needed. If the map $S^3 \rightarrow SO(3)$ were injective, each pair of rotations would correspond to a single pair of quaternions and there would be nothing to choose. It is the “two-to-one” property of Theorem 11.10(iv) that produces two distinct paths on S^3 with the same endpoints in $SO(3)$; and they are distinct *even as paths in $SO(3)$* , because by Theorem 30.3(iv) they sweep different rotations (2Ω versus $2\pi - 2\Omega$) about opposite axes. The sign rule chooses between the two the one of smaller rotation.

Step 5 — numerical check. With $q_0 = 1$ and $q_1 = \frac{1}{2}(1+i+j+k)$ one has $\langle q_0, q_1 \rangle = 0.5 > 0$, $\Omega = 60^\circ$, and rotation swept 120° ; with $-q_1$ one would have $\langle q_0, -q_1 \rangle = -0.5$, $\Omega' = 120^\circ$, and rotation swept 240° : both bring the body to the same final orientation, but the second makes it turn two-thirds of a revolution more. $120^\circ + 240^\circ = 360^\circ \checkmark$, as predicted by Step 2. $\square$

30.3.4 The degenerate case and comparison with linear interpolation

Proposition 30.6: Limit as $\Omega \rightarrow 0$: SLERP degenerates to the linear one. For

$a \in [0, 1]$ and $\Omega \in (0, \pi)$ set $F(a, \Omega) = \frac{\sin(a\Omega)}{\sin \Omega}$. Then:

- (i) $\lim_{\Omega \rightarrow 0^+} F(a, \Omega) = a$ for every $a \in [0, 1]$;
- (ii) for $0 < \Omega \leq 1$ the quantitative estimate holds

$$\left| F(a, \Omega) - a - \frac{a(1-a^2)}{6} \Omega^2 \right| \leq \frac{\Omega^4}{15};$$

- (iii) consequently $\text{slerp}(q_0, q_1; t) \rightarrow (1-t)q_0 + tq_1$ as $\Omega \rightarrow 0^+$, uniformly in $t \in [0, 1]$: in the limit of nearby orientations SLERP is linear interpolation, and the discrepancy is $O(\Omega^2)$.

Proof. **Step 1 — (i).** If $a = 0$ the statement is trivial. If $a > 0$,

$$F(a, \Omega) = \frac{\sin(a\Omega)}{a\Omega} \cdot \frac{\Omega}{\sin \Omega} \cdot a \xrightarrow{\Omega \rightarrow 0^+} 1 \cdot 1 \cdot a = a,$$

by the standard limit $\lim_{x \rightarrow 0} \frac{\sin x}{x} = 1$ applied twice.

Step 2 — Taylor’s formula with Lagrange remainder. For every $x \in \mathbb{R}$, the degree-4 Taylor polynomial of $\sin$ at 0 is $x - \frac{x^3}{6}$ (the degree-4 term vanishes) and the Lagrange remainder is $\frac{\cos \xi}{120} x^5$ for some ξ between 0 and x ; hence

$$\left| \sin x - \left(x - \frac{x^3}{6} \right) \right| \leq \frac{|x|^5}{120}, \quad \text{and for } 0 < x \leq 1 \text{ also } \sin x \geq x - \frac{x^3}{6} \geq \frac{5}{6}x,$$

the second because for $0 < x \leq 1 < \frac{\pi}{2}$ one has $\xi \in (0, x)$ and $\cos \xi > 0$, and because $x - \frac{x^3}{6} = x(1 - \frac{x^2}{6}) \geq x(1 - \frac{1}{6})$.

Step 3 — the numerator of the difference. For $0 < \Omega \leq 1$ and $a \in [0, 1]$, with $r_1 = \sin(a\Omega) - (a\Omega - \frac{a^3\Omega^3}{6})$ and $r_2 = \sin \Omega - (\Omega - \frac{\Omega^3}{6})$, one has $|r_1| \leq \frac{a^5\Omega^5}{120} \leq \frac{\Omega^5}{120}$ and $|r_2| \leq \frac{\Omega^5}{120}$, and

$$\sin(a\Omega) - a \sin \Omega = \left(a\Omega - \frac{a^3\Omega^3}{6} + r_1 \right) - a \left(\Omega - \frac{\Omega^3}{6} + r_2 \right) = \frac{a(1-a^2)}{6} \Omega^3 + \varepsilon,$$

with $\varepsilon = r_1 - ar_2$ and $|\varepsilon| \leq \frac{2\Omega^5}{120} = \frac{\Omega^5}{60}$.

Step 4 — dividing by $\sin \Omega$. Hence

$$F(a, \Omega) - a = \frac{a(1-a^2)}{6} \frac{\Omega^3}{\sin \Omega} + \frac{\varepsilon}{\sin \Omega} = \frac{a(1-a^2)}{6} \Omega^2 \cdot \frac{\Omega}{\sin \Omega} + \frac{\varepsilon}{\sin \Omega}.$$

By Step 2, $\sin \Omega \geq \Omega(1 - \frac{\Omega^2}{6}) > 0$, hence

$$1 \leq \frac{\Omega}{\sin \Omega} \leq \frac{1}{1 - \frac{\Omega^2}{6}} = 1 + \frac{\Omega^2/6}{1 - \Omega^2/6} \leq 1 + \frac{\Omega^2}{5}$$

(the last step because $\Omega \leq 1$ gives $1 - \frac{\Omega^2}{6} \geq \frac{5}{6}$).

Step 5 — (ii), the estimate. Subtracting the leading term,

$$\left| F(a, \Omega) - a - \frac{a(1-a^2)}{6} \Omega^2 \right| \leq \frac{a(1-a^2)}{6} \Omega^2 \cdot \frac{\Omega^2}{5} + \frac{\Omega^5/60}{\frac{5}{6}\Omega} \leq \frac{\Omega^4}{30} + \frac{\Omega^4}{50} = \frac{8\Omega^4}{150} < \frac{\Omega^4}{15},$$

having bounded $a(1-a^2) \leq 1$ on $[0, 1]$.

Step 6 — (iii). Applying (i) with $a = 1 - t$ and with $a = t$ to the two coefficients of the formula of Theorem 30.2 gives pointwise convergence to $(1-t)q_0 + tq_1$; estimate (ii), valid uniformly in $a \in [0, 1]$, makes it uniform in t , with error

$$\left\| \text{slerp}(q_0, q_1; t) - [(1-t)q_0 + tq_1] \right\| \leq \frac{\Omega^2}{6} \left[(1-t)t(2-t) + t(1-t)(1+t) \right] + \frac{2\Omega^4}{15} = \frac{t(1-t)}{2} \Omega^2 + \frac{2\Omega^4}{15},$$

where $\|q_0\| = \|q_1\| = 1$, the triangle inequality, and $(2-t) + (1+t) = 3$ were used.

Step 7 — numerical check. For $\Omega = 0.1$ and $t = 0.3$ (i.e. $a = 0.7$ for the first coefficient) the exact formula gives $F = 0.700595548933$, the linear one gives 0.7 , and the predicted correction term is $\frac{0.7 \cdot 0.51}{6} \cdot 0.01 = 5.950 \cdot 10^{-4}$, against an actual discrepancy of $5.955 \cdot 10^{-4}$: a difference of $5 \cdot 10^{-7}$, well within the bound $\Omega^4/15 = 6.7 \cdot 10^{-6}$. ✓ For $\Omega = 10^{-2}$ the actual discrepancy is $5.950 \cdot 10^{-6}$ and the prediction $5.950 \cdot 10^{-6}$; for $\Omega = 10^{-3}$ both are $5.950 \cdot 10^{-8}$: the ratio scales as Ω^2 , with a factor 100 per decade. ✓ □

Best practice. Implementing SLERP without losing digits. As $\Omega \rightarrow 0$ the formula of Theorem 30.2 divides two quantities that both tend to zero, and in finite arithmetic loses significant digits. Proposition 30.6 says exactly when it is safe to switch: if $\Omega \leq \Omega_*$ the discrepancy between SLERP and linear interpolation is at most $\frac{t(1-t)}{2} \Omega^2 + \frac{2}{15} \Omega^4 \leq \frac{\Omega_*^2}{8} + \frac{2\Omega_*^4}{15}$. For $\Omega_* = 10^{-3}$ rad the bound is $1.3 \cdot 10^{-7}$, below the resolution of a 22-bit encoder over one turn ($2\pi/2^{22} = 1.5 \cdot 10^{-6}$ rad); one then uses the linear formula, followed by a normalization. Above that threshold one uses the exact formula. The same Proposition 30.6 supplies the criterion: not “when Ω is small”, but “when $\Omega^2/8$ is below the required tolerance”.

Definition 30.4: Normalized linear interpolation (NLERP). For $q_0, q_1 \in S^3$ with $q_1 \neq -q_0$, the **NLERP** is the curve

$$\text{nlerp}(q_0, q_1; t) = \frac{(1-t)q_0 + tq_1}{\|(1-t)q_0 + tq_1\|}, \quad t \in [0, 1].$$

Proposition 30.7: NLERP traces the same arc, but not at constant speed. Let $q_0, q_1 \in S^3$ with $\Omega = \arccos \langle q_0, q_1 \rangle \in (0, \pi)$, and let E be as in Lemma 30.2. Then:

- (i) $\text{nlerp}(q_0, q_1; t) = \cos \phi(t) q_0 + \sin \phi(t) E$, where $\phi(t) \in [0, \Omega]$ is the argument of the complex number $(1-t) + t e^{i\Omega}$; when $(1-t) + t \cos \Omega > 0$ — in particular always, if $\Omega \leq \frac{\pi}{2}$ — this argument is written

$$\phi(t) = \arctan \frac{t \sin \Omega}{(1-t) + t \cos \Omega}.$$

In particular NLERP traces the same minor arc as SLERP, with the same endpoints;

(ii) its angular velocity equals

$$\phi'(t) = \frac{\sin \Omega}{D(t)}, \quad D(t) = 1 - 2t(1-t)(1 - \cos \Omega) \in \left[\cos^2 \frac{\Omega}{2}, 1 \right];$$

(iii) ϕ' attains its minimum $\sin \Omega$ at $t = 0$ and $t = 1$ and its maximum $2 \tan \frac{\Omega}{2}$ at $t = \frac{1}{2}$, with

$$\frac{\phi'(1/2)}{\phi'(0)} = \frac{1}{\cos^2 \frac{\Omega}{2}} > 1 \quad \text{for every } \Omega \in (0, \pi);$$

hence ϕ' is constant if and only if $\Omega = 0$: NLERP never has constant angular velocity when the two orientations are distinct;

(iv) the ratio between maximum speed and mean speed equals $\frac{2 \tan \frac{\Omega}{2}}{\Omega}$, which tends to 1 as $\Omega \rightarrow 0^+$ and to $+\infty$ as $\Omega \rightarrow \pi^-$.

Proof. Step 1 — components in the basis $\{q_0, E\}$. By Lemma 30.2, $q_1 = \cos \Omega q_0 + \sin \Omega E$, hence

$$v(t) := (1-t)q_0 + tq_1 = \underbrace{[(1-t) + t \cos \Omega]}_{\mathcal{A}(t)} q_0 + \underbrace{t \sin \Omega}_{\mathcal{B}(t)} E.$$

Step 2 — the norm. By orthonormality,

$$\|v(t)\|^2 = \mathcal{A}^2 + \mathcal{B}^2 = (1-t)^2 + 2t(1-t) \cos \Omega + t^2 \cos^2 \Omega + t^2 \sin^2 \Omega = (1-t)^2 + t^2 + 2t(1-t) \cos \Omega,$$

and since $(1-t)^2 + t^2 = 1 - 2t(1-t)$,

$$\|v(t)\|^2 = 1 - 2t(1-t)(1 - \cos \Omega) = D(t).$$

On $[0, 1]$ the function $2t(1-t)$ ranges between 0 (endpoints) and $\frac{1}{2}$ (at $t = \frac{1}{2}$), hence D ranges between $1 - \frac{1 - \cos \Omega}{2} = \frac{1 + \cos \Omega}{2} = \cos^2 \frac{\Omega}{2}$ and 1; in particular $D > 0$ for $\Omega < \pi$ and NLERP is well defined.

Step 3 — (i). Dividing by $\|v\| = \sqrt{D}$ gives a unit vector of Π , which by Lemma 30.2 is written $\cos \phi q_0 + \sin \phi E$ with $\cos \phi = \mathcal{A}/\sqrt{D}$ and $\sin \phi = \mathcal{B}/\sqrt{D}$; that is, ϕ is the argument of the complex number $\mathcal{A} + i\mathcal{B} = (1-t) + t e^{i\Omega}$. Since $(\mathcal{A}, \mathcal{B})$ is a combination with nonnegative coefficients of $(1, 0)$ (the value at $t = 0$) and of $(\cos \Omega, \sin \Omega)$ (the value at $t = 1$), the point $\mathcal{A} + i\mathcal{B}$ lies in the convex sector of opening $\Omega < \pi$ bounded by those two rays, and is never zero because $\mathcal{A}^2 + \mathcal{B}^2 = D > 0$: hence $\phi(t) \in [0, \Omega]$, with $\phi(0) = 0$ and $\phi(1) = \Omega$. If moreover $\mathcal{A} > 0$ — which holds for every $t \in [0, 1]$ when $\cos \Omega \geq 0$, since $\mathcal{A}$ is a convex combination of 1 and $\cos \Omega$ — the argument in the right half-plane is $\arctan(\mathcal{B}/\mathcal{A})$. The curve therefore traces the same minor arc as SLERP.

Step 4 — (ii), the derivative. The argument of a nowhere-vanishing differentiable curve $t \mapsto \mathcal{A}(t) + i\mathcal{B}(t)$ has derivative $\frac{\mathcal{B}'\mathcal{A} - \mathcal{A}'\mathcal{B}}{\mathcal{A}^2 + \mathcal{B}^2}$ (this is checked locally by writing the argument as $\arctan(\mathcal{B}/\mathcal{A})$ where $\mathcal{A} \neq 0$ and as $-\arctan(\mathcal{A}/\mathcal{B}) + \text{const}$ where $\mathcal{B} \neq 0$; the two cases cover the whole curve and the expressions agree where both hold). With $\mathcal{A}' = \cos \Omega - 1$, $\mathcal{B}' = \sin \Omega$, and $\mathcal{A}^2 + \mathcal{B}^2 = D$,

$$\phi' = \frac{\sin \Omega [(1-t) + t \cos \Omega] - (\cos \Omega - 1) t \sin \Omega}{D(t)}.$$

The numerator equals $\sin \Omega [(1-t) + t \cos \Omega - t \cos \Omega + t] = \sin \Omega \cdot 1 = \sin \Omega$: the terms in $t \cos \Omega$ cancel. Hence $\phi' = \sin \Omega / D$.

Step 5 — (iii). By Step 2, D has maximum 1 at the endpoints and minimum $\cos^2 \frac{\Omega}{2}$ at $t = \frac{1}{2}$; since $\phi' = \sin \Omega / D$ with $\sin \Omega > 0$, the angular velocity has minimum $\sin \Omega$ at $t \in \{0, 1\}$ and maximum

$$\frac{\sin \Omega}{\cos^2 \frac{\Omega}{2}} = \frac{2 \sin \frac{\Omega}{2} \cos \frac{\Omega}{2}}{\cos^2 \frac{\Omega}{2}} = 2 \tan \frac{\Omega}{2}$$

at $t = \frac{1}{2}$. The ratio is $\frac{2 \tan \frac{\Omega}{2}}{\sin \Omega} = \frac{2 \tan \frac{\Omega}{2}}{2 \sin \frac{\Omega}{2} \cos \frac{\Omega}{2}} = \frac{1}{\cos^2 \frac{\Omega}{2}}$, which is > 1 as soon as $\cos \frac{\Omega}{2} < 1$, i.e. $\Omega > 0$. If instead ϕ' were constant, the ratio would be 1 and one would have $\Omega = 0$.

Step 6 — (iv). The mean speed is $\frac{\phi(1) - \phi(0)}{1 - 0} = \Omega$; the ratio to the maximum is $2 \tan \frac{\Omega}{2} / \Omega$. As $\Omega \rightarrow 0^+$ one has $\tan x \sim x$ and the ratio tends to 1; as $\Omega \rightarrow \pi^-$ one has $\tan \frac{\Omega}{2} \rightarrow +\infty$ and the ratio diverges.

Step 7 — numerical check ($\Omega = 90^\circ$). One has $\sin \Omega = 1$, $\cos \Omega = 0$, so $D(t) = 1 - 2t(1 - t)$ and $\phi'(t) = 1/(1 - 2t + 2t^2)$. Then $\phi'(0) = 1$, $\phi'(\frac{1}{4}) = 1/(1 - \frac{1}{2} + \frac{1}{8}) = 1/0.625 = 1.6$, $\phi'(\frac{1}{2}) = 1/0.5 = 2$: the angular velocity *doubles* at midpoint, in agreement with $1/\cos^2 45^\circ = 2$. ✓ Compared to the mean $\Omega = \pi/2 = 1.5707963$, the peak equals $2/1.5707963 = 1.2732395$: a 27.3% overspeed, which matches $2 \tan 45^\circ / (\pi/2) = 1.2732395$. ✓ *Independent check:* difference quotients of step 10^{-6} on $\phi(t) = \arctan \frac{t}{1-t}$ give $\phi'(0) = 1.000001$, $\phi'(0.25) = 1.600000$, $\phi'(0.5) = 2.000000$. ✓

Step 8 — the angular discrepancy. Still for $\Omega = 90^\circ$, the maximum of $|\phi(t) - t\Omega|$ occurs at $t = 0.239$ and equals 4.0746° out of 90° : NLERP *lags* in the first half and catches up in the second. In terms of rotation of the body the error doubles (Theorem 30.3(iv)): 8.1° out of 180° . □

Remark 30.3: The same time law as the circular NURBS. Theorem 30.1(iii) gives for the circular arc in rational Bézier form the time law $\psi(t) = 2 \arctan \frac{t \sin \frac{\theta}{2}}{(1-t) + t \cos \frac{\theta}{2}}$, and Proposition 30.7(i) gives for NLERP $\phi(t) = \arctan \frac{t \sin \Omega}{(1-t) + t \cos \Omega}$: they are the same function, with $\Omega = \frac{\theta}{2}$ and a factor 2. This is no coincidence: both arise from normalizing (dividing respectively by $\bar{w}$ and by $\|v\|$) a linear combination of the two endpoints. The practical consequence is that a NURBS interpolator that traverses an arc at equally spaced t does not traverse it at constant speed — the very defect that Proposition 30.7 charges to NLERP, and for the same reason. This is why CNC controllers reparametrize arcs by arc length before applying the velocity profile of Section 30.4: the rational parametrization is exact as a set of points, not as a time law.

Remark 30.4: Squad, dual quaternions, and ScLERP: what remains imported.

To concatenate more than two orientations with C^1 continuity one uses *squad* (spherical spline quaternion), a quaternion spline construction for interpolating more than two orientations, attributed to Shoemake; to interpolate position and orientation simultaneously (that is, in $SE(3)$) one uses **dual quaternions**, which encode a screw motion (Chasles's theorem, Chapter 29) in a single algebraic object, and the corresponding ScLERP (screw linear interpolation). Of these two tools the chapter gives only the operational definition: their properties — that *squad* is indeed C^1 at the knots and that ScLERP is a geodesic of $SE(3)$ for a suitable metric — remain imported, that is, assumed without proof. What is missing, precisely, is: (a) the computation of the derivative of *squad* at the knots, which requires the differentiation formula for q^t with respect to t and the choice of intermediate control quaternions; (b) the construction of the metric on $SE(3)$ with respect to which ScLERP minimizes — and it must be noted that on $SE(3)$ there is no bi-invariant metric, so the statement “ScLERP is the geodesic of $SE(3)$ ” is meaningless until the metric is fixed. Nothing proved in this chapter depends on (a) or (b). The source for both is Shoemake (1985) for *squad*

Figure 30.2: SLERP versus NLERP on the arc between two orientations at $\Omega = 90^\circ$ (a two-dimensional cross-section of S^3 seen as a circle; drawing radius 3). Nine equally spaced instants $t = 0, \frac{1}{8}, \dots, 1$. The black points (SLERP) fall at the angles $0^\circ, 11.25^\circ, \dots, 90^\circ$, exactly equally spaced (Proposition 30.5). The red squares (NLERP) fall at the angles $\arctan \frac{t}{1-t}$, i.e. $0^\circ, \arctan \frac{1}{7} = 8.130^\circ, \arctan \frac{1}{3} = 18.435^\circ, \arctan \frac{2}{5} = 30.964^\circ, 45^\circ$, and symmetrically: they are *crowded at the endpoints* and sparse at the center, because by Proposition 30.7(iii) the angular velocity of NLERP is minimal at the endpoints and double at midpoint. Hence the tool's non-uniform motion.

and the literature on rigid-body kinematics (Lynch and Park, *Modern Robotics, Chapters 3 and 9*) for $SE(3)$.

Exercise 30.3. Compute slerp at $t = 1/2$ between $q_0 = 1$ and $q_1 = \cos 45^\circ + \sin 45^\circ k$, and the total rotation swept.

Solution. $\cos \Omega = \langle q_0, q_1 \rangle = \cos 45^\circ = 1/\sqrt{2}$, hence $\Omega = 45^\circ$. At $t = \frac{1}{2}$ the two coefficients of the formula of Theorem 30.2 are equal and equal $\sin 22.5^\circ / \sin 45^\circ = 0.5411961$, and the result is $q_{1/2} = \cos 22.5^\circ + \sin 22.5^\circ k$: by Corollary 30.2 it is already unit, with no renormalization. The total rotation swept is $2\Omega = 90^\circ$ about z (Theorem 30.3(iv)), and at midpoint the body has rotated by 45° : the exact half, at constant angular velocity (Proposition 30.5). *Independent check:* $\|q_{1/2}\|^2 = \cos^2 22.5^\circ + \sin^2 22.5^\circ = 1 \checkmark$; and $\langle q_0, q_{1/2} \rangle = \cos 22.5^\circ$, i.e. angle $22.5^\circ = \Omega/2 \checkmark$.

30.4. Motion profiles: trapezoidal and jerk-limited

Once the geometric curve has been chosen, it remains to decide *when* to traverse each of its points: this is the problem of the time law. The two standard laws are the trapezoidal velocity profile (piecewise-constant acceleration) and the S-curve profile (bounded jerk). This section derives in full the matching conditions and the times involved.

Definition 30.5: Trapezoidal profile and S-curve profile. Given $L, V, A > 0$, a **trapezoidal profile** for a travel of length L is a motion $s : [0, T] \rightarrow \mathbb{R}$ with $s(0) = 0, s(T) = L, v(0) = v(T) = 0$, whose velocity $v = \dot{s}$ is continuous, piecewise linear, with $|v| \leq V$ and $|\dot{v}| \leq A$: the acceleration is piecewise constant, hence discontinuous, and the **jerk** $j = \dot{a}$ is impulsive. Given in addition $J > 0$, an **S-curve profile** is a motion with $|v| \leq V, |a| \leq A$, and $|j| \leq J$ almost everywhere, with a continuous: the acceleration is continuous and the jerk is bounded.

Theorem 30.4: Minimum time with velocity and acceleration limits. Let $L, V, A > 0$ and, for $T > 0$, let $\mathcal{C}(T)$ be the set of motions $s : [0, T] \rightarrow \mathbb{R}$ with $v = \dot{s}$ absolutely continuous, $s(0) = 0$, $s(T) = L$, $v(0) = v(T) = 0$, $|v| \leq V$ on $[0, T]$, and $|\dot{v}| \leq A$ almost everywhere. Set

$$T^* = \begin{cases} \frac{L}{V} + \frac{V}{A} & \text{if } L \geq \frac{V^2}{A} \quad (\text{trapezoidal case}), \\ 2\sqrt{\frac{L}{A}} & \text{if } L < \frac{V^2}{A} \quad (\text{triangular case}). \end{cases}$$

Then $\mathcal{C}(T) \neq \emptyset$ if and only if $T \geq T^*$, and $\mathcal{C}(T^*)$ contains exactly one element, that of velocity

$$v^*(t) = \min\{V, At, A(T^* - t)\}.$$

In the trapezoidal case v^* rises linearly to V at $t_a = V/A$, stays at V for $t_v = \frac{L}{V} - \frac{V}{A}$, and falls in t_a ; in the triangular case the peak velocity is $v_p = \sqrt{AL} < V$, reached at $t_a = \sqrt{L/A}$.

Proof. Step 1 — three bounds on the velocity. Let $s \in \mathcal{C}(T)$. From $v(0) = 0$ and $|\dot{v}| \leq A$ it follows, for every t , that $v(t) = \int_0^t \dot{v} \leq At$; from $v(T) = 0$ it follows that $v(t) = -\int_t^T \dot{v} \leq A(T - t)$; and by hypothesis $v(t) \leq V$. Hence

$$v(t) \leq m_T(t) := \min\{V, At, A(T - t)\} \quad \text{for every } t \in [0, T].$$

Step 2 — the function F . Integrating, $L = \int_0^T v \leq \int_0^T m_T =: F(T)$. F is computed by distinguishing two cases. (a) $T \geq 2V/A$. Then $At \leq V$ for $t \leq V/A \leq T/2$, and by symmetry $A(T - t) \leq V$ for $t \geq T - V/A$; in between the minimum is V . Hence

$$F(T) = 2 \int_0^{V/A} At \, dt + V \left(T - \frac{2V}{A} \right) = \frac{V^2}{A} + VT - \frac{2V^2}{A} = VT - \frac{V^2}{A}.$$

(b) $T < 2V/A$. Then $At < V$ for every $t < T/2$ and the minimum is At on $[0, T/2]$, $A(T - t)$ on $[T/2, T]$:

$$F(T) = 2 \int_0^{T/2} At \, dt = \frac{AT^2}{4}.$$

The two expressions agree at $T = 2V/A$ (both equal V^2/A), so F is continuous; it is strictly increasing because for $T' > T$ one has $m_{T'} \geq m_T$ on $[0, T]$ and $m_{T'} > 0$ on $(T, T']$; and it is surjective onto $(0, +\infty)$ because $F(0^+) = 0$ and $F(+\infty) = +\infty$.

Step 3 — T^* is the solution of $F(T) = L$. In the case $L \geq V^2/A$ the solution is sought in branch (a): $VT - \frac{V^2}{A} = L$ gives $T = \frac{L}{V} + \frac{V}{A}$, and this is $\geq \frac{2V}{A}$ if and only if $\frac{L}{V} \geq \frac{V}{A}$, that is $L \geq \frac{V^2}{A}$: consistent. In the case $L < V^2/A$ the solution is sought in branch (b): $\frac{AT^2}{4} = L$ gives $T = 2\sqrt{L/A}$, which is $< \frac{2V}{A}$ if and only if $\sqrt{L/A} < V/A$, that is $L < \frac{V^2}{A}$: consistent. In both cases $F(T^*) = L$.

Step 4 — necessity. If $s \in \mathcal{C}(T)$ then $L \leq F(T)$ by Step 2; since F is strictly increasing and $F(T^*) = L$, it follows that $T \geq T^*$.

Step 5 — sufficiency and construction. Define $v^* = m_{T^*}$ and $s^*(t) = \int_0^t v^*$. Then v^* is continuous, piecewise linear, with $v^*(0) = v^*(T^*) = 0$ (because $m_{T^*}(0) = \min\{V, 0, AT^*\} = 0$ and likewise at T^*), $0 \leq v^* \leq V$, and $|\dot{v}^*| \leq A$ almost everywhere (the slopes are $A, 0, -A$). Finally $s^*(T^*) = F(T^*) = L$ by Step 3: hence $s^* \in \mathcal{C}(T^*)$. For $T > T^*$ an element of $\mathcal{C}(T)$ is constructed by lengthening the constant-velocity segment (trapezoidal case) or by lowering the peak until $\int v = L$ holds; alternatively, $F(T) > L$ and the function $\lambda \mapsto \int_0^T \min\{\lambda, At, A(T - t)\} \, dt$ is continuous and increasing from 0 to $F(T)$, so it takes the value L for some $\lambda \in (0, V]$, which gives an element of $\mathcal{C}(T)$.

Step 6 — uniqueness at T^* . If $s \in \mathcal{C}(T^*)$ then $\int_0^{T^*} (m_{T^*} - v) = F(T^*) - L = 0$ with continuous, non-negative integrand (Step 1): hence $v \equiv m_{T^*} = v^*$ and, integrating with $s(0) = 0$, $s \equiv s^*$.

Step 7 — reading the two cases. In the trapezoidal case $t_a = V/A$ is the instant at which At reaches V ; the constant-velocity segment lasts $T^* - 2t_a = \frac{L}{V} + \frac{V}{A} - \frac{2V}{A} = \frac{L}{V} - \frac{V}{A} = t_v$. In the triangular case the peak occurs at $t = T^*/2 = \sqrt{L/A} = t_a$ and equals $v_p = A\sqrt{L/A} = \sqrt{AL}$, which is $< V$ because $L < V^2/A$.

Step 8 — numerical check. With $L = 1$ m, $V = 1$ m/s, $A = 2$ m/s² one has $V^2/A = 0.5 \leq 1 = L$: trapezoidal case, $t_a = 0.5$ s, $t_v = 1 - 0.5 = 0.5$ s, $T^* = 1 + 0.5 = 1.5$ s. *Independent check:* the distance travelled, computed by numerical integration of the profile with $2 \cdot 10^6$ steps, equals 0.99999999996 against $L = 1$. ✓ With $L = 0.1$ m and the same V, A one has $V^2/A = 0.5 > 0.1$: triangular case, $t_a = \sqrt{0.05} = 0.2236068$ s, $T^* = 0.4472136$ s, $v_p = \sqrt{0.2} = 0.4472136$ m/s. *Check:* the distance is $2 \cdot \frac{1}{2} At_a^2 = At_a^2 = 2 \cdot 0.05 = 0.1 = L$ ✓, whereas the trapezoidal formula would erroneously give $0.1 + 0.5 = 0.6$ s, a value *larger* than the true one: applying the wrong formula does not make the motion slower, it makes it impossible (it would require $v > V$ or a longer travel). □

30.4.1 The seven-segment S-curve profile

Bounding the jerk by a maximum J means making the acceleration continuous. The resulting profile has up to **seven segments**: positive jerk, constant acceleration, negative jerk, constant velocity, negative jerk, constant deceleration, positive jerk. Position, velocity, and acceleration remain continuous; only the jerk is discontinuous (in finite steps), no longer impulsive as in the trapezoidal profile. The lemma that follows is the key to the computation: it says that the acceleration phase, however complicated, covers exactly the distance it would cover at the average velocity $V/2$.

Lemma 30.3: Antisymmetry of the acceleration phase. Let $T_a > 0$ and let $j : [0, T_a] \rightarrow \mathbb{R}$ be bounded and measurable with $j(T_a - \sigma) = -j(\sigma)$ for almost every σ . Setting $a(t) = \int_0^t j$ and $v(t) = \int_0^t a$, one has:

$$a(T_a) = 0, \quad a(T_a - \sigma) = a(\sigma), \quad v(\sigma) + v(T_a - \sigma) = v(T_a), \quad \int_0^{T_a} v = \frac{T_a}{2} v(T_a).$$

Proof. Step 1 — $a(T_a) = 0$. With the substitution $\sigma = T_a - r$,

$$a(T_a) = \int_0^{T_a} j(\sigma) d\sigma = \int_0^{T_a} j(T_a - r) dr = - \int_0^{T_a} j(r) dr = -a(T_a),$$

hence $a(T_a) = 0$.

Step 2 — symmetry of a . For every $\sigma \in [0, T_a]$,

$$a(T_a - \sigma) = a(T_a) - \int_{T_a - \sigma}^{T_a} j = 0 - \int_0^{\sigma} j(T_a - r) dr = \int_0^{\sigma} j(r) dr = a(\sigma).$$

Step 3 — antisymmetry of v . Likewise, using Step 2,

$$v(T_a - \sigma) = v(T_a) - \int_{T_a - \sigma}^{T_a} a = v(T_a) - \int_0^{\sigma} a(T_a - r) dr = v(T_a) - \int_0^{\sigma} a(r) dr = v(T_a) - v(\sigma).$$

Step 4 — the integral. With the substitution $\sigma \rightarrow T_a - \sigma$ and Step 3,

$$\int_0^{T_a} v(\sigma) d\sigma = \int_0^{T_a} v(T_a - \sigma) d\sigma = \int_0^{T_a} [v(T_a) - v(\sigma)] d\sigma = T_a v(T_a) - \int_0^{T_a} v,$$

whence $2 \int_0^{T_a} v = T_a v(T_a)$. □

Theorem 30.5: The S-curve profile: matching, durations, and total time. Let $L, V, A, J > 0$.

(a) Seven-segment case. If $V \geq \frac{A^2}{J}$ and $L \geq V\left(\frac{V}{A} + \frac{A}{J}\right)$, set

$$t_j = \frac{A}{J}, \quad t_a = \frac{V}{A} - \frac{A}{J}, \quad T_a = 2t_j + t_a = \frac{V}{A} + \frac{A}{J}, \quad t_v = \frac{L}{V} - T_a,$$

and let j be the piecewise-constant function equal to $+J, 0, -J, 0, -J, 0, +J$ on seven consecutive intervals of durations $t_j, t_a, t_j, t_v, t_j, t_a, t_j$, with $a(0) = v(0) = s(0) = 0$. Then $t_j, t_a, t_v \geq 0$ and the resulting motion satisfies: a continuous, v of class C^1 , s of class C^2 ; $\max |a| = A$, $\max v = V$; $a(T) = v(T) = 0$ and $s(T) = L$; and

$$T = \frac{L}{V} + \frac{V}{A} + \frac{A}{J}.$$

(b) Four-segment case (the acceleration never reaches A). If $V < \frac{A^2}{J}$ and $L \geq 2V\sqrt{V/J}$, the same statement holds with $t_j = \sqrt{V/J}$, $t_a = 0$, $T_a = 2\sqrt{V/J}$, $t_v = \frac{L}{V} - T_a$, $\max |a| = \sqrt{VJ} < A$, and

$$T = \frac{L}{V} + 2\sqrt{\frac{V}{J}}.$$

Proof. Step 1 — sign of the durations. In case (a), $t_j > 0$ and $t_a = \frac{V}{A} - \frac{A}{J} \geq 0$ is equivalent to $VJ \geq A^2$, that is to the hypothesis $V \geq A^2/J$; $t_v = \frac{L}{V} - \frac{V}{A} - \frac{A}{J} \geq 0$ is equivalent to $L \geq V\left(\frac{V}{A} + \frac{A}{J}\right)$, the second hypothesis. In case (b), $t_j = \sqrt{V/J} > 0$ and $t_v \geq 0$ is equivalent to $L \geq 2V\sqrt{V/J}$.

Step 2 — regularity and matching. The jerk j is piecewise constant and bounded, so $a(t) = \int_0^t j$ is continuous and piecewise linear, $v = \int_0^t a$ is of class C^1 (continuous derivative a), and $s = \int_0^t v$ is of class C^2 . The matching conditions — continuity of s, v, a at every junction — are automatic because s, v, a are defined as integrals of bounded functions; what is *not* automatic, and what determines the durations, are the three terminal conditions $a(T) = 0$, $v(T) = 0$, $s(T) = L$, verified in the steps that follow.

Step 3 — the acceleration phase, case (a). On $[0, T_a]$ the jerk equals $+J, 0, -J$ on intervals of durations t_j, t_a, t_j : it is antisymmetric about the midpoint $T_a/2$, because $j(T_a - \sigma) = -J = -j(\sigma)$ for $\sigma \in (0, t_j)$ and $j = 0$ on the central segment. Integrating explicitly:

$$a(t_j) = Jt_j = A, \quad v(t_j) = \frac{1}{2}Jt_j^2 = \frac{A^2}{2J},$$

$$a(t_j + t_a) = A, \quad v(t_j + t_a) = \frac{A^2}{2J} + At_a = \frac{A^2}{2J} + V - \frac{A^2}{J} = V - \frac{A^2}{2J},$$

$$a(T_a) = A - Jt_j = 0, \quad v(T_a) = V - \frac{A^2}{2J} + \left(At_j - \frac{1}{2}Jt_j^2\right) = V - \frac{A^2}{2J} + \frac{A^2}{2J} = V.$$

Hence at the end of the acceleration phase the velocity is exactly V and the acceleration has returned to zero; the maximum of $|a|$ is A (reached on the central segment) and v is increasing, so $\max v = V$. By Lemma 30.3 the distance covered in this phase is

$$\int_0^{T_a} v = \frac{T_a}{2} V.$$

Step 4 — the constant-velocity phase and the deceleration. On $[T_a, T_a + t_v]$ the jerk is zero and $a(T_a) = 0$: hence $a \equiv 0$ and $v \equiv V$, with distance Vt_v . On $[T_a + t_v, 2T_a + t_v]$ the

jerk is $-J, 0, +J$ over durations t_j, t_a, t_j , that is, the opposite of that of the acceleration phase: by linearity of integration the acceleration is the opposite of that of the acceleration phase, $a(T_a + t_v + \sigma) = -a(\sigma)$, and hence the velocity is $v(T_a + t_v + \sigma) = V - v(\sigma)$ for $\sigma \in [0, T_a]$; in particular it falls from V to $V - V = 0$ and the acceleration returns to 0. The distance covered in deceleration is therefore

$$\int_0^{T_a} (V - v(\sigma)) d\sigma = V T_a - \frac{T_a}{2} V = \frac{T_a}{2} V,$$

again by Lemma 30.3: equal to that of the acceleration phase, as symmetry requires.

Step 5 — the total distance and time. Summing the three contributions,

$$s(T) = \frac{T_a}{2} V + V t_v + \frac{T_a}{2} V = V(T_a + t_v) = V \left(\frac{V}{A} + \frac{A}{J} + \frac{L}{V} - \frac{V}{A} - \frac{A}{J} \right) = L,$$

and the total duration is

$$T = 2T_a + t_v = 2 \left(\frac{V}{A} + \frac{A}{J} \right) + \frac{L}{V} - \frac{V}{A} - \frac{A}{J} = \frac{L}{V} + \frac{V}{A} + \frac{A}{J}.$$

Step 6 — case (b). If $V < A^2/J$ there is no constant-acceleration segment: the jerk equals $+J, -J$ on two intervals of duration t_j . Then $a(t_j) = Jt_j$, $v(t_j) = \frac{1}{2}Jt_j^2$, and at the end $a(2t_j) = 0$, $v(2t_j) = \frac{1}{2}Jt_j^2 + (Jt_j \cdot t_j - \frac{1}{2}Jt_j^2) = Jt_j^2$. Imposing $v(2t_j) = V$ gives $t_j = \sqrt{V/J}$ and $\max |a| = Jt_j = \sqrt{VJ}$, which is $< A$ because $V < A^2/J$: the acceleration constraint is not active. The jerk remains antisymmetric about $T_a/2 = t_j$, so Lemma 30.3 again gives distance $\frac{T_a}{2} V$, and Steps 4–5 repeat identically with $T_a = 2\sqrt{V/J}$, giving $T = \frac{L}{V} + 2\sqrt{V/J}$.

Step 7 — numerical check. With $L = 1$ m, $V = 1$ m/s, $A = 2$ m/s², $J = 10$ m/s³: $A^2/J = 0.4 \leq 1 = V$ (case (a)); $t_j = 0.2$ s, $t_a = 0.5 - 0.2 = 0.3$ s, $T_a = 0.7$ s, $V T_a = 0.7 \leq 1 = L$ ✓, $t_v = 1 - 0.7 = 0.3$ s. The durations sum to $0.2 + 0.3 + 0.2 + 0.3 + 0.2 + 0.3 + 0.2 = 1.7$ s, which agrees with $\frac{L}{V} + \frac{V}{A} + \frac{A}{J} = 1 + 0.5 + 0.2 = 1.7$ s. ✓ *Independent check:* integrating exactly segment by segment (constant jerk, formulas $s = v\delta + \frac{1}{2}a\delta^2 + \frac{1}{6}j\delta^3$) gives $s(T) = 1.000000000$, $v(T) = -5.1 \cdot 10^{-17}$, $a(T) = 1.3 \cdot 10^{-16}$, $\max v = 1.000000000$, $\max |a| = 2.000000000$. ✓ The S-curve profile costs $1.7 - 1.5 = 0.2$ s more than the trapezoidal one (Theorem 30.4), that is 13.3%; and the additional term is exactly A/J . □

Proposition 30.8: How far the S-curve profile is from the absolute minimum time. Let $L, V, A, J > 0$ with $V \geq \frac{A^2}{J}$ and $L \geq V \left(\frac{V}{A} + \frac{A}{J} \right)$, and let $\mathcal{S}(T)$ be the set of motions $s : [0, T] \rightarrow \mathbb{R}$ with $a = \ddot{s}$ absolutely continuous, $s(0) = 0$, $s(T) = L$, $v(0) = v(T) = 0$, $a(0) = a(T) = 0$, $|v| \leq V$, $|a| \leq A$, and $|\dot{a}| \leq J$ almost everywhere. Then every T with $\mathcal{S}(T) \neq \emptyset$ satisfies

$$T > T_{\text{inf}} := \frac{L}{V} + \frac{V}{A} + \frac{A}{J} - \frac{A^3}{12J^2V} = T_S - \frac{A^3}{12J^2V},$$

where T_S is the time of the seven-segment profile (Theorem 30.5). The seven-segment profile is thus optimal up to $\frac{A^3}{12J^2V}$ in absolute value, that is, up to a fraction $\frac{A^3}{12J^2VT_S}$ of the total time.

Proof. Step 1 — bounding the acceleration. Let $s \in \mathcal{S}(T)$. From $a(0) = 0$ and $|\dot{a}| \leq J$ it follows that $a(\sigma) \leq J\sigma$; from $a(T) = 0$ it follows that $-a(\sigma) \leq J(T - \sigma)$. With $|a| \leq A$:

$$a(\sigma) \leq \min\{A, J\sigma\}, \quad -a(\sigma) \leq \min\{A, J(T - \sigma)\}.$$

Figure 30.3: Seven-segment S-curve profile for $L = 1$ m, $V = 1$ m/s, $A = 2$ m/s², $J = 10$ m/s³ (Theorem 30.5, case (a)). Matching instants, in seconds: 0, 0.2, 0.5, 0.7, 1.0, 1.2, 1.5, 1.7; at those instants the acceleration equals 0, 2, 2, 0, 0, -2, -2, 0 (m/s²), the velocity 0; 0.2; 0.8; 1; 1; 0.8; 0.2; 0 (m/s), and the position 0; 0.0133; 0.1633; 0.35; 0.65; 0.8367; 0.9867; 1 (m). The jerk is piecewise constant, the acceleration is continuous (trapezoidal), the velocity is C^1 , and the position C^2 . The ordinates of the drawing are to scale: $J \rightarrow 0.5$, $A \rightarrow 0.7$, $V \rightarrow 1.6$ units.

Step 2 — bounding the velocity. Setting $G(t) = \int_0^t \min\{A, Jr\} dr$, that is,

$$G(t) = \begin{cases} \frac{Jt^2}{2} & t \leq \frac{A}{J}, \\ \frac{A^2}{2J} + A\left(t - \frac{A}{J}\right) & t \geq \frac{A}{J}, \end{cases}$$

one has $v(t) = \int_0^t a \leq G(t)$ and $v(t) = -\int_t^T a \leq \int_t^T \min\{A, J(T - \sigma)\} d\sigma = G(T - t)$. With $v \leq V$:

$$v(t) \leq \mu_T(t) := \min\{V, G(t), G(T - t)\}.$$

Step 3 — computing $F_J(T) = \int_0^T \mu_T$. Let t_1 be the instant at which G reaches V : from $\frac{A^2}{2J} + A(t_1 - \frac{A}{J}) = V$ one obtains $t_1 = \frac{V}{A} + \frac{A}{2J}$, and $t_1 \geq \frac{A}{J}$ because $V \geq \frac{A^2}{J} \geq \frac{A^2}{2J}$. Assuming $T \geq 2t_1$ (verified a posteriori in Step 5),

$$F_J(T) = 2 \int_0^{t_1} G + V(T - 2t_1).$$

Now, setting $\tau = \frac{A}{J}$,

$$\int_0^\tau G = \int_0^\tau \frac{Jr^2}{2} dr = \frac{J\tau^3}{6} = \frac{A\tau^2}{6},$$

$$\int_\tau^{t_1} G = \int_\tau^{t_1} \left(Ar - \frac{A\tau}{2}\right) dr = \frac{A}{2}(t_1^2 - \tau^2) - \frac{A\tau}{2}(t_1 - \tau) = \frac{A}{2}(t_1 - \tau)(t_1 + \tau - \tau) = \frac{A}{2}t_1(t_1 - \tau),$$

having used $\frac{A^2}{2J} - \frac{A^2}{J} = -\frac{A^2}{2J} = -\frac{A\tau}{2}$. Hence

$$F_J(T) = VT - 2Vt_1 + \frac{A\tau^2}{3} + At_1^2 - At_1\tau.$$

Substituting $t_1 = \frac{V}{A} + \frac{\tau}{2}$:

$$2Vt_1 = \frac{2V^2}{A} + V\tau, \quad At_1^2 = \frac{V^2}{A} + V\tau + \frac{A\tau^2}{4}, \quad At_1\tau = V\tau + \frac{A\tau^2}{2},$$

and summing algebraically

$$F_J(T) = VT - \frac{V^2}{A} - V\tau + A\tau^2\left(\frac{1}{3} + \frac{1}{4} - \frac{1}{2}\right) = VT - \frac{V^2}{A} - \frac{VA}{J} + \frac{A^3}{12J^2},$$

since $\frac{1}{3} + \frac{1}{4} - \frac{1}{2} = \frac{1}{12}$ and $A\tau^2 = \frac{A^3}{J^2}$.

Step 4 — the inequality. By Step 2, $L = \int_0^T v \leq F_J(T)$, and F_J is strictly increasing in T (the bound μ_T grows with T pointwise and the domain widens). Solving $F_J(T) = L$ gives

$$T = \frac{L}{V} + \frac{V}{A} + \frac{A}{J} - \frac{A^3}{12J^2V} = T_{\text{inf}},$$

hence $\mathcal{S}(T) \neq \emptyset$ implies $T \geq T_{\text{inf}}$.

Step 5 — consistency of the hypothesis $T \geq 2t_1$. One has $2t_1 = \frac{2V}{A} + \frac{A}{J}$ and $T_{\text{inf}} \geq \frac{L}{V} + \frac{V}{A} + \frac{A}{J} - \frac{A^3}{12J^2V}$; since $L \geq V(\frac{V}{A} + \frac{A}{J})$ gives $\frac{L}{V} \geq \frac{V}{A} + \frac{A}{J}$, one obtains $T_{\text{inf}} \geq \frac{2V}{A} + \frac{2A}{J} - \frac{A^3}{12J^2V}$. It thus suffices to check $\frac{A}{J} \geq \frac{A^3}{12J^2V}$, that is $12JV \geq A^2$, true because $JV \geq A^2$ by hypothesis.

Step 6 — the inequality is strict. If $T = T_{\text{inf}}$ held for some $s \in \mathcal{S}(T)$, Step 4 would give $\int_0^T (\mu_T - v) = 0$ with continuous, non-negative integrand, hence $v \equiv \mu_T$. But μ_T is not differentiable with J -Lipschitz derivative: at $t = t_1$ the left derivative is $G'(t_1) = A$ and the right one is 0 (because there the minimum switches from $G(t)$ to V), and $t_1 < T - t_1$ by Step 5, so the jump is effective. The acceleration $a = \dot{v}$ would then jump by A at an instant, against $|\dot{a}| \leq J$. Hence no element of $\mathcal{S}(T_{\text{inf}})$ exists and the inequality is strict.

Step 7 — numerical check. With $L = 1$, $V = 1$, $A = 2$, $J = 10$ (the units of Theorem 30.5): $\frac{A^3}{12J^2V} = \frac{8}{1200} = 0.0066667$ s, hence $T_{\text{inf}} = 1.7 - 0.0066667 = 1.6933333$ s against $T_S = 1.7$ s: the seven-segment profile wastes at most 0.392% of the time. *Independent check:* $t_1 = \frac{V}{A} + \frac{A}{2J} = 0.5 + 0.1 = 0.6$ s and $2t_1 = 1.2 \leq 1.6933$ ✓; and re-evaluating the formula of Step 3 at $T = 1.6933333$, with $\frac{V^2}{A} = 0.5$, $\frac{VA}{J} = 0.2$, and $\frac{A^3}{12J^2} = 0.0066667$,

$$F_J(T) = 1.6933333 - 0.5 - 0.2 + 0.0066667 = 1.0000000 = L. \quad \checkmark$$

□

Remark 30.5: Why bound the jerk. Jerk is the number-one enemy of motion quality: an abrupt change in acceleration excites the elastic modes of the mechanics (gearboxes, belts, long shafts, flexible arms), producing residual vibrations that degrade precision and finish and fatigue the actuators. A real mechanical system is not a rigid body: it is a collection of masses and springs with natural frequencies ω_n , and a “hard” command drives them into resonance. Quantitatively: in the trapezoidal profile the acceleration jumps by A at an instant, that is, the jerk is a Dirac distribution of intensity A , whose spectrum is flat and therefore excites all frequencies equally; in the S-curve profile the jerk is bounded by J and its spectrum decays, the more rapidly the longer the ramp $t_j = A/J$. The price, by Theorem 30.5, is exactly A/J seconds more: the very same t_j that softens the command. Section 30.5 tackles the same problem from the other side — not softening the command, but cancelling the vibration with a second command in phase opposition — and achieves a delay of $T_d/2$, that is, half the period of the mode to be suppressed.

Exercise 30.4. An axis must travel $L = 1$ m with maximum velocity $V = 1$ m/s and acceleration $A = 2$ m/s² (trapezoidal profile). How long does the motion last? And with $J = 10$ m/s³?

Solution. Since $V^2/A = 0.5 \leq 1 = L$, this is the trapezoidal case of Theorem 30.4: acceleration time $t_a = V/A = 0.5$ s, distance in acceleration $\frac{1}{2}At_a^2 = 0.25$ m (equal in deceleration), total 0.5 m in the ramp phases; the remaining 0.5 m at constant velocity, in 0.5 s. Total time $T = t_a + t_v + t_a = 0.5 + 0.5 + 0.5 = 1.5$ s, in agreement with $T^* = \frac{L}{V} + \frac{V}{A} = 1 + 0.5$. With the jerk limit, since $A^2/J = 0.4 \leq V$ and $V(\frac{V}{A} + \frac{A}{J}) = 0.7 \leq L$, Theorem 30.5 gives $T = \frac{L}{V} + \frac{V}{A} + \frac{A}{J} = 1 + 0.5 + 0.2 = 1.7$ s: 0.2 s more, that is, 13.3%. *Independent check:* the seven durations $0.2 + 0.3 + 0.2 + 0.3 + 0.2 + 0.3 + 0.2$ sum to 1.7 s ✓.

30.5. Residual vibration and shaped command

A jerk-limited profile attenuates the excitation of the elastic modes, but does not cancel it. The technique of *input shaping* does something different and more radical: it replaces the command with its convolution with a short train of impulses, chosen so that the vibrations produced by the individual impulses cancel *exactly*. This section derives in full the two classical shapers, ZV and ZVD.

Definition 30.6: Elastic mode and residual vibration. An **elastic mode** of natural frequency $\omega_n > 0$ and damping $\zeta \in [0, 1)$ is the second-order linear system

$$\ddot{y} + 2\zeta\omega_n\dot{y} + \omega_n^2 y = \omega_n^2 u, \quad \text{that is} \quad H(s) = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2}$$

(Definition 25.1), with $\beta = \sqrt{1 - \zeta^2}$, $\omega_d = \omega_n\beta$, $T_d = 2\pi/\omega_d$, and $K = e^{-\zeta\pi/\beta}$. If the command u is zero (or constant) from some instant t_N onward, the amplitude of the oscillation of y for $t \geq t_N$, that is, the coefficient C in the expression $y(t) = y_\infty + C e^{-\zeta\omega_n t} \sin(\omega_d t + \vartheta)$, is called the **residual vibration**.

Lemma 30.4: Impulse and step response of an elastic mode. With the notation of Definition 30.6:

(i) the **impulse response**, that is, the solution of $\ddot{h} + 2\zeta\omega_n\dot{h} + \omega_n^2 h = 0$ with $h(0) = 0$ and $\dot{h}(0) = \omega_n^2$, is

$$h(t) = \frac{\omega_n^2}{\omega_d} e^{-\zeta\omega_n t} \sin(\omega_d t), \quad t \geq 0;$$

(ii) the unit **step response**, that is, the solution of $\ddot{g} + 2\zeta\omega_n\dot{g} + \omega_n^2 g = \omega_n^2$ with $g(0) = \dot{g}(0) = 0$, is

$$g(t) = 1 - e^{-\zeta\omega_n t} \left(\cos \omega_d t + \frac{\zeta}{\beta} \sin \omega_d t \right) = 1 - \frac{1}{\beta} e^{-\zeta\omega_n t} \sin(\omega_d t + \varphi),$$

where $\varphi \in (0, \pi)$ is defined by $\cos \varphi = \zeta$, $\sin \varphi = \beta$;

(iii) $\dot{g}(t) = \frac{\omega_n}{\beta} e^{-\zeta\omega_n t} \sin(\omega_d t)$, hence g is increasing on $[0, \pi/\omega_d]$ and its first maximum equals $g(\pi/\omega_d) = 1 + K$.

Proof. Step 1 — roots of the characteristic equation. The polynomial $s^2 + 2\zeta\omega_n s + \omega_n^2$ has discriminant $4\zeta^2\omega_n^2 - 4\omega_n^2 = -4\omega_n^2\beta^2 < 0$ for $\zeta < 1$: the roots are $s_\pm = -\zeta\omega_n \pm i\omega_d$,

complex conjugates and distinct. The general integral of the homogeneous equation is thus $e^{-\zeta\omega_n t}(C_1 \cos \omega_d t + C_2 \sin \omega_d t)$.

Step 2 — (i). Imposing $h(0) = C_1 = 0$ and $\dot{h}(0) = -\zeta\omega_n C_1 + \omega_d C_2 = \omega_d C_2 = \omega_n^2$ gives $C_2 = \omega_n^2/\omega_d$, that is, the formula of the statement. *Independent check:* from the table of transforms (Volume III, Appendix C), $\mathcal{L}\{e^{-at} \sin(bt)\} = \frac{b}{(s+a)^2 + b^2}$, hence

$$\mathcal{L}\{h\} = \frac{\omega_n^2}{\omega_d} \cdot \frac{\omega_d}{(s + \zeta\omega_n)^2 + \omega_d^2} = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \zeta^2\omega_n^2 + \omega_n^2 - \zeta^2\omega_n^2} = H(s). \quad \checkmark$$

Step 3 — (ii). The constant function 1 is a particular solution of the equation with forcing term ω_n^2 ; the general integral is thus $g = 1 + e^{-\zeta\omega_n t}(C_1 \cos \omega_d t + C_2 \sin \omega_d t)$. From $g(0) = 1 + C_1 = 0$ it follows that $C_1 = -1$; from $\dot{g}(0) = -\zeta\omega_n C_1 + \omega_d C_2 = \zeta\omega_n + \omega_d C_2 = 0$ it follows that $C_2 = -\zeta\omega_n/\omega_d = -\zeta/\beta$. For the compact form:

$$\cos \omega_d t + \frac{\zeta}{\beta} \sin \omega_d t = \frac{1}{\beta} (\beta \cos \omega_d t + \zeta \sin \omega_d t) = \frac{1}{\beta} \sin(\omega_d t + \varphi)$$

with $\sin \varphi = \beta$ and $\cos \varphi = \zeta$, which is legitimate because $\zeta^2 + \beta^2 = 1$; and $\varphi \in (0, \pi)$ because $\beta > 0$.

Step 4 — (iii). Differentiating the first form of (ii),

$$\dot{g} = \zeta\omega_n e^{-\zeta\omega_n t} \left(\cos \omega_d t + \frac{\zeta}{\beta} \sin \omega_d t \right) - e^{-\zeta\omega_n t} \left(-\omega_d \sin \omega_d t + \frac{\zeta\omega_d}{\beta} \cos \omega_d t \right).$$

The cos terms cancel because $\frac{\zeta\omega_d}{\beta} = \zeta\omega_n$; the sin terms give the coefficient $\frac{\zeta^2\omega_n}{\beta} + \omega_d = \frac{\zeta^2\omega_n + \omega_n\beta^2}{\beta} = \frac{\omega_n}{\beta}$. Hence $\dot{g} = \frac{\omega_n}{\beta} e^{-\zeta\omega_n t} \sin(\omega_d t)$, which is ≥ 0 for $\omega_d t \in [0, \pi]$: g increases on $[0, \pi/\omega_d]$. Its value at the first endpoint is

$$g\left(\frac{\pi}{\omega_d}\right) = 1 - e^{-\zeta\omega_n\pi/\omega_d} (\cos \pi + 0) = 1 + e^{-\zeta\pi/\beta} = 1 + K.$$

□

Theorem 30.6: *The residual vibration is the modulus of the shaper's transform at the pole. Let $A_1, \dots, A_N \in \mathbb{R}$ and $0 = t_1 < t_2 < \dots < t_N$, and let*

$$\widehat{A}(s) = \sum_{i=1}^N A_i e^{-st_i}$$

be the Laplace transform of the impulse train $\sum_i A_i \delta(t - t_i)$. Let $s_0 = -\zeta\omega_n + i\omega_d$ be the pole of the elastic mode. Then, for every $t \geq t_N$:

(i) *the response to the impulse train equals*

$$y(t) = \frac{\omega_n^2}{\omega_d} |\widehat{A}(s_0)| e^{-\zeta\omega_n t} \sin(\omega_d t + \arg \widehat{A}(s_0));$$

(ii) *the response to the shaped step $u(t) = \sum_i A_i \mathbf{1}_{[t_i, +\infty)}(t)$ equals*

$$y(t) = \sum_{i=1}^N A_i - \frac{1}{\beta} |\widehat{A}(s_0)| e^{-\zeta\omega_n t} \sin(\omega_d t + \varphi + \arg \widehat{A}(s_0));$$

(iii) *in both cases the residual vibration is zero if and only if $\widehat{A}(s_0) = 0$.*

Proof. Step 1 — superposition. The system is linear and time-invariant, hence for $t \geq t_N$ (that is, once all the impulses have already acted) $y(t) = \sum_i A_i h(t - t_i)$ with h from Lemma 30.4(i).

Step 2 — sum of damped sinusoids. Using $\sin x = \operatorname{Im} e^{ix}$,

$$y(t) = \frac{\omega_n^2}{\omega_d} \sum_i A_i e^{-\zeta\omega_n(t-t_i)} \operatorname{Im} e^{i\omega_d(t-t_i)} = \frac{\omega_n^2}{\omega_d} e^{-\zeta\omega_n t} \operatorname{Im} \left[e^{i\omega_d t} \sum_i A_i e^{(\zeta\omega_n - i\omega_d)t_i} \right],$$

having pulled out of the sum the factors that do not depend on i and used the linearity of Im with respect to real coefficients.

Step 3 — recognizing the transform. Since $-s_0 = \zeta\omega_n - i\omega_d$, the sum is $\sum_i A_i e^{-s_0 t_i} = \hat{A}(s_0)$. Writing $\hat{A}(s_0) = |\hat{A}(s_0)| e^{i \arg \hat{A}(s_0)}$ gives

$$\operatorname{Im} [e^{i\omega_d t} \hat{A}(s_0)] = |\hat{A}(s_0)| \sin(\omega_d t + \arg \hat{A}(s_0)),$$

that is, (i).

Step 4 — (ii). For $t \geq t_N$ each step $\mathbf{1}_{[t_i, \infty)}$ is already active, hence $y(t) = \sum_i A_i g(t - t_i)$ with g from Lemma 30.4(ii). Separating the constant part,

$$y(t) = \sum_i A_i - \frac{1}{\beta} \sum_i A_i e^{-\zeta\omega_n(t-t_i)} \sin(\omega_d(t-t_i) + \varphi),$$

and repeating Steps 2–3 with $e^{i(\omega_d t + \varphi)}$ in place of $e^{i\omega_d t}$ gives the formula of the statement.

Step 5 — (iii). If $\hat{A}(s_0) = 0$ the oscillating term is identically zero. Conversely, if the oscillating term is zero for every $t \geq t_N$, then $|\hat{A}(s_0)| e^{-\zeta\omega_n t} \sin(\omega_d t + \vartheta) \equiv 0$; since $e^{-\zeta\omega_n t} > 0$ and $\sin(\omega_d t + \vartheta)$ is not identically zero on any interval (it has isolated zeros), it must be that $|\hat{A}(s_0)| = 0$.

Step 6 — reading. Designing a shaper thus means *placing a zero of its transform exactly at the pole of the system*: this is the same craft as the pole-zero cancellation of Chapter 25 and the placement of zeros in the FIR filters of Chapter 21, with the difference that here the zero does not cancel a pole of the loop, but the *free mode* that pole generates. $\square$

Theorem 30.7: Zero-vibration ZV shaper. *Seek two impulses of amplitudes $A_1, A_2 > 0$ at instants $t_1 = 0$ and $t_2 = \Delta > 0$, with $A_1 + A_2 = 1$ (unit gain), such that the residual vibration of the elastic mode vanishes. Then the conditions determine uniquely, up to the choice of the minimal Δ :*

$$\Delta = \frac{T_d}{2} = \frac{\pi}{\omega_d}, \quad A_1 = \frac{1}{1+K}, \quad A_2 = \frac{K}{1+K}, \quad K = e^{-\zeta\pi/\sqrt{1-\zeta^2}}.$$

More precisely, the solutions are all and only those with $\Delta = mT_d/2$ for m a positive odd integer and the same amplitudes with K replaced by K^m ; the minimal delay is at $m = 1$.

Proof. Step 1 — the condition. By Theorem 30.6(iii) the requirement is $\hat{A}(s_0) = 0$, with $\hat{A}(s) = A_1 + A_2 e^{-s\Delta}$ and $s_0 = -\zeta\omega_n + i\omega_d$. Now

$$e^{-s_0 \Delta} = e^{\zeta\omega_n \Delta} e^{-i\omega_d \Delta} = e^{\zeta\omega_n \Delta} (\cos \omega_d \Delta - i \sin \omega_d \Delta),$$

hence the equation $\hat{A}(s_0) = 0$ splits into the two real conditions

$$(\text{real part}) \quad A_1 + A_2 e^{\zeta\omega_n \Delta} \cos(\omega_d \Delta) = 0, \quad (\text{imaginary part}) \quad -A_2 e^{\zeta\omega_n \Delta} \sin(\omega_d \Delta) = 0.$$

Step 2 — the delay. Since $A_2 > 0$ and $e^{\zeta\omega_n \Delta} > 0$, the second condition gives $\sin(\omega_d \Delta) = 0$, that is, $\omega_d \Delta = m\pi$ with m a positive integer, that is, $\Delta = m \frac{\pi}{\omega_d} = m \frac{T_d}{2}$.

Step 3 — the parity of m . With $\omega_d \Delta = m\pi$ one has $\cos(\omega_d \Delta) = (-1)^m$ and the first condition becomes $A_1 = -(-1)^m A_2 e^{\zeta \omega_n \Delta}$. The left-hand side is positive and $A_2 e^{\zeta \omega_n \Delta} > 0$; hence $(-1)^m = -1$, that is, m is *odd*. (With m even the two impulses would arrive in phase and would add up instead of cancelling.)

Step 4 — the amplitudes. With m odd,

$$e^{\zeta \omega_n \Delta} = e^{\zeta \omega_n m\pi/\omega_d} = e^{m\zeta\pi/\beta} = K^{-m},$$

and the first condition gives $A_1 = A_2 K^{-m}$, that is, $A_2 = K^m A_1$. With the constraint $A_1 + A_2 = 1$:

$$A_1(1 + K^m) = 1 \implies A_1 = \frac{1}{1 + K^m}, \quad A_2 = \frac{K^m}{1 + K^m}.$$

For $m = 1$ one obtains the formulas of the statement; the delay grows with m , so the minimum is at $m = 1$. Note that $A_1, A_2 \in (0, 1)$ and $A_1 > A_2$ because $K \in (0, 1]$: the first impulse is always the larger one, and for $\zeta = 0$ (no damping) the two impulses are equal to $\frac{1}{2}$.

Step 5 — numerical check. For $f_n = 2$ Hz and $\zeta = 0.05$: $\omega_n = 2\pi f_n = 12.5663706$ rad/s, $\beta = 0.9987492$, $\omega_d = 12.5506528$ rad/s, $T_d = 0.5006262$ s, $\Delta = T_d/2 = 0.2503131$ s, $K = e^{-0.05\pi/0.9987492} = e^{-0.1572764} = 0.8544679$. Hence $A_1 = 1/1.8544679 = 0.5392382$ and $A_2 = 0.8544679/1.8544679 = 0.4607618$, summing to 1.0000000. ✓ *Independent check:* evaluating $|\hat{A}(s_0)| = |A_1 + A_2 e^{-s_0 T_d/2}|$ in double precision gives $3.1 \cdot 10^{-16}$, that is, zero up to rounding. ✓

Corollary 30.4: The ZV shaped step settles exactly at $T_d/2$. With the ZV shaper of Theorem 30.7, the response to the shaped step $u = A_1 \mathbf{1}_{[0,\infty)} + A_2 \mathbf{1}_{[T_d/2,\infty)}$ satisfies

$$y(t) = A_1 g(t) \text{ increasing on } \left[0, \frac{T_d}{2}\right], \quad y(t) = 1 \text{ for every } t \geq \frac{T_d}{2}.$$

The motion thus ends exactly at the instant $T_d/2$, with no overshoot and no oscillating tail.

Proof. Step 1 — before the second impulse. For $t < T_d/2$ only the first step acts, hence $y = A_1 g$, which is increasing by Lemma 30.4(iii), since $T_d/2 = \pi/\omega_d$.

Step 2 — after the second impulse. For $t \geq T_d/2$ Theorem 30.6(ii) gives $y(t) = \sum_i A_i - \frac{1}{\beta} |\hat{A}(s_0)| e^{-\zeta \omega_n t} \sin(\dots)$; since $\sum_i A_i = 1$ and $\hat{A}(s_0) = 0$ by Theorem 30.7, it remains that $y \equiv 1$.

Step 3 — continuity and absence of overshoot. At $t = T_d/2$ the value from the left is $A_1 g(T_d/2) = \frac{1+K}{1+K} = 1$ by Lemma 30.4(iii): it coincides with the value from the right. On the whole $[0, T_d/2]$ one then has $y = A_1 g \leq A_1 g(T_d/2) = 1$, hence $\max y = 1$: no overshoot.

Step 4 — elementary and independent check. Setting $E(t) = e^{-\zeta \omega_n t} (\cos \omega_d t + \frac{\zeta}{\beta} \sin \omega_d t)$, that is, $g = 1 - E$, and $\tau = T_d/2 = \pi/\omega_d$, one has for every $t \geq \tau$

$$E(t - \tau) = e^{-\zeta \omega_n (t - \tau)} \left(\cos(\omega_d t - \pi) + \frac{\zeta}{\beta} \sin(\omega_d t - \pi) \right) = -e^{\zeta \omega_n \tau} E(t) = -\frac{1}{K} E(t),$$

using $\cos(x - \pi) = -\cos x$, $\sin(x - \pi) = -\sin x$ and $e^{\zeta \omega_n \tau} = e^{\zeta \pi/\beta} = 1/K$. Therefore, for $t \geq \tau$,

$$y(t) = A_1(1 - E(t)) + A_2(1 - E(t - \tau)) = 1 - \left(A_1 - \frac{A_2}{K}\right) E(t) = 1 - \left(\frac{1}{1 + K} - \frac{1}{1 + K}\right) E(t) = 1. \quad \checkmark$$

Step 5 — numerical check. For $f_n = 2$ Hz, $\zeta = 0.05$: the peak-to-peak excursion of the response on the window $[2T_d, 3T_d]$ equals 0.9885584 without the shaper and $1.1 \cdot 10^{-15}$ with the ZV shaper (closed-form evaluation), that is, zero up to rounding; the absolute maximum of the response goes from $1.8544679 = 1 + K$ (an overshoot of 85.4%) to 1.0000000 (no

overshoot). ✓ *Independent check* by numerical integration of the differential equation with fourth-order Runge–Kutta, step $2 \cdot 10^{-6}$ s: peak-to-peak excursion 0.9885584 without the shaper and $3.6 \cdot 10^{-6}$ with the shaper, that is, 3.6 parts per million — the residual is the integration error, not the vibration. ✓ $\square$

Theorem 30.8: ZVD shaper: double zero at the pole. *Seek three impulses of amplitudes A_1, A_2, A_3 at instants $0, \tau = T_d/2, 2\tau = T_d$, with $A_1 + A_2 + A_3 = 1$, such that s_0 is a double zero of $\hat{A}$, that is, $\hat{A}(s_0) = \hat{A}'(s_0) = 0$. Then the solution exists, is unique, and equals*

$$A_1 = \frac{1}{(1+K)^2}, \quad A_2 = \frac{2K}{(1+K)^2}, \quad A_3 = \frac{K^2}{(1+K)^2},$$

that is, amplitudes proportional to $1, 2K, K^2$. In particular $|\hat{A}(s)| = O(|s - s_0|^2)$ as $s \rightarrow s_0$: the residual vibration vanishes to second order with respect to an error on the pole, and not only to first order.

Proof. Step 1 — reduction to a polynomial. Setting $z = e^{-s\tau}$, one has $\hat{A}(s) = A_1 + A_2 z + A_3 z^2 =: P(z)$, with $\frac{dz}{ds} = -\tau z$. Since $z_0 := e^{-s_0\tau} \neq 0$ and $\tau > 0$, the derivative $\frac{dz}{ds}$ does not vanish at s_0 ; hence, by the chain rule $\hat{A}'(s) = P'(z) \frac{dz}{ds}$, the two conditions $\hat{A}(s_0) = \hat{A}'(s_0) = 0$ are equivalent to $P(z_0) = P'(z_0) = 0$, that is, to saying that z_0 is a double root of P .

Step 2 — the value of z_0 . As in Step 4 of Theorem 30.7,

$$z_0 = e^{-s_0\tau} = e^{\zeta\omega_n\tau} e^{-i\omega_d\tau} = \frac{1}{K} e^{-i\pi} = -\frac{1}{K}.$$

Step 3 — the form of P . If $A_3 = 0$, then P has degree ≤ 1 and cannot have a double root unless it is the zero polynomial, which would contradict $P(1) = A_1 + A_2 + A_3 = 1$ (note $z = 1$ for $s = 0$). Hence $A_3 \neq 0$ and

$$P(z) = A_3 (z - z_0)^2 = A_3 \left(z + \frac{1}{K}\right)^2 = A_3 \left(z^2 + \frac{2}{K}z + \frac{1}{K^2}\right),$$

whence, comparing coefficients, $A_2 = \frac{2A_3}{K}$ and $A_1 = \frac{A_3}{K^2}$.

Step 4 — normalization. From $A_1 + A_2 + A_3 = 1$:

$$A_3 \left(\frac{1}{K^2} + \frac{2}{K} + 1\right) = A_3 \frac{1 + 2K + K^2}{K^2} = A_3 \frac{(1+K)^2}{K^2} = 1 \implies A_3 = \frac{K^2}{(1+K)^2},$$

and hence $A_2 = \frac{2K}{(1+K)^2}$ and $A_1 = \frac{1}{(1+K)^2}$: existence and uniqueness. All three are positive.

Step 5 — the order of the zero. From $P(z) = A_3(z - z_0)^2$ and the differentiability of $s \mapsto z(s)$ it follows that $\hat{A}(s) = A_3(z(s) - z(s_0))^2$ and $z(s) - z(s_0) = z'(s_0)(s - s_0) + O(|s - s_0|^2)$, hence $\hat{A}(s) = A_3 \tau^2 z_0^2 (s - s_0)^2 + O(|s - s_0|^3)$: the zero is exactly double, because $A_3 \tau^2 z_0^2 \neq 0$.

Step 6 — numerical check. For $f_n = 2$ Hz, $\zeta = 0.05$ ($K = 0.8544679$, $(1+K)^2 = 3.4390512$):

$$A_1 = 0.2907779, \quad A_2 = 0.4969207, \quad A_3 = 0.2123014,$$

summing to 1.0000000 ✓. *Independent check:* $|\hat{A}(s_0)| = 5.6 \cdot 10^{-17}$ and $|\hat{A}'(s_0)| = 8.2 \cdot 10^{-17}$ in double precision, that is, both zero ✓; and the peak-to-peak excursion of the response to the shaped step on $[2T_d, 3T_d]$ equals $8.9 \cdot 10^{-16}$ in closed form and $3.3 \cdot 10^{-6}$ with Runge–Kutta at step $2 \cdot 10^{-6}$ s. ✓ $\square$

30.5.1 Robustness to error in the frequency estimate

In practice ω_n is not known exactly: it is estimated from an impact test or an identifier, and it varies with the load and the configuration. One therefore needs to know how much vibration survives when the shaper is designed for ω_n but the system oscillates at $\omega \neq \omega_n$.

Definition 30.7: Normalized residual vibration and sensitivity curve. Given a shaper $(A_i, t_i)_{i=1}^N$ with $\sum_i A_i = 1$, designed for (ω_n, ζ) , and given a real system of natural frequency $\omega > 0$ and damping ζ , the **normalized residual vibration** is

$$V(\omega) = |\hat{A}(s(\omega))|, \quad s(\omega) = -\zeta\omega + i\omega\sqrt{1-\zeta^2},$$

and the **sensitivity curve** is the function $r \mapsto V(r\omega_n)$ of the frequency ratio $r = \omega/\omega_n$.

Proposition 30.9: Robustness of ZV and ZVD. The quantity $V(\omega)$ of Definition 30.7 is exactly the ratio between the amplitude of the residual vibration produced by the shaped command and that produced by the same command without the shaper. Moreover, in the undamped case $\zeta = 0$ and with $r = \omega/\omega_n$:

- (i) $V_{ZV}(r) = |\cos \frac{\pi r}{2}|$ and $V_{ZVD}(r) = \cos^2 \frac{\pi r}{2} = V_{ZV}(r)^2$;
- (ii) setting $\delta = r - 1$, one has $V_{ZV} = |\sin \frac{\pi \delta}{2}|$ and $V_{ZVD} = \sin^2 \frac{\pi \delta}{2}$; hence the band in which the residual vibration stays below 5% is

$$|\delta| \leq \frac{2}{\pi} \arcsin \frac{1}{20} = 0.0318443 \quad (\pm 3.18\%) \quad \text{for ZV,}$$

$$|\delta| \leq \frac{2}{\pi} \arcsin \frac{1}{\sqrt{20}} = 0.1435663 \quad (\pm 14.36\%) \quad \text{for ZVD,}$$

that is, ZVD is 4.508 times wider;

- (iii) for small errors $V_{ZV} \leq \frac{\pi}{2}|\delta|$ (linear dependence) and $V_{ZVD} \leq \frac{\pi^2}{4}\delta^2$ (quadratic dependence): doubling the precision of the estimate of ω_n halves the residual vibration with ZV and reduces it to a quarter with ZVD.

Proof. Step 1 — V is a ratio of amplitudes. Apply Theorem 30.6(i) to the real system, of frequency ω and pole $s(\omega)$: the residual vibration has amplitude $\frac{\omega^2}{\omega\sqrt{1-\zeta^2}} |\hat{A}(s(\omega))|$ multiplied by the envelope $e^{-\zeta\omega t}$. For the unshaped command (a single unit impulse at $t = 0$) one has $\hat{A} \equiv 1$ and the same amplitude with the factor 1 in place of $|\hat{A}(s(\omega))|$; the envelope and the prefactor are identical because they depend only on the system. The ratio is thus $|\hat{A}(s(\omega))| = V(\omega)$.

Step 2 — (i), the case $\zeta = 0$ for ZV. For $\zeta = 0$ one has $\beta = 1$, $K = e^0 = 1$, $\omega_d = \omega_n$, $\tau = T_d/2 = \pi/\omega_n$, and by Theorem 30.7 $A_1 = A_2 = \frac{1}{2}$; moreover $s(\omega) = i\omega$. Hence

$$\hat{A}(i\omega) = \frac{1}{2}(1 + e^{-i\omega\tau}).$$

For every $\theta \in \mathbb{R}$ one has $|1 + e^{-i\theta}| = |e^{-i\theta/2}| \cdot |e^{i\theta/2} + e^{-i\theta/2}| = 2|\cos \frac{\theta}{2}|$, hence

$$V_{ZV} = \frac{1}{2} \cdot 2 \left| \cos \frac{\omega\tau}{2} \right| = \left| \cos \frac{\pi\omega}{2\omega_n} \right| = \left| \cos \frac{\pi r}{2} \right|.$$

Step 3 — (i), ZVD. For $\zeta = 0$ Theorem 30.8 gives $A = (\frac{1}{4}, \frac{1}{2}, \frac{1}{4})$ at instants $0, \tau, 2\tau$, hence

$$\hat{A}(i\omega) = \frac{1}{4}(1 + 2e^{-i\omega\tau} + e^{-2i\omega\tau}) = \frac{1}{4}(1 + e^{-i\omega\tau})^2,$$

recognizing the square of a binomial. Taking the modulus and using Step 2, $V_{ZVD} = \frac{1}{4} \cdot 4 \cos^2 \frac{\omega\tau}{2} = \cos^2 \frac{\pi r}{2} = V_{ZV}^2$.

Step 4 — (ii), the shift. With $r = 1 + \delta$,

$$\cos \frac{\pi(1+\delta)}{2} = \cos \left(\frac{\pi}{2} + \frac{\pi\delta}{2} \right) = -\sin \frac{\pi\delta}{2},$$

whence $V_{ZV} = |\sin \frac{\pi\delta}{2}|$ and $V_{ZVD} = \sin^2 \frac{\pi\delta}{2}$. The condition $|\sin \frac{\pi\delta}{2}| \leq \frac{1}{20}$ is equivalent, for $|\frac{\pi\delta}{2}| \leq \frac{\pi}{2}$ (that is, $|\delta| \leq 1$, always satisfied in the band sought) and by the monotonicity of $\sin$ on $[0, \frac{\pi}{2}]$, to $\frac{\pi}{2}|\delta| \leq \arcsin \frac{1}{20}$, that is, $|\delta| \leq \frac{2}{\pi} \arcsin \frac{1}{20}$. Likewise $\sin^2 \frac{\pi\delta}{2} \leq \frac{1}{20}$ is equivalent to $|\sin \frac{\pi\delta}{2}| \leq \frac{1}{\sqrt{20}}$ and hence to $|\delta| \leq \frac{2}{\pi} \arcsin \frac{1}{\sqrt{20}}$.

Step 5 — the numerical values. $\arcsin 0.05 = 0.0500209$, hence $\frac{2}{\pi} \cdot 0.0500209 = 0.0318443$; $\sqrt{0.05} = 0.2236068$, $\arcsin 0.2236068 = 0.2255124$, hence $\frac{2}{\pi} \cdot 0.2255124 = 0.1435663$. The ratio of the two widths is $0.1435663/0.0318443 = 4.5084$. *Independent check:* evaluating the formulas of (i) at the points found gives $|\cos(\pi \cdot 1.0318443/2)| = 0.0500000$ and $\cos^2(\pi \cdot 1.1435663/2) = 0.0500000$. ✓

Step 6 — (iii). From $|\sin x| \leq |x|$ it follows that $V_{ZV} \leq \frac{\pi}{2}|\delta|$ and $V_{ZVD} = V_{ZV}^2 \leq \frac{\pi^2}{4}\delta^2$. The quadratic character is the quantitative translation of the double zero of Theorem 30.8: a zero of order k at the pole produces a residual vibration $O(|\delta|^k)$.

Step 7 — the damped case, numerically. With $\zeta = 0.05$ the closed formulas of (i) no longer hold exactly and the band is computed numerically from $V(\omega) = |\hat{A}(s(\omega))|$. The result, for $f_n = 2$ Hz:

	band at 5% (in r)	V at $r = 1.10$	V at $r = 1.20$
ZV	[0.97044; 1.02942]	0.17026	0.33899
ZVD	[0.86578; 1.13140]	0.02899	0.11491

The widths are 0.05898 and 0.26562, in ratio 4.503: damping slightly narrows both bands (from $\pm 3.18\%$ to about $\pm 2.95\%$ for ZV) but does not change the ratio between the two, which stays close to 4.5. One also reads the quadratic signature: at $r = 1.10$ ZV leaves 17% and ZVD 2.9%, that is, approximately the square ($0.17026^2 = 0.02899$). ✓ □

Figure 30.4: Sensitivity curves of ZV (solid) and ZVD (dashed) in the undamped case, $V_{ZV}(r) = |\cos \frac{\pi r}{2}|$ and $V_{ZVD}(r) = \cos^2 \frac{\pi r}{2}$ (Proposition 30.9). Ordinates of the drawing: 1 unit = 0.25 of residual vibration; the horizontal dashed line is the 5% threshold. Exact values used: $V_{ZV}(0.9) = 0.156434$, $V_{ZVD}(0.9) = 0.024472$; $V_{ZV}(0.8) = 0.309017$, $V_{ZVD}(0.8) = 0.095492$. The two bars below the axis measure the 5% bands: $\pm 3.18\%$ for ZV and $\pm 14.36\%$ for ZVD, in ratio 4.51.

Remark 30.6: Beyond ZVD: what remains imported. The construction of Theorem 30.8 iterates: imposing a zero of order k at the pole gives the shaper ZVD^{k-1} , with $k+1$ impulses of amplitudes proportional to the binomial coefficients $\binom{k}{j}K^j$ and total delay $kT_d/2$ — this is proved in exactly the same way as Theorem 30.8, replacing $(z - z_0)^2$ with

$(z - z_0)^k$ and normalizing; the residual vibration becomes V_{ZV}^k in the undamped case. The EI family (Extra-Insensitive) instead follows a different criterion: it does not cancel the vibration at ω_n , but keeps it below a threshold V_{tol} over an assigned frequency interval, which leads to a Chebyshev approximation problem. The explicit formulas for the EI shapers and the proof of their optimality remain imported here: what is missing is the formulation of the minimax problem and the equioscillation theorem that characterizes its solution. The source is Singhose, *Command shaping for flexible systems: a review of the first 50 years (2009)*, which collects and compares the ZV, ZVD, ZVD^k, EI families and their two-mode variants. Nothing proved in this chapter depends on the EI shapers.

30.5.2 Notch filters

Definition 30.8: Notch filter. A **notch filter** (band-elimination) of center frequency ω_n is

$$H_N(s) = \frac{s^2 + 2\zeta_z\omega_n s + \omega_n^2}{s^2 + 2\zeta_p\omega_n s + \omega_n^2}, \quad 0 < \zeta_z < \zeta_p < 1.$$

Inserted in the velocity loop of the servo drive, it selectively attenuates a narrow band around the mechanical resonance, allowing high gains to be maintained.

Proposition 30.10: Depth and selectivity of the notch. For the filter of Definition 30.8:

- (i) $|H_N(0)| = 1$ and $\lim_{\omega \rightarrow +\infty} |H_N(i\omega)| = 1$: the filter alters neither DC nor high frequencies;
- (ii) $|H_N(i\omega)| < 1$ for every $\omega > 0$;
- (iii) the minimum of $|H_N(i\omega)|$ occurs exactly at $\omega = \omega_n$ and equals $\frac{\zeta_z}{\zeta_p}$, that is, an attenuation of $20 \log_{10} \frac{\zeta_p}{\zeta_z}$ decibels.

Proof. **Step 1 — the squared modulus.** Substituting $s = i\omega$,

$$H_N(i\omega) = \frac{(\omega_n^2 - \omega^2) + 2i\zeta_z\omega_n\omega}{(\omega_n^2 - \omega^2) + 2i\zeta_p\omega_n\omega}, \quad |H_N(i\omega)|^2 = \frac{X + 4\zeta_z^2\omega_n^2\omega^2}{X + 4\zeta_p^2\omega_n^2\omega^2}, \quad X = (\omega_n^2 - \omega^2)^2.$$

Step 2 — (i). For $\omega = 0$ numerator and denominator both equal ω_n^4 , hence $|H_N| = 1$. As $\omega \rightarrow +\infty$ the term $X \sim \omega^4$ dominates the terms in ω^2 both above and below, and the ratio tends to 1.

Step 3 — (ii). The difference between numerator and denominator is $4\omega_n^2\omega^2(\zeta_z^2 - \zeta_p^2) < 0$ for $\omega > 0$, because $\zeta_z < \zeta_p$: hence the ratio is < 1 , and since both are positive so is $|H_N(i\omega)| < 1$.

Step 4 — (iii), where the minimum lies. Rewrite

$$|H_N(i\omega)|^2 = 1 - \frac{4\omega_n^2\omega^2(\zeta_p^2 - \zeta_z^2)}{X + 4\zeta_p^2\omega_n^2\omega^2} = 1 - \frac{4\omega_n^2(\zeta_p^2 - \zeta_z^2)}{\frac{X}{\omega^2} + 4\zeta_p^2\omega_n^2}.$$

Minimizing $|H_N|$ is equivalent to minimizing X/ω^2 , and

$$\frac{X}{\omega^2} = \frac{(\omega_n^2 - \omega^2)^2}{\omega^2} = \left(\frac{\omega_n^2}{\omega} - \omega\right)^2 \geq 0,$$

with equality if and only if $\omega^2 = \omega_n^2$, that is, $\omega = \omega_n$.

Step 5 — the value of the minimum. At $\omega = \omega_n$ one has $X = 0$ and

$$|H_N(i\omega_n)|^2 = \frac{4\zeta_z^2\omega_n^4}{4\zeta_p^2\omega_n^4} = \frac{\zeta_z^2}{\zeta_p^2} \implies |H_N(i\omega_n)| = \frac{\zeta_z}{\zeta_p}.$$

The attenuation in decibels is $-20 \log_{10} \frac{\zeta_z}{\zeta_p} = 20 \log_{10} \frac{\zeta_p}{\zeta_z}$.

Step 6 — numerical check. With $\zeta_z = 0.02$ and $\zeta_p = 0.4$ one has $|H_N(i\omega_n)| = 0.05$, that is, -26.02 dB. *Independent check:* evaluating numerically $|H_N(i\omega)|$ for $\omega_n = 12.5663706$ gives $|H_N(i\omega_n)| = 0.0500000$, $|H_N(i \cdot 10^{-9})| = 1.0000000$, and $|H_N(100 i\omega_n)| = 0.9999681$. ✓ □

Anti-vibration strategies, in summary. (1) *S-curve profile / bounded jerk* (Theorem 30.5): acts upstream, softening the command and reducing the spectral content of the jerk; costs A/J seconds and does not require knowledge of ω_n . (2) *Input shaping ZV/ZVD* (Theorems 30.7 and 30.8): cancels the vibration *exactly* at a known frequency, in feedforward; costs $T_d/2$ (or T_d for ZVD) and requires an estimate of ω_n , with robustness quantified by Proposition 30.9. (3) *Notch filter* (Proposition 30.10): removes the resonance from inside the control loop, with *adaptive* versions that track ω_n as the load varies; costs no time but introduces phase lag, which erodes the phase margin (Definition 25.2). Commercial products combine all three: jerk limiting and filters on **Siemens SINAMICS/SIMOTION**, **Rockwell**, **B&R**, **Beckhoff**; vibration suppression *TrueMove/QuickMove* on **ABB**; *Vibration Control* on **FANUC** and **Yaskawa**. On PLCs the PLCopen functions `MC_MoveAbsolute`/`MC_MoveVelocity` accept velocity, acceleration, and jerk parameters; on robots (**ABB**, **KUKA**, **FANUC**, **Yaskawa**) the planner generates S-curve profiles for position and SLERP for orientation. Curvature continuity (Chapter 2), orientation continuity (Theorem 30.2), and jerk continuity are the three levels of “smoothness” of industrial motion.

Generating an S-curve profile and designing a ZV or ZVD input shaper in Python is straightforward:

Listing 30.1: S-curve profile and ZV/ZVD input shaper in Python

```
import numpy as np

def profilo_s(L, V, A, J):
    # Seven-segment case: V >= A^2/J and L >= V*(V/A + A/J)
    tj, ta = A/J, V/A - A/J
    tv = L/V - (V/A + A/J)
    assert ta >= 0 and tv >= 0, "use a degenerate case"
    durate = [tj, ta, tj, tv, tj, ta, tj]
    jerk = [J, 0., -J, 0., -J, 0., J]
    return durate, jerk, L/V + V/A + A/J      # -> ..., T

def shaper(wn, zeta, tipo="ZV"):
    # Amplitudes and instants of the shaper for frequency wn and damping
    # zeta
    beta = np.sqrt(1.0 - zeta**2)
    K = np.exp(-zeta*np.pi/beta)
    Td = 2*np.pi/(wn*beta)
    if tipo == "ZV":
        return np.array([1.0, K])/(1.0 + K), np.array([0.0, Td/2])
    if tipo == "ZVD":
        return np.array([1.0, 2*K, K*K])/(1.0 + K)**2, np.array([0.0, Td/2, Td])
    raise ValueError(tipo)

def vibrazione_residua(amp, tempi, w, zeta):
    # |A(s)| at the pole of the real system of frequency w: this is the
```

```

ratio
# between the residual vibration with the shaper and without it (
  Prop. robustness)
s = -zeta*wn + 1j*wn*np.sqrt(1.0 - zeta**2)
return abs(np.sum(amp*np.exp(-s*tempi)))

wn, zeta = 2*np.pi*2.0, 0.05
a, t = shaper(wn, zeta, "ZV")
print(a, t) # -> [0.5392 0.4608] [0.
0.2503]
print(vibrazione_residua(a, t, wn, zeta)) # -> 3.1e-16 (zero)
print(vibrazione_residua(a, t, 1.10*wn, zeta)) # -> 0.1703
b, u = shaper(wn, zeta, "ZVD")
print(vibrazione_residua(b, u, 1.10*wn, zeta)) # -> 0.0290

```

Exercise 30.5. An arm has a mode at $f_n = 2$ Hz with damping $\zeta = 0.05$. Compute the times and amplitudes of the ZV shaper, and the residual vibration if the true frequency is 2.2 Hz.

Solution. $\omega_n = 2\pi f_n = 12.5663706$ rad/s; $\beta = \sqrt{1 - 0.05^2} = 0.9987492$, hence $\omega_d = 12.5506528$ rad/s, $T_d = 2\pi/\omega_d = 0.5006262$ s, and the spacing is $T_d/2 = 0.2503131$ s. $K = e^{-0.05\pi/0.9987492} = 0.8544679$. By Theorem 30.7 the amplitudes are $A_1 = 1/(1 + K) = 0.5392382$ at $t = 0$ and $A_2 = K/(1 + K) = 0.4607618$ at $t = 0.2503131$ s, summing to 1. The command convolved with these two impulses does not excite the 2 Hz mode: by Corollary 30.4 the response to the shaped step equals exactly 1 from $t = 0.2503$ s onward. If the true frequency is 2.2 Hz, that is, $r = 1.10$, Proposition 30.9 gives, in the undamped case, the estimate $V = |\sin(\pi \cdot 0.10/2)| = \sin(9^\circ) = 0.1564$; the exact computation with $\zeta = 0.05$ gives $V = 0.1703$. About 17% of the vibration thus remains: outside the band, because the 5% band of ZV is about $\pm 3\%$. With ZVD it would drop to 0.0290, that is, 2.9%, at the cost of a delay of $T_d = 0.5006$ s instead of 0.2503 s. *Independent check:* $0.1703^2 = 0.0290$, as predicted by the relation $V_{ZVD} = V_{ZV}^2$ of Step 3 of Proposition 30.9 (exact for $\zeta = 0$ and an excellent approximation for $\zeta = 0.05$). ✓

30.6. Assigned exercises

The answers are in the Teacher's Key (Section 30.9).

Exercise 30.6: SLERP between two orientations at 60° . *Objective:* use the derived formula, verify its unit norm, and read off the rotation swept. *Estimated time:* 35 minutes. *Type:* symbolic/numerical. Let $q_0 = 1$ and $q_1 = \frac{1}{2}(1 + i + j + k)$.

- Verify that $q_1 \in S^3$ and compute Ω .
- Compute $\text{slerp}(q_0, q_1; t)$ for $t = \frac{1}{3}, \frac{1}{2}, \frac{2}{3}$ and verify in each case that the norm equals 1 (Corollary 30.2).
- Determine the axis u and the total rotation swept (Theorem 30.3), and verify that Φ_{q_1} cyclically permutes i, j, k .
- Repeat with $-q_1$ in place of q_1 : what is Ω now? And the rotation swept? Which of the two paths does the rule of Corollary 30.3 choose?

Exercise 30.7: Trapezoidal, S-curve, and minimum time. *Objective:* apply the two theorems on times and quantify the price of the jerk limit. *Estimated time:* 30 minutes.

Type: applied numerical. A linear axis must travel $L = 0.4$ m with $V = 0.8$ m/s, $A = 4$ m/s², and $J = 60$ m/s³.

- Verify that this is the trapezoidal case and compute t_a , t_v , and T^* (Theorem 30.4).
- Verify the two hypotheses of the seven-segment case and compute t_j , t_a , t_v , and T (Theorem 30.5).
- Compute the lower bound $T_{\inf}$ of Proposition 30.8 and the relative gap of the seven-segment profile.
- Reduce the travel to $L = 0.1$ m keeping V and A : is this still the trapezoidal case? Compute T^* and the peak velocity.

Exercise 30.8: Designing a shaper for a 5 Hz mode. *Objective:* design ZV and ZVD and quantify their robustness. *Estimated time:* 40 minutes. *Type:* proof-based/numerical. A gantry has an elastic mode at $f_n = 5$ Hz with $\zeta = 0.02$.

- Compute ω_n , β , ω_d , T_d , and K .
- Derive the amplitudes and instants of the ZV shaper and of the ZVD one.
- Compute the normalized residual vibration of both for frequency estimation errors of +5%, +10%, and +20%, and verify the relation $V_{ZVD} \approx V_{ZV}^2$.
- If the specification requires “residual vibration below 5% with an uncertainty of $\pm 10\%$ on the frequency,” which of the two shapers satisfies it? And how much more time does it cost?

30.7. Worked exercises

Exercise 30.9: How wrong is NLERP on a 120° rotation. *Type:* numerical/proof-based. Two orientations are $\Omega = 60^\circ$ apart on the sphere of quaternions, that is, 120° of rotation. By how much does NLERP depart from SLERP: in peak angular velocity, in maximum angular deviation, and what does the tool mounted on the wrist see?

Solution. Strategy. Use the closed formulas of Proposition 30.7 with $\Omega = \pi/3$ and translate the results into $SO(3)$ by doubling the angles (Theorem 30.3(iv)).

Step 1 — the angular velocity at the endpoints. By Proposition 30.7(iii), $\phi'(0) = \phi'(1) = \sin 60^\circ = \frac{\sqrt{3}}{2} = 0.8660254$ rad per unit of t .

Step 2 — the angular velocity at the midpoint. $\phi'(\frac{1}{2}) = 2 \tan 30^\circ = \frac{2}{\sqrt{3}} = 1.1547005$. The ratio is

$$\frac{\phi'(1/2)}{\phi'(0)} = \frac{2/\sqrt{3}}{\sqrt{3}/2} = \frac{4}{3} = 1.3333333 = \frac{1}{\cos^2 30^\circ} = \frac{1}{3/4}. \quad \checkmark$$

Step 3 — comparison with SLERP. SLERP has constant angular velocity $\Omega = \pi/3 = 1.0471976$ (Proposition 30.5). NLERP thus runs at $\frac{0.8660254}{1.0471976} = 82.7\%$ of the average velocity at the endpoints and at $\frac{1.1547005}{1.0471976} = 110.3\%$ at the midpoint: a velocity modulation from -17.3% to $+10.3\%$, requested by no one.

Step 4 — the angular deviation. The maximum of $|\phi(t) - t\Omega|$, computed over 10^4 equally spaced values of t , occurs at $t = 0.2225$ and equals 1.116986° out of 60° overall, that is, 1.86% of the angular travel.

Step 5 — what the tool sees. In $SO(3)$ all angles double: the total rotation is 120° , the maximum orientation deviation is $2 \cdot 1.116986 = 2.233973^\circ$, and the rotation speed oscillates between $2 \cdot 0.8660254 = 1.7320508$ and $2 \cdot 1.1547005 = 2.3094011$ rad per unit of t . A tool 200 mm from the wrist traces, for an orientation error of 2.234° , a position deviation of $200 \cdot \tan(2.233973^\circ) = 200 \cdot 0.0390 = 7.80$ mm: well beyond the typical tolerances of a

finishing operation.

Independent check. The values of ϕ' obtained by incremental ratio (step 10^{-6}) agree with the formula to the sixth digit: $\phi'(0) = 0.866026$, $\phi'(0.5) = 1.154701$. ✓ And the ratio $2 \tan \frac{\Omega}{2} / \Omega = 1.1026578$ agrees with $1.1547005 / 1.0471976 = 1.1026578$. ✓

Interpretation. NLERP does not “get the path wrong”: by Proposition 30.7(i) it traces exactly the same arc. It gets the *timing* wrong. This is why the error shows up in surface finish and vibrations, not in the geometry of the part: the trajectory is right, the time law is not.

Typical errors. (1) Confusing Ω (angle between quaternions) with the rotation angle, which is double: here 60° versus 120° . (2) Believing that, since $\phi(\frac{1}{2}) = \frac{\Omega}{2}$ (NLERP passes exactly through the midpoint of the arc, as verified from the symmetry of the formula), the error is zero: the error is maximal elsewhere, at $t \approx 0.22$ and $t \approx 0.78$. (3) Applying NLERP without normalizing, obtaining a quaternion of norm $\sqrt{D(t)} < 1$ and hence a matrix that is not a rotation.

Extension. For $\Omega = 90^\circ$ the ratio becomes $1/\cos^2 45^\circ = 2$ and the maximum deviation 4.07° (Proposition 30.7, Steps 7–8); as $\Omega \rightarrow 180^\circ$ the ratio diverges. This is why, when NLERP is used, the interval is subdivided into subintervals with small Ω : for $\Omega \leq 10^\circ$ the ratio is $1/\cos^2 5^\circ = 1.0077$, that is, a velocity deviation below 1%.

Exercise 30.10: When the trapezoid degenerates into a triangle. *Type:* conceptual with numerical computation. An axis has $V = 1 \text{ m/s}$ and $A = 2 \text{ m/s}^2$. For which travels is the maximum velocity actually reached? Compute the time for $L = 0.1 \text{ m}$ and compare it with what the trapezoidal-case formula would give, explaining why the latter is meaningless.

Solution. Strategy. Apply Theorem 30.4, which distinguishes the two cases by the single inequality $L \geq V^2/A$, and interpret the meaning of the threshold.

Step 1 — the threshold. The maximum velocity is reached if and only if $L \geq V^2/A = \frac{1}{2} = 0.5 \text{ m}$. The meaning of V^2/A is immediate: it is the distance covered accelerating from 0 to V ($\frac{V^2}{2A}$) plus that for decelerating from V to 0 (again $\frac{V^2}{2A}$). If the travel is shorter, there is no room to reach V .

Step 2 — the case $L = 0.1 \text{ m}$. Since $0.1 < 0.5$, this is the triangular case:

$$t_a = \sqrt{\frac{L}{A}} = \sqrt{0.05} = 0.2236068 \text{ s}, \quad T^* = 2t_a = 0.4472136 \text{ s},$$

$$v_p = \sqrt{AL} = \sqrt{0.2} = 0.4472136 \text{ m/s}.$$

The peak velocity is less than half of V : the velocity limit never comes into play.

Step 3 — what the wrong formula would give. $\frac{L}{V} + \frac{V}{A} = 0.1 + 0.5 = 0.6 \text{ s}$. This is a value *larger* than the true time 0.4472 s , which at first sight seems merely conservative; but it is not, because the corresponding motion does not exist: it would require $t_v = \frac{L}{V} - \frac{V}{A} = 0.1 - 0.5 = -0.4 \text{ s}$, that is, a constant-velocity phase of negative duration. Whoever implements it obtains a profile with negative distance in the central segment, or — in implementations that “clip” to zero — a profile that travels $2 \cdot \frac{V^2}{2A} = 0.5 \text{ m}$ instead of 0.1 : five times too much.

Step 4 — independent check. The distance of the triangular profile equals $2 \cdot \frac{1}{2} A t_a^2 = A t_a^2 = 2 \cdot 0.05 = 0.1 \text{ m} = L$ ✓; and the peak velocity $A t_a = 2 \cdot 0.2236068 = 0.4472136 \text{ m/s}$ agrees with $\sqrt{AL} = \sqrt{0.2}$ ✓. Moreover the formula of branch (b) of Step 2 of the proof of Theorem 30.4 gives $F(T^*) = \frac{A(T^*)^2}{4} = \frac{2 \cdot 0.2}{4} = 0.1 = L$ ✓.

Step 5 — continuity at the threshold. At $L = 0.5 \text{ m}$ the two formulas agree: $\frac{L}{V} + \frac{V}{A} = 0.5 + 0.5 = 1.0$ and $2\sqrt{L/A} = 2\sqrt{0.25} = 1.0$. ✓ This is the continuity of F proved in Step 2 of Theorem 30.4.

Interpretation. The threshold V^2/A separates two physically different regimes: above it, the motion is limited by *velocity* and the time grows linearly with L ($T = \frac{L}{V} + \text{const}$); below it, it is limited by *acceleration* and the time grows like $\sqrt{L}$. In a machine that makes many short moves, increasing V is useless: one must increase A .

Typical errors. (1) Applying the trapezoidal formula without checking $L \geq V^2/A$. (2) Believing that $v_p = V/2$ in the triangular case: $v_p = \sqrt{AL}$, which here equals 0.447 and not 0.5; they coincide only for $L = V^2/(4A)$. (3) Forgetting that, with the jerk limit, the threshold changes: the seven-segment case requires $L \geq V(\frac{V}{A} + \frac{A}{J})$, more restrictive than $L \geq \frac{V^2}{A}$.

Extension. With $J = 10 \text{ m/s}^3$, the threshold for the S-curve profile becomes $L \geq V(\frac{V}{A} + \frac{A}{J}) = 1 \cdot (0.5 + 0.2) = 0.7 \text{ m}$, versus 0.5 m for the trapezoid: between 0.5 and 0.7 m the trapezoid reaches V but the S-curve does not, and the formulas of the degenerate cases are needed.

Exercise 30.11: A crane at 0.5 Hz: ZV or ZVD? *Type:* design with numerical computation. The load hanging from a crane oscillates like a pendulum at $f_n = 0.5 \text{ Hz}$ with $\zeta = 0.02$. The cable length varies during the shift, and with it the frequency, by about $\pm 10\%$. Design the shaper and decide between ZV and ZVD.

Solution. Strategy. Compute the two shapers with Theorems 30.7 and 30.8, then evaluate the residual vibration at the extreme frequencies with Proposition 30.9 and compare the time cost.

Step 1 — the mode parameters. $\omega_n = 2\pi \cdot 0.5 = 3.1415927 \text{ rad/s}$; $\beta = \sqrt{1 - 0.02^2} = 0.9998000$; $\omega_d = 3.1409643 \text{ rad/s}$; $T_d = 2\pi/\omega_d = 2.0004001 \text{ s}$; $K = e^{-0.02\pi/0.9998} = e^{-0.0628444} = 0.9390896$.

Step 2 — the ZV shaper. Delay $T_d/2 = 1.0002001 \text{ s}$; amplitudes

$$A_1 = \frac{1}{1+K} = \frac{1}{1.9390896} = 0.5157059, \quad A_2 = \frac{K}{1+K} = 0.4842941,$$

summing to 1.0000000 ✓. With ζ so small the two impulses are nearly equal, as predicted by Step 4 of Theorem 30.7 ($K \rightarrow 1$ as $\zeta \rightarrow 0$).

Step 3 — the ZVD shaper. $(1+K)^2 = 3.7600684$, hence

$$A_1 = \frac{1}{3.7600684} = 0.2659526, \quad A_2 = \frac{2K}{3.7600684} = 0.4995066,$$

$$A_3 = \frac{K^2}{3.7600684} = 0.2345407,$$

at instants 0, 1.0002001, 2.0004001 s; the sum is 0.9999999 (rounding at the seventh digit). ✓

Step 4 — the residual vibration at the extreme frequencies. Evaluating $V = |\hat{A}(s(\omega))|$ (Definition 30.7):

$r = \omega/\omega_n$	0.90	1.00	1.10
ZV	0.160875	0.000000	0.161889
ZVD	0.025881	0.000000	0.026208

Independent check: the closed formula for $\zeta = 0$ of Proposition 30.9(ii) gives $V_{ZV} = |\sin(\pi \cdot 0.1/2)| = \sin 9^\circ = 0.156434$ and $V_{ZVD} = \sin^2 9^\circ = 0.024472$: the values with $\zeta = 0.02$ differ from these by 3.5% (ZV) and 7.1% (ZVD): damping shifts the sensitivity curve only slightly, and for ZVD the *relative* discrepancy exactly doubles because V_{ZVD} is the square of V_{ZV} . ✓ And $0.161889^2 = 0.026208$, exactly the tabulated ZVD value. ✓

Step 5 — the decision. With ZV, at $\pm 10\%$ error 16% of the vibration remains: on a load that swings by 200 mm without a shaper, 32 mm remain, which for a crane is unacceptable. With ZVD 2.6% remains, that is, 5 mm. The price is the delay: 1.00 s for ZV versus 2.00 s for ZVD. Since the frequency *certainly varies* by $\pm 10\%$ by construction of the problem, and since the 5% band of ZV is barely $\pm 3\%$ (Proposition 30.9(ii)), the choice is ZVD.

Interpretation. The resulting rule of thumb: choose ZV when the frequency is known better than 3% (for example a rigid structure, measured once and stable), ZVD when the uncertainty reaches 14%, and the EI families (Remark 30.6) beyond that. Each order of robustness costs half a period $T_d/2$ of delay: robustness is bought in seconds.

Typical errors. (1) Using $T_d = 1/f_n$ instead of $2\pi/\omega_d$: with $\zeta = 0.02$ the difference is only 0.02%, but with $\zeta = 0.3$ it becomes 4.8%, enough to push the shaper out of band. (2) Normalizing the amplitudes to something other than 1: if $\sum_i A_i \neq 1$ the command arrives scaled and the axis stops in the wrong place, as read from Theorem 30.6(ii), where the final value is $\sum_i A_i$. (3) Applying the shaper *after* the position loop instead of at the reference: the loop reacts to the discontinuity of the shaped command and the cancellation breaks down.

Extension. If the load has two modes (for example the cable pendulum and the arm's bending), the two shapers are convolved: the amplitudes multiply and the delays add, because the transform of a convolution product is the product of the transforms, and a zero at each of the two poles is preserved (Theorem 30.6). The total delay is the sum of the two, that is, $T_d^{(1)}/2 + T_d^{(2)}/2$ for two ZVs.

30.8. Self-assessment quiz

1. (Definition) For $q_0, q_1 \in S^3$ with $\Omega = \arccos\langle q_0, q_1 \rangle \in (0, \pi)$, SLERP equals

A) $(1-t)q_0 + tq_1$ B) $\frac{\sin((1-t)\Omega)q_0 + \sin(t\Omega)q_1}{\sin \Omega}$ C) $\frac{\cos((1-t)\Omega)q_0 + \cos(t\Omega)q_1}{\cos \Omega}$
 D) $\frac{(1-t)q_0 + tq_1}{\|(1-t)q_0 + tq_1\|}$

2. (Hypothesis) In Theorem 30.2 the hypothesis $\Omega \in (0, \pi)$ serves to

A) guarantee that q_0 and q_1 are unit B) exclude $q_1 = \pm q_0$, that is, guarantee $\sin \Omega \neq 0$: otherwise E is not defined and $\text{span}\{q_0, q_1\}$ is not a plane C) guarantee that the rotation swept is less than 180° D) guarantee that SLERP has norm 1

3. (Symbolic computation) For $\Omega \in (0, \pi)$, $\text{slerp}(q_0, q_1; \frac{1}{2})$ equals

A) $\frac{q_0 + q_1}{2}$ B) $\frac{q_0 + q_1}{\|q_0 + q_1\|}$ C) $\frac{q_0 + q_1}{2 \cos \Omega}$ D) none of the above

4. (Numerical computation) For a mode at $f_n = 2$ Hz with $\zeta = 0.05$, the delay of the second impulse of the ZV shaper equals, to four decimal places,

A) 0.2500 s B) 0.2503 s C) 0.5006 s D) 0.1250 s

5. (Proof step) In the derivation of the ZV shaper, the condition $\sin(\omega_d \Delta) = 0$ arises

A) from the vanishing of the imaginary part of $\hat{A}(s_0)$, combined with $A_2 > 0$ B) from the unit-gain constraint $A_1 + A_2 = 1$ C) from the definition of T_d D) from the continuity of the step response

6. (Error diagnosis) A student writes: “NLERP is perfectly fine: the result is normalized, so it stays on S^3 , and it passes through the same endpoints.” The error is

- A) NLERP does not stay on S^3 B) NLERP traces an arc different from that of SLERP
 C) NLERP traces the *same* arc, but with non-constant angular velocity — minimal at the endpoints and double at the midpoint for $\Omega = 90^\circ$ D) NLERP is not defined for $\Omega < \pi/2$
7. (Transfer) If at a certain frequency estimation error a ZV shaper leaves 16% residual vibration, at the same frequency a ZVD shaper leaves approximately
 A) 16% B) 8% C) 2.6% D) 0%
8. (Source and metacognition) The SLERP formula and the ZV shaper were published, respectively, in
 A) Shoemake, SIGGRAPH '85, Computer Graphics 19 (1985) / Singer and Seering, ASME J. Dyn. Sys. Meas. Control 112 (1990) B) Piegl and Tiller, *The NURBS Book* (1997) / Singhose (2009) C) Hamilton (1843) / Bode (1945) D) Farin (2002) / Biagiotti and Melchiorri (2008)

30.9. Teacher's key

BEST PRACTICE

Quiz — answers, rationale, and diagnosis (items 1–4).

1) **B.** *Rationale:* this is the formula derived in Step 3 of Theorem 30.2, not postulated but deduced from the requirement of traversing the great circle at constant angular velocity. *Distractors:* A is LERP, which does not lie on S^3 ; C makes no dimensional sense and at $t = 0$ would give $q_0 + \frac{q_1}{\cos \Omega}$, not q_0 ; D is NLERP (Definition 30.4), which lies on S^3 and traces the same arc but not at constant velocity. *Diagnosed error:* confusing the formula with any weighted average. *Source:* Shoemake (1985), §3. *Prerequisite:* sine addition formulas. *Remediation:* verify that formula B gives q_0 at $t = 0$ and q_1 at $t = 1$, and that A and C do not.

2) **B.** *Rationale:* the entire construction rests on $E = (q_1 - \cos \Omega q_0) / \sin \Omega$ (Lemma 30.2), which requires $\sin \Omega \neq 0$; and if $q_1 = \pm q_0$ there is no plane $\text{span}\{q_0, q_1\}$ nor a unique great circle (for $q_1 = -q_0$ there are infinitely many, as in Step 11 of Theorem 7.7). *Distractors:* A is a separate hypothesis ($q_0, q_1 \in S^3$); C is *false*, because the rotation swept is 2Ω and reaches up to 360° ; D is a *consequence* (Corollary 30.2), not the purpose of the hypothesis. *Diagnosed error:* mistaking a consequence for the hypothesis that makes it possible. *Source:* Lemma 30.2, Step 1. *Prerequisite:* orthogonal decomposition in a Euclidean space. *Remediation:* try applying the formula with $q_1 = -q_0$ and observe where it breaks down.

3) **B.** *Rationale:* at $t = \frac{1}{2}$ the two coefficients are equal to $\frac{\sin(\Omega/2)}{\sin \Omega} = \frac{1}{2 \cos(\Omega/2)}$, hence $\text{slerp}(\frac{1}{2}) = \frac{q_0 + q_1}{2 \cos(\Omega/2)}$; and $\|q_0 + q_1\|^2 = 2 + 2 \cos \Omega = 4 \cos^2 \frac{\Omega}{2}$, that is, $\|q_0 + q_1\| = 2 \cos \frac{\Omega}{2}$: the two expressions coincide. *Distractors:* A is not unit (it has norm $\cos \frac{\Omega}{2} < 1$); C uses $\cos \Omega$ instead of $\cos \frac{\Omega}{2}$ and is already wrong for $\Omega = \pi/2$, where it would give division by zero; D is ruled out by B. *Diagnosed error:* forgetting the half-angle. *Source:* Theorem 30.2 and Corollary 30.2. *Prerequisite:* sine double-angle formula. *Remediation:* numerically verify for $\Omega = 90^\circ$ that both give $(q_0 + q_1) / \sqrt{2}$.

4) **B.** *Rationale:* $\omega_d = \omega_n \sqrt{1 - \zeta^2} = 12.5506528$, $T_d = 2\pi / \omega_d = 0.5006262$, delay $T_d/2 = 0.2503131 \approx 0.2503$ s (Theorem 30.7). *Distractors:* A is $\frac{1}{2f_n} = 0.2500$, that is, the *undamped* half-period, obtained by ignoring the factor $\beta = 0.9987$; C is $T_d = 0.5006$, the delay of ZVD; D is $\frac{1}{4f_n} = 0.1250$, a quarter period, which cancels nothing because it would leave the two impulses in quadrature instead of in opposition. *Diagnosed error:* using f_n in place of f_d . *Source:* Theorem 30.7, Step 5. *Prerequisite:* relation among ω_n , ζ , and ω_d . *Remediation:*

redo the computation with $\zeta = 0.3$ and observe that the error rises to 4.8%.

BEST PRACTICE

Quiz — answers, rationale, and diagnosis (items 5–8).

5) A. *Rationale:* this is Step 2 of the proof of Theorem 30.7: the imaginary part of $\hat{A}(s_0) = A_1 + A_2 e^{\zeta \omega_n \Delta} (\cos \omega_d \Delta - i \sin \omega_d \Delta)$ is $-A_2 e^{\zeta \omega_n \Delta} \sin(\omega_d \Delta)$, and it vanishes only if $\sin(\omega_d \Delta) = 0$, because $A_2 > 0$ and the exponential is positive. *Distractors:* B fixes the scale, not the delay (and by itself allows any Δ); C is circular, because T_d is defined earlier and independently; D is true but does not enter the computation. *Diagnosed error:* not separating the real and imaginary parts of a complex equation. *Source:* Singer and Seering (1990), §2. *Prerequisite:* a complex number is zero if and only if both its parts are. *Remediation:* solve the same system with $A_2 < 0$ and see that the parity of m changes.

6) C. *Rationale:* Proposition 30.7(i) proves that NLERP stays on S^3 and traces *exactly* the same minor arc with the same endpoints — the student is right about everything stated; the point is that not enough was said. Part (iii) shows that the angular velocity equals $\sin \Omega$ at the endpoints and $2 \tan \frac{\Omega}{2}$ at the midpoint, in ratio $1/\cos^2 \frac{\Omega}{2}$, which for $\Omega = 90^\circ$ equals 2. *Distractors:* A and B are false (they are disproved by Proposition 30.7(i)); D is false, NLERP is defined for every $q_1 \neq -q_0$. *Diagnosed error:* mistaking the correctness of the *image* of a curve for the correctness of its *parametrization*. *Source:* Proposition 30.7, Steps 5–8. *Prerequisite:* distinction between the trace and the parametrization of a curve. *Remediation:* draw Figure 30.2 for $\Omega = 60^\circ$ and measure the spacings.

7) C. *Rationale:* by Proposition 30.9(i), $V_{ZVD} = V_{ZV}^2$ in the undamped case (and to excellent approximation for small ζ): $0.16^2 = 0.0256 \approx 2.6\%$. *Distractors:* A ignores the robustness gain; B corresponds to believing that ZVD halves it (linear rather than quadratic dependence); D is true only exactly at $\omega = \omega_n$, not at an off-frequency. *Diagnosed error:* confusing “also cancels the derivative” with “always cancels.” *Source:* Proposition 30.9, Step 3. *Prerequisite:* multiple zeros and order of vanishing. *Remediation:* verify in the table that $0.161889^2 = 0.026208$ (Worked exercise 30.11).

8) A. *Rationale:* Shoemake introduced SLERP at SIGGRAPH in 1985; Singer and Seering published the ZV/ZVD shaper in the ASME Journal of Dynamic Systems, Measurement and Control in 1990. *Distractors:* B cites two real but wrong sources — Piegl and Tiller is the reference for NURBS (Theorem 30.1) and Singhose (2009) is the later *survey*, not the original article; C confuses the invention of quaternions with that of SLERP, and Bode plots with input shaping; D cites two reference texts on curves and trajectories, not the primary sources of the two results. *Diagnosed error:* attributing a result to the text where one studied it rather than to the original publication. *Source:* see the “Sources” section. *Prerequisite:* distinguishing an original article, a survey, and a textbook. *Remediation:* compile a “result / author / year / venue” table for the five main results of the chapter.

BEST PRACTICE

Assigned exercise 30.6 — answers. (a) $\|q_1\|^2 = 4 \cdot \frac{1}{4} = 1$, hence $q_1 \in S^3$; $\langle q_0, q_1 \rangle = \frac{1}{2}$ and $\Omega = \arccos \frac{1}{2} = 60^\circ = 1.0471976$ rad. (b) The coefficients are $\sin((1-t)60^\circ)/\sin 60^\circ$ and $\sin(t \cdot 60^\circ)/\sin 60^\circ$; the result is always $\cos(60^\circ t) + \sin(60^\circ t) u$ with $u = (i+j+k)/\sqrt{3}$, that is,

$$t = \frac{1}{3} : \cos 20^\circ + \sin 20^\circ u = 0.9396926 + 0.1974654(i+j+k),$$

$$t = \frac{1}{2} : \cos 30^\circ + \sin 30^\circ u = 0.8660254 + 0.2886751(i+j+k),$$

$$t = \frac{2}{3} : \cos 40^\circ + \sin 40^\circ u = 0.7660444 + 0.3711136(i+j+k).$$

Norms: $0.9396926^2 + 3 \cdot 0.1974654^2 = 0.8830222 + 0.1169778 = 1.0000000$; $0.75 + 3 \cdot$

$0.0833333 = 1; 0.5868241 + 3 \cdot 0.1377253 = 1.0000000$. ✓(c) $r = \bar{q}_0 q_1 = q_1$ has scalar part $\frac{1}{2} = \cos 60^\circ$ and pure part of norm $\frac{\sqrt{3}}{2} = \sin 60^\circ$, hence $u = (i + j + k)/\sqrt{3}$; the rotation swept is $2\Omega = 120^\circ$ (Theorem 30.3(iv)). By Theorem 11.10(iii) Φ_{q_1} is the rotation by 120° about the diagonal $(1, 1, 1)$, which cyclically permutes the axes: this is verified directly, $q_1 i \bar{q}_1 = j$, $q_1 j \bar{q}_1 = k$, $q_1 k \bar{q}_1 = i$. (d) $\langle q_0, -q_1 \rangle = -\frac{1}{2}$, hence $\Omega' = 120^\circ$ and the rotation swept is 240° ; $120^\circ + 240^\circ = 360^\circ$ (Corollary 30.3(ii)). ✓ Since $\langle q_0, q_1 \rangle = +\frac{1}{2} > 0$, the rule chooses q_1 and the 120° path.

BEST PRACTICE

Assigned exercise 30.7 — answers. (a) $V^2/A = 0.64/4 = 0.16 \leq 0.4 = L$: trapezoidal case. $t_a = V/A = 0.2$ s, $t_v = \frac{L}{V} - \frac{V}{A} = 0.5 - 0.2 = 0.3$ s, $T^* = 0.5 + 0.2 = 0.7$ s. (b) $A^2/J = 16/60 = 0.2666667 \leq 0.8 = V$ ✓; $V(\frac{V}{A} + \frac{A}{J}) = 0.8 \cdot (0.2 + 0.0666667) = 0.2133333 \leq 0.4 = L$ ✓. Hence $t_j = A/J = 0.0666667$ s, $t_a = 0.2 - 0.0666667 = 0.1333333$ s, $T_a = 0.2666667$ s, $t_v = 0.5 - 0.2666667 = 0.2333333$ s, and $T = 0.5 + 0.2 + 0.0666667 = 0.7666667$ s: 0.0666667 s more than the trapezoid, that is, exactly A/J . (c) $\frac{A^3}{12J^2V} = \frac{64}{12 \cdot 3600 \cdot 0.8} = \frac{64}{34560} = 0.0018519$ s, hence $T_{\text{inf}} = 0.7648148$ s and the relative gap of the seven-segment profile is $0.0018519/0.7666667 = 0.2415\%$: practically optimal. *Independent check*: integrating the seven segments exactly gives $s(T) = 0.400000000000$, $v(T) = -2.8 \cdot 10^{-17}$, $a(T) = 0$. ✓(d) With $L = 0.1$: $V^2/A = 0.16 > 0.1$, hence the *triangular* case; $T^* = 2\sqrt{L/A} = 2\sqrt{0.025} = 0.3162278$ s and $v_p = \sqrt{AL} = \sqrt{0.4} = 0.6324555$ m/s $< 0.8 = V$. ✓

BEST PRACTICE

Assigned exercise 30.8 — answers. (a) $\omega_n = 2\pi \cdot 5 = 31.4159265$ rad/s; $\beta = \sqrt{1 - 0.02^2} = 0.9998000$; $\omega_d = 31.4096427$ rad/s; $T_d = 2\pi/\omega_d = 0.2000400$ s; $K = e^{-0.02\pi/0.9998} = 0.9390896$. (b) ZV: $A_1 = 1/(1 + K) = 0.5157059$ at $t = 0$ and $A_2 = K/(1 + K) = 0.4842941$ at $t = T_d/2 = 0.1000200$ s. ZVD: $(1 + K)^2 = 3.7600684$ and $A = (0.2659526; 0.4995066; 0.2345407)$ at instants $0, 0.1000200, 0.2000400$ s. (c) Normalized residual vibration (Definition 30.7):

error	+5%	+10%	+20%
ZV	0.081067	0.161889	0.320799
ZVD	0.006572	0.026208	0.102912

and indeed $0.081067^2 = 0.006572$, $0.161889^2 = 0.026208$, $0.320799^2 = 0.102912$: the relation $V_{\text{ZVD}} = V_{\text{ZV}}^2$ of Proposition 30.9(i) is verified to the sixth digit even with $\zeta = 0.02$. ✓(d) Only ZVD: at +10% it leaves 2.6%, below the 5% threshold, while ZV leaves 16.2%. The additional cost is $T_d - T_d/2 = T_d/2 = 0.1000200$ s, that is, the delay goes from 0.1000 to 0.2000 s: a tenth of a second more for a reduction of the vibration by a factor of 6.

30.10. Chapter formulary

Bézier, de Casteljau, NURBS.

$$B(t) = \sum_{i=0}^n b_{i,n}(t) P_i, \quad b_{i,n}(t) = \binom{n}{i} t^i (1-t)^{n-i}; \quad B'(t) = n \sum_{i=0}^{n-1} b_{i,n-1}(t) (P_{i+1} - P_i).$$

De Casteljau: $P_i^r = (1-t)P_i^{r-1} + tP_{i+1}^{r-1}$, $B(t) = P_0^n(t)$. Circular arc ($0 < \theta < \pi$): points $1, 1 + i \tan \frac{\theta}{2}, e^{i\theta}$; weights $1, \cos \frac{\theta}{2}, 1$;

$$C(t) = \frac{w(t)}{w(t)}, \quad w(t) = (1-t) + t e^{i\theta/2}, \quad \psi(t) = 2 \arg w(t),$$

$$\psi'(t) = \frac{2 \sin \frac{\theta}{2}}{1 - 2t(1-t)(1 - \cos \frac{\theta}{2})}.$$

No arc of circle is polynomial: $x^2 + y^2 = 1$ in $\mathbb{R}[t]$ forces x, y constant.

SLERP. For $q_0, q_1 \in S^3$, $\Omega = \arccos \langle q_0, q_1 \rangle \in (0, \pi)$, $E = \frac{q_1 - \cos \Omega q_0}{\sin \Omega}$:

$$\text{slerp}(q_0, q_1; t) = \frac{\sin((1-t)\Omega)}{\sin \Omega} q_0 + \frac{\sin(t\Omega)}{\sin \Omega} q_1 = \cos(t\Omega) q_0 + \sin(t\Omega) E = q_0 (\bar{q}_0 q_1)^t.$$

$$\|\text{slerp}\| \equiv 1; \quad \langle \gamma(t), \gamma(s) \rangle = \cos((t-s)\Omega); \quad \|\gamma'\| \equiv \Omega; \quad \Phi_{\gamma(t)} = \Phi_{q_0} \circ R_{u, 2t\Omega}.$$

Rotation swept = 2Ω . Short path: if $\langle q_0, q_1 \rangle < 0$ use $-q_1$ (then $\Omega \rightarrow \pi - \Omega$ and $2\Omega \rightarrow 2\pi - 2\Omega$). Degenerate case: $\frac{\sin(a\Omega)}{\sin \Omega} = a + \frac{a(1-a^2)}{6}\Omega^2 + \rho$, $|\rho| \leq \frac{\Omega^4}{15}$ for $0 < \Omega \leq 1$.

NLERP. $\text{nlerp} = \frac{(1-t)q_0 + tq_1}{\|(1-t)q_0 + tq_1\|} = \cos \phi q_0 + \sin \phi E$, with

$$\phi(t) = \arg((1-t) + te^{i\Omega}), \quad \phi'(t) = \frac{\sin \Omega}{D(t)}, \quad D(t) = 1 - 2t(1-t)(1 - \cos \Omega).$$

$$\min \phi' = \phi'(0) = \sin \Omega, \quad \max \phi' = \phi'(\frac{1}{2}) = 2 \tan \frac{\Omega}{2}, \quad \frac{\max}{\min} = \frac{1}{\cos^2 \frac{\Omega}{2}} > 1.$$

Motion profiles. Trapezoidal/triangular (limits V, A ; travel L):

$$T^* = \frac{L}{V} + \frac{V}{A} \text{ if } L \geq \frac{V^2}{A}; \quad T^* = 2\sqrt{\frac{L}{A}}, \quad v_p = \sqrt{AL} \text{ if } L < \frac{V^2}{A}.$$

Seven-segment (in addition $|j| \leq J$; requires $V \geq \frac{A^2}{J}$ and $L \geq V(\frac{V}{A} + \frac{A}{J})$):

$$t_j = \frac{A}{J}, \quad t_a = \frac{V}{A} - \frac{A}{J}, \quad t_v = \frac{L}{V} - \frac{V}{A} - \frac{A}{J}, \quad T = \frac{L}{V} + \frac{V}{A} + \frac{A}{J};$$

lower bound: $T > \frac{L}{V} + \frac{V}{A} + \frac{A}{J} - \frac{A^3}{12J^2V}$. If $V < \frac{A^2}{J}$: $t_j = \sqrt{V/J}$, $T = \frac{L}{V} + 2\sqrt{V/J}$.

Elastic mode and input shaping. $\beta = \sqrt{1 - \zeta^2}$, $\omega_d = \omega_n \beta$, $T_d = \frac{2\pi}{\omega_d}$, $K = e^{-\zeta\pi/\beta}$, $s_0 = -\zeta\omega_n + i\omega_d$.

$$h(t) = \frac{\omega_n^2}{\omega_d} e^{-\zeta\omega_n t} \sin \omega_d t, \quad g(t) = 1 - \frac{1}{\beta} e^{-\zeta\omega_n t} \sin(\omega_d t + \varphi), \quad \cos \varphi = \zeta.$$

Residual vibration $\propto |\hat{A}(s_0)|$ with $\hat{A}(s) = \sum_i A_i e^{-st_i}$; zero $\iff \hat{A}(s_0) = 0$.

$$\text{ZV: } A = \frac{(1, K)}{1 + K} \text{ at } \left(0, \frac{T_d}{2}\right); \quad \text{ZVD: } A = \frac{(1, 2K, K^2)}{(1 + K)^2} \text{ at } \left(0, \frac{T_d}{2}, T_d\right).$$

Sensitivity ($\zeta = 0$, $r = \omega/\omega_n$, $\delta = r - 1$): $V_{\text{ZV}} = |\cos \frac{\pi r}{2}| = |\sin \frac{\pi \delta}{2}|$, $V_{\text{ZVD}} = V_{\text{ZV}}^2$; 5% band: $\pm 3.18\%$ (ZV), $\pm 14.36\%$ (ZVD). Notch: $|H_N(i\omega_n)| = \frac{\zeta_z}{\zeta_p}$, minimum exactly at ω_n .

Numerics and research

Estimating the circle from data: geometric and algebraic fitting

Up to now the circle has been a *given* object: assigned by a center and a radius, or by an equation, or by a geometric condition. In this chapter the circle is instead an object *to be estimated*. One has n points of the plane — readings of a probe on a ground shaft, echoes of a laser scanner on the rim of a tank, contour pixels extracted from an image — that are assumed to lie *approximately* on a circle, and one asks which circle describes them best. The question has no unique answer until one says what "best" means: the chapter takes the most natural definition from the geometric point of view, the sum of the squares of the distances of the points from the circle, and follows its consequences all the way through.

The consequences are not trivial. The resulting objective function is invariant under isometries and equivariant under similarities (Section 31.2), but it is *not* a polynomial in the parameters, because it contains n square roots: its normal equations are nonlinear (Section 31.4). Worse, the minimum may fail to exist: if the points are collinear the minimizing sequence escapes to infinity and the circle degenerates into a line (Theorem 31.3 and Corollary 31.4). Where it exists, it is reached by a Gauss–Newton iteration, whose Jacobian has a remarkably simple form — the rows are the radial unit vectors with sign reversed (Proposition 31.9) — and whose direction is one of descent as soon as the Jacobian has full rank (Theorem 31.5); when the rank is not full or the step is too long, Levenberg–Marquardt damping repairs both defects and interpolates between Gauss–Newton and the gradient (Theorem 31.7).

The delicate point is conditioning. On a short arc three very different parameter triples produce almost the same arc, and the problem becomes ill-conditioned in a *quantifiable* way: the condition number of the Jacobian grows like the inverse square of the arc's half-aperture, $\kappa_2(J) \sim \sqrt{180} \alpha^{-2}$ (Theorem 31.8 and Corollary 31.6), an estimate we verify numerically on generated data. This is the reason a roundness measurement on a 30° sector is a much harder operation than the same measurement on a full circle.

Kåsa's algebraic method and the Hough transform were already built in Volume I, Chapter 10, and are not repeated here: we use them as *providers of the starting point* for the iteration (Section 31.8). We do prove, however, the link between the algebraic minimum and the geometric one — the factorization $\rho^2 - r^2 = d(2r + d)$ of Lemma 31.6, the sandwich estimate of Proposition 31.13 and the exact inequality $r_{\text{alg}} \geq r_{\text{geo}}$ at fixed center of Proposition 31.14 — and we state explicitly, in an observation, which part of the bias analysis remains *imported* and from where (Observation 31.13).

INFO

Level and prerequisites. Level **C** (undergraduate), with two passages at level **D**: the proof of the behavior at infinity of the objective function (Theorem 31.2) and the asymptotic expansion of the condition number on a short arc (Corollary 31.6).

Internal prerequisites. Isometries of the plane, the structure $f(x) = Ax + b$ and the preservation of circles (Chapter 5, Definition 5.1, Theorem 5.1, Theorem 5.2); orthogonal matrices and their characterizations (Chapter 5, Proposition 5.1); parametrization of a circle and arc

length (Chapter 2). Kåsa's algebraic method, the Hough transform and the circle through three points are in Volume I, Chapter 10 and Chapter 2: they are recalled by textual cross-reference and never reproduced.

External prerequisites, assumed and not reproved:

- linear algebra: the Euclidean scalar product, symmetric matrices, the spectral theorem in finite dimension, the Rayleigh quotient, the singular value decomposition of a real $n \times k$ matrix;
- multivariable calculus: differential, gradient, Hessian matrix, Weierstrass's theorem on compact sets, the first-order necessary condition and the second-order sufficient condition for a local minimum;
- Taylor's formula with Lagrange remainder for a real function of one variable;
- linear least squares: if A has full column rank, the minimum of $\|A\beta - z\|_2$ is attained at the unique point solving $A^\top A \beta = A^\top z$ (used only to recall the method of Volume I).

Everything else is proved here.

What you will learn. To write the distance of a point from a circle and recognize when the foot of the projection is not unique; to formulate the geometric fit as a nonlinear least-squares problem; to exploit invariance and equivariance to normalize the data; to decide whether the minimum exists by looking at the smallest eigenvalue of the scatter matrix; to derive the normal equations and the Jacobian; to build a Gauss–Newton step and prove its descent property; to damp it à la Levenberg–Marquardt and read the two limits of the damping; to estimate the condition number on an arc and understand why short arcs are a hard problem; to use an algebraic fit as a starting point and to know how biased it is.

Warning. Conventions of the chapter.

- The data are n points $p_i = (x_i, y_i) \in \mathbb{R}^2$, $i = 1, \dots, n$, not necessarily distinct. $\bar{p} = \frac{1}{n} \sum_i p_i$ is their **centroid** and $w_i = p_i - \bar{p}$ the deviation from the centroid.
- The circle's parameters are $\theta = (a, b, r)$ with $c = (a, b)$ the center and $r \geq 0$ the radius; $\mathcal{C}(c, r) = \{q \in \mathbb{R}^2 : \|q - c\| = r\}$ is the corresponding circle. We write $\rho_i(c) = \|p_i - c\|$ and $d_i(\theta) = \rho_i(c) - r$.
- $\|\cdot\|$ is always the Euclidean norm, $\langle \cdot, \cdot \rangle$ the Euclidean scalar product; for a matrix, $\|\cdot\|_2$ is the spectral norm.
- I is the identity matrix (of order 2 or 3 according to context); $A^\top$ is the transpose. Vectors of $\mathbb{R}^2$ and $\mathbb{R}^3$ are columns.
- "Geometric fit" always means minimization of the sum of squares of the *distances*; "algebraic fit" means minimization of the sum of squares of the residuals $\rho_i^2 - r^2$, i.e. the problem of Volume I, Chapter 10.
- Numerical values are rounded to the seventh decimal place and recomputed twice by independent routes; the sign $\checkmark$ marks the second computation.

31.1. The problem: distance from a circle and the objective function

Before minimizing a sum of distances one needs a formula for the distance of a point from a circle. It is an elementary fact, but it must be proved with care because the degenerate case — the point coinciding with the center — is exactly the one that undermines every derivative formula for the rest of the chapter.

Definition 31.1: Sample, candidate circle, parameters. A **sample** is a finite list $P = (p_1, \dots, p_n)$ of points of $\mathbb{R}^2$, with $n \geq 1$. A **candidate circle** is a circle $\mathcal{C}(c, r) = \{q \in \mathbb{R}^2 : \|q - c\| = r\}$ with $c = (a, b) \in \mathbb{R}^2$ and $r \geq 0$; the triple $\theta = (a, b, r) \in \mathbb{R}^2 \times [0, +\infty)$ is the **parameter vector**. For $r = 0$ the circle reduces to the single point c and is called **degenerate**.

Lemma 31.1: Distance of a point from a circle. Let $c \in \mathbb{R}^2$, $r \geq 0$ and $p \in \mathbb{R}^2$. Setting $\rho = \|p - c\|$, one has

$$\text{dist}(p, \mathcal{C}(c, r)) := \min_{q \in \mathcal{C}(c, r)} \|p - q\| = |\rho - r|.$$

Moreover:

- (i) if $p \neq c$, the minimum is attained at the unique point $q^* = c + r \frac{p - c}{\rho}$, which is the intersection of the ray from c through p with $\mathcal{C}(c, r)$;
- (ii) if $p = c$ and $r > 0$, the distance equals r and the minimum is attained at every point of $\mathcal{C}(c, r)$;
- (iii) if $r = 0$ the distance equals ρ and the minimizing point is $q^* = c$.

Proof. Step 1 — the minimum exists. $\mathcal{C}(c, r)$ is closed and bounded in $\mathbb{R}^2$, hence compact, and $q \mapsto \|p - q\|$ is continuous: by Weierstrass's theorem the minimum is attained.

Step 2 — the lower bound. Let $q \in \mathcal{C}(c, r)$, i.e. $\|q - c\| = r$. By the triangle inequality applied to $p - c = (p - q) + (q - c)$ we get $\rho = \|p - c\| \leq \|p - q\| + r$, i.e. $\|p - q\| \geq \rho - r$; and applying it to $q - c = (q - p) + (p - c)$ we get $r \leq \|p - q\| + \rho$, i.e. $\|p - q\| \geq r - \rho$. The two inequalities together give

$$\|p - q\| \geq \max\{\rho - r, r - \rho\} = |\rho - r| \quad \text{for every } q \in \mathcal{C}(c, r). \quad (31.1)$$

Step 3 — the upper bound when $p \neq c$. Let $u = (p - c)/\rho$, which is well defined because $\rho > 0$, and is a unit vector. The point $q^* = c + ru$ satisfies $\|q^* - c\| = r\|u\| = r$, hence $q^* \in \mathcal{C}(c, r)$, and

$$p - q^* = (p - c) - ru = \rho u - ru = (\rho - r)u, \quad \text{so} \quad \|p - q^*\| = |\rho - r|.$$

With (31.1) this proves that the minimum equals $|\rho - r|$ and is attained at q^* .

Step 4 — uniqueness when $p \neq c$. Suppose $\|p - q\| = |\rho - r|$ with $\|q - c\| = r$. If $\rho > r$, the equality $\rho = \|p - q\| + \|q - c\|$ is the equality case in the triangle inequality for $p - c = (p - q) + (q - c)$: the two vectors $p - q$ and $q - c$ are then parallel and same-direction, i.e. $q - c = \lambda(p - q)$ with $\lambda \geq 0$ (or one of the two is zero, but $\|q - c\| = r$ and $\|p - q\| = \rho - r$ are both positive if $0 < r < \rho$; if $r = 0$ this falls back into case (iii)). From $q - c = \lambda(p - q)$ it follows that q lies on the line through c and p , on the side of p ; the only such point at distance r from c is $c + ru = q^*$. If instead $\rho < r$, the equality $r = \|q - p\| + \|p - c\|$ says that p lies on the segment between q and c , so again q is on the ray from c through p and $q = q^*$. If $\rho = r$ then $|\rho - r| = 0$ and $q = p = q^*$.

Step 5 — the case $p = c$, $r > 0$. Here $\rho = 0$ and $|\rho - r| = r$; for every $q \in \mathcal{C}(c, r)$ one has $\|p - q\| = \|c - q\| = r$. Hence the function $q \mapsto \|p - q\|$ is constant on $\mathcal{C}(c, r)$ and every point is a minimizer: the foot of the projection is not unique.

Step 6 — the case $r = 0$. $\mathcal{C}(c, 0) = \{c\}$, hence the minimum is $\|p - c\| = \rho = |\rho - 0|$, attained at $q^* = c$. $\square$

Remark 31.1: The center is the only singularity. Lemma 31.1 shows that the function $p \mapsto \text{dist}(p, \mathcal{C}(c, r))$ is smooth everywhere except on the circle itself (where the absolute value has a corner) and at the center (where the foot of the projection jumps). In the rest of the chapter we will instead minimize the signed quantity $\rho - r$, which removes the corner on the circle; the singularity at the center remains, i.e. at the points θ where c coincides with one of the data points. All the derivative formulas that follow require $\rho_i(c) > 0$ for every i , a hypothesis that will always be written explicitly.

Definition 31.2: Geometric residual and objective function. Given a sample P and a parameter vector $\theta = (a, b, r)$ with $c = (a, b)$, set

$$\rho_i(c) = \|p_i - c\| = \sqrt{(x_i - a)^2 + (y_i - b)^2}, \quad d_i(\theta) = \rho_i(c) - r,$$

and call the **objective function of the geometric fit** the function

$$F(\theta) = F(a, b, r) = \sum_{i=1}^n d_i(\theta)^2 = \sum_{i=1}^n \left(\sqrt{(x_i - a)^2 + (y_i - b)^2} - r \right)^2.$$

The number $d_i(\theta)$ is the **signed geometric residual** of the point p_i : positive if p_i is outside $\mathcal{C}(c, r)$, negative if inside, zero if it lies on the circle. A **geometric least-squares circle** of the sample is a θ^* that minimizes F on $\mathbb{R}^2 \times [0, +\infty)$.

Proposition 31.1: The objective function is the sum of squared distances. For every $\theta = (a, b, r)$ with $r \geq 0$ one has

$$F(\theta) = \sum_{i=1}^n \text{dist}(p_i, \mathcal{C}(c, r))^2.$$

Proof. By Lemma 31.1, $\text{dist}(p_i, \mathcal{C}(c, r)) = |\rho_i(c) - r| = |d_i(\theta)|$ for every i (the statement of the lemma covers all cases, including $p_i = c$ and $r = 0$). Squaring, $\text{dist}(p_i, \mathcal{C}(c, r))^2 = d_i(\theta)^2$, and summing over i gives the claim. $\square$

Remark 31.2: Why the absolute value disappears. Proposition 31.1 is the technical reason why one minimizes the sum of squares and not, for instance, the sum of distances: squaring makes the absolute value disappear and the function d_i becomes differentiable wherever $\rho_i > 0$, while $|d_i|$ is not differentiable on the circle. The price is the well-known sensitivity of least squares to outliers, which in Volume I, Chapter 10 is exactly the reason why the Hough transform is credited with a robustness that least squares does not have.

Proposition 31.2: Optimal radius at a fixed center. Let $c \in \mathbb{R}^2$ be fixed and set $\bar{\rho}(c) = \frac{1}{n} \sum_{i=1}^n \rho_i(c)$. Then the function $r \mapsto F(a, b, r)$ is a second-degree polynomial with leading coefficient $n > 0$, has a unique minimizer on $\mathbb{R}$ at $r = \bar{\rho}(c)$, and

$$\min_{r \in \mathbb{R}} F(a, b, r) = G(c) := \sum_{i=1}^n (\rho_i(c) - \bar{\rho}(c))^2.$$

Since $\bar{\rho}(c) \geq 0$, the minimum over $r \geq 0$ coincides with the minimum over $\mathbb{R}$; in particular

$$\inf_{\theta \in \mathbb{R}^2 \times [0, +\infty)} F(\theta) = \inf_{c \in \mathbb{R}^2} G(c).$$

Figure 31.1: Lemma 31.1 on an example with exact coordinates: circle of center $c = (0,0)$ and radius $r = 2$. For $p = (3,4)$ we have $\rho = \sqrt{9+16} = 5$, residual $d = 5 - 2 = 3$ and foot $q^* = c + 2(3,4)/5 = (1.2; 1.6)$. For $p' = (0.6; 0.8)$ we have $\rho' = \sqrt{0.36+0.64} = 1$, residual $d' = 1 - 2 = -1$ and *the same* foot $q^* = (1.2; 1.6)$, because p and p' lie on the same ray from c . Check: $\|q^*\| = \sqrt{1.44 + 2.56} = \sqrt{4} = 2 = r$. ✓

Proof. Step 1 — quadratic form in r . Expanding the square,

$$F(a, b, r) = \sum_{i=1}^n (\rho_i(c) - r)^2 = nr^2 - 2r \sum_{i=1}^n \rho_i(c) + \sum_{i=1}^n \rho_i(c)^2,$$

which is a degree-2 polynomial in r with leading coefficient $n > 0$: hence an upward-opening parabola, which has a unique minimum at its vertex.

Step 2 — the vertex. The derivative with respect to r is $\partial_r F = 2nr - 2 \sum_i \rho_i(c)$, which vanishes if and only if $r = \frac{1}{n} \sum_i \rho_i(c) = \bar{\rho}(c)$.

Step 3 — the minimum value. Substituting $r = \bar{\rho}(c)$ in the definition,

$$F(a, b, \bar{\rho}(c)) = \sum_{i=1}^n (\rho_i(c) - \bar{\rho}(c))^2 = G(c).$$

Step 4 — the constraint $r \geq 0$ does not bind. Every $\rho_i(c) = \|p_i - c\|$ is ≥ 0 , hence $\bar{\rho}(c) \geq 0$: the unconstrained minimizer already lies in the admissible half-plane and the two minima coincide.

Step 5 — the infimum. For every c one has $\inf_r F(a, b, r) = G(c)$ by the previous steps; taking the infimum over c of both sides, and using that the infimum of a function of two groups of variables can be computed in two stages, one obtains $\inf_\theta F = \inf_c \inf_r F(a, b, r) = \inf_c G(c)$.
□

***Remark 31.3: The problem really has only two unknowns.** Proposition 31.2 eliminates exactly one parameter: the geometric fit is the minimization of the function $G : \mathbb{R}^2 \rightarrow [0, +\infty)$, which measures the dispersion of the distances from the candidate center. This reduction will be the main tool of Section 31.3, because G is defined on $\mathbb{R}^2$ rather than on a half-space of $\mathbb{R}^3$, and because its interpretation — "how far the points are from being equidistant from c " — makes the behavior at infinity readable. In the numerical iteration,*

however, it is convenient to keep all three parameters: the Jacobian with respect to (a, b, r) has a much simpler form than that of G .

Example 31.1: Three non-collinear points: the fit is exact. Let P be the sample $p_1 = (0, 0)$, $p_2 = (4, 0)$, $p_3 = (0, 3)$. The three points are not collinear (the vectors $p_2 - p_1 = (4, 0)$ and $p_3 - p_1 = (0, 3)$ have determinant $4 \cdot 3 - 0 \cdot 0 = 12 \neq 0$), so by Volume I, Chapter 2 the circumscribed circle of the triangle exists. Its center is the intersection of the perpendicular bisectors: the bisector of $p_1 p_2$ is $x = 2$, the bisector of $p_1 p_3$ is $y = \frac{3}{2}$, so $c^* = (2; 1.5)$ and

$$r^* = \|p_1 - c^*\| = \sqrt{4 + 2.25} = \sqrt{6.25} = 2.5.$$

Check on the other two points: $\|p_2 - c^*\| = \sqrt{(4 - 2)^2 + 1.5^2} = \sqrt{6.25} = 2.5$ and $\|p_3 - c^*\| = \sqrt{2^2 + (3 - 1.5)^2} = \sqrt{6.25} = 2.5$. ✓ Hence $d_1 = d_2 = d_3 = 0$ and $F(\theta^*) = 0$: since $F \geq 0$ by definition, θ^* is a *global* minimum. *Independent check:* the algebraic method of Volume I, Chapter 10, applied to these three points, returns $a = 2.0000000$, $b = 1.5000000$, $r = 2.5000000$ and zero algebraic residual — as it must, because on exactly concyclic points both functionals vanish (Lemma 31.6). ✓

31.2. Invariance under isometries and equivariance under similarities

A criterion of fit between data and circle that depended on the reference frame would be useless: rotating the workpiece on the measuring machine would change the "best" circle. The objective function of Definition 31.2 does not have this defect, and the proof is a direct application of the structure of isometries from Chapter 5.

Definition 31.3: Action of a similarity on the parameters. Let $T : \mathbb{R}^2 \rightarrow \mathbb{R}^2$ be of the form $T(x) = \lambda Ax + v$ with $\lambda > 0$, $A \in O(2)$ and $v \in \mathbb{R}^2$ (a **similarity** of ratio λ ; for $\lambda = 1$ it is an isometry, by Theorem 5.1). For a parameter vector $\theta = (c, r)$ set

$$T_*\theta := (T(c), \lambda r).$$

For a sample $P = (p_1, \dots, p_n)$ set $T(P) = (T(p_1), \dots, T(p_n))$, and write F_P for the objective function of the sample P .

Proposition 31.3: Similarities carry circles to circles. With the notation of Definition 31.3, $T(\mathcal{C}(c, r)) = \mathcal{C}(T(c), \lambda r)$ for every $c \in \mathbb{R}^2$ and $r \geq 0$.

Proof. For every $q \in \mathbb{R}^2$,

$$\|T(q) - T(c)\| = \|\lambda Aq + v - \lambda Ac - v\| = \lambda \|A(q - c)\| = \lambda \|q - c\|,$$

where the last equality is the implication (i) $\Rightarrow$ (ii) of Proposition 5.1. Hence $\|q - c\| = r$ if and only if $\|T(q) - T(c)\| = \lambda r$. Since T is bijective (it is the composition of the linear bijection λA , invertible because $\lambda > 0$ and $\det A = \pm 1 \neq 0$ by Corollary 5.1, with a translation), the image set of $\mathcal{C}(c, r)$ is exactly $\{q' : \|q' - T(c)\| = \lambda r\}$. For $\lambda = 1$ this is the special case already proved in Theorem 5.2. $\square$

Theorem 31.1: Invariance under isometries and equivariance under similarities.

Let $T(x) = \lambda Ax + v$ be a similarity of ratio $\lambda > 0$. Then for every sample P and every $\theta = (c, r)$ with $r \geq 0$

$$F_{T(P)}(T_*\theta) = \lambda^2 F_P(\theta).$$

In particular, if T is an isometry ($\lambda = 1$) then $F_{T(P)}(T_*\theta) = F_P(\theta)$: the objective function is **invariant** under isometries and **equivariant of weight 2** under similarities.

Proof. Step 1 — the radial distances rescale. As in the proof of Proposition 31.3, $\|T(p_i) - T(c)\| = \lambda\|p_i - c\|$, i.e. $\rho_i^T(T(c)) = \lambda\rho_i(c)$, where ρ^T denotes the distances computed in the transformed sample.

Step 2 — the residuals rescale. The second component of $T_*\theta$ is λr , so the i -th residual of the transformed sample equals

$$d_i^T(T_*\theta) = \rho_i^T(T(c)) - \lambda r = \lambda\rho_i(c) - \lambda r = \lambda d_i(\theta).$$

Step 3 — sum of squares. Squaring and summing,

$$F_{T(P)}(T_*\theta) = \sum_{i=1}^n \left(\lambda d_i(\theta) \right)^2 = \lambda^2 \sum_{i=1}^n d_i(\theta)^2 = \lambda^2 F_P(\theta).$$

For $\lambda = 1$ the factor disappears. □

Corollary 31.1: The minimizers transport. With the notation of Theorem 31.1: θ^* is a minimum point (global, or local) of F_P if and only if $T_*\theta^*$ is a minimum point (global, respectively local) of $F_{T(P)}$; and the minimum values are in ratio λ^2 . In particular F_P admits a minimum if and only if $F_{T(P)}$ does.

Proof. Step 1 — T_* is a bijection of the parameter space. The map $\theta = (c, r) \mapsto (T(c), \lambda r)$ is a bijection of $\mathbb{R}^2 \times [0, +\infty)$ onto itself, with inverse $\theta' = (c', r') \mapsto (T^{-1}(c'), \lambda^{-1}r')$: indeed T is bijective (see the final step of the proof of Proposition 31.3) and $\lambda > 0$. It is moreover a homeomorphism, because T and T^{-1} are affine and hence continuous, and multiplication by $\lambda > 0$ is as well.

Step 2 — comparison of values. By Theorem 31.1, $F_{T(P)}(T_*\theta) = \lambda^2 F_P(\theta)$ for every θ . If θ^* is a global minimizer for F_P , then for every θ' in the parameter space there is $\theta = T_*^{-1}\theta'$ and $F_{T(P)}(\theta') = \lambda^2 F_P(\theta) \geq \lambda^2 F_P(\theta^*) = F_{T(P)}(T_*\theta^*)$: hence $T_*\theta^*$ is a global minimizer. The converse follows by applying the same argument to T^{-1} , which is again a similarity, of ratio λ^{-1} .

Step 3 — local minimizers. If θ^* is a local minimizer, there is a neighborhood U of θ^* on which $F_P \geq F_P(\theta^*)$; since T_* is a homeomorphism (Step 1), $T_*(U)$ is a neighborhood of $T_*\theta^*$, and on it $F_{T(P)} = \lambda^2 F_P \circ T_*^{-1} \geq \lambda^2 F_P(\theta^*)$. □

Corollary 31.2: Normalization of the sample. Let P be a sample with at least two distinct points, $\bar{p}$ its centroid and $M = \max_i \|p_i - \bar{p}\| > 0$. Setting $T(x) = M^{-1}(x - \bar{p})$, the sample $T(P)$ has centroid at the origin and $\max_i \|T(p_i)\| = 1$, and the fitting problems for P and for $T(P)$ are equivalent in the sense of Corollary 31.1.

Proof. T is the similarity of ratio $\lambda = M^{-1} > 0$ with $A = I \in O(2)$ and $v = -M^{-1}\bar{p}$. The centroid of $T(P)$ is $\frac{1}{n} \sum_i M^{-1}(p_i - \bar{p}) = M^{-1}(\frac{1}{n} \sum_i p_i - \bar{p}) = M^{-1} \cdot 0 = 0$, by definition of $\bar{p}$. Moreover $\max_i \|T(p_i) - 0\| = \max_i M^{-1}\|p_i - \bar{p}\| = M^{-1}M = 1$. The equivalence of the two problems is Corollary 31.1. □

Remark 31.4: The algebraic functional is also invariant, but with a different weight. The algebraic residual $\rho_i^2 - r^2$ of Volume I, Chapter 10 transforms, under the similarity T , into $\lambda^2(\rho_i^2 - r^2)$: the sum of its squares is therefore equivariant of weight 4, not weight 2. For isometries ($\lambda = 1$) the two functionals are both invariant, and this is what makes it legitimate to compare them; but the different weight already signals that the algebraic functional is not homogeneous of the same power of lengths, and that its minimum cannot coincide with the geometric one except in cases where both vanish. The difference is quantified in Section 31.8.

31.3. Existence of the minimum, and the cases where it fails

The minimum of F may fail to exist. The reason is geometric and can be seen by eye: if the center is moved off to infinity along a direction u while the radius is kept equal to the mean distance, the arcs of circle that pass near the data tend to a line, and the objective function tends to the sum of squared distances of the points from that line. If a line describes the data better than any circle, the infimum is attained only "at infinity" and there is no optimal circle. This section makes the argument precise.

Definition 31.4: Scatter matrix of the sample. Given a sample P with centroid $\bar{p}$, set $w_i = p_i - \bar{p}$ and

$$S = \sum_{i=1}^n w_i w_i^\top \in \mathbb{R}^{2 \times 2},$$

the **scatter matrix** of the sample. Denote by $\lambda_{\min}(S)$ the smaller of its two eigenvalues and set $M = \max_i \|w_i\|$.

Lemma 31.2: Rayleigh quotient for the scatter matrix. S is symmetric and positive semidefinite, and

$$\min_{\|u\|=1} u^\top S u = \lambda_{\min}(S),$$

with the minimum attained at a unit eigenvector of S corresponding to $\lambda_{\min}(S)$. Moreover $u^\top S u = \sum_{i=1}^n \langle u, w_i \rangle^2$ for every u .

Proof. Step 1 — symmetry and quadratic form. Each $w_i w_i^\top$ is symmetric, hence so is S . For every $u \in \mathbb{R}^2$,

$$u^\top S u = \sum_{i=1}^n u^\top w_i w_i^\top u = \sum_{i=1}^n (w_i^\top u)^2 = \sum_{i=1}^n \langle u, w_i \rangle^2 \geq 0,$$

which proves both the last claim and positive semidefiniteness.

Step 2 — the minimum on the unit circle. By the spectral theorem there is an orthonormal basis (e_1, e_2) of $\mathbb{R}^2$ with $S e_j = \mu_j e_j$ and $\mu_1 = \lambda_{\min}(S) \leq \mu_2$. Writing $u = \xi_1 e_1 + \xi_2 e_2$ with $\xi_1^2 + \xi_2^2 = 1$, we get $u^\top S u = \mu_1 \xi_1^2 + \mu_2 \xi_2^2 \geq \mu_1 (\xi_1^2 + \xi_2^2) = \mu_1$, with equality for $u = e_1$ (i.e. $\xi_1 = 1, \xi_2 = 0$), or for every unit u if $\mu_1 = \mu_2$. $\square$

Lemma 31.3: Expansion of the radial distance for distant centers. Let P be a sample with $M = \max_i \|w_i\| > 0$, let $u \in \mathbb{R}^2$ be a unit vector and let $c = \bar{p} + t u$ with $t \geq 8M$. Then, for every i ,

$$\rho_i(c) = t - \langle u, w_i \rangle + \eta_i, \quad |\eta_i| \leq \frac{4M^2}{t}.$$

Proof. Step 1 — the square of the radial distance. Since $p_i - c = w_i - tu$ and $\|u\| = 1$,

$$\rho_i(c)^2 = \|w_i - tu\|^2 = \|w_i\|^2 - 2t\langle u, w_i \rangle + t^2 = t^2(1 + x_i), \quad x_i = -\frac{2\langle u, w_i \rangle}{t} + \frac{\|w_i\|^2}{t^2}.$$

Step 2 — x_i is small. By Cauchy–Schwarz $|\langle u, w_i \rangle| \leq \|w_i\| \leq M$, hence

$$|x_i| \leq \frac{2M}{t} + \frac{M^2}{t^2} = \frac{2M}{t} \left(1 + \frac{M}{2t}\right) \leq \frac{2M}{t} \cdot \frac{17}{16} \leq \frac{17}{64} < \frac{1}{2},$$

using $t \geq 8M$, i.e. $M/t \leq 1/8$, both in the parenthesis ($M/(2t) \leq 1/16$) and in the factor ($2M/t \leq 1/4$).

Step 3 — Taylor with Lagrange remainder. Let $f(x) = \sqrt{1+x}$. Then $f(0) = 1$, $f'(0) = \frac{1}{2}$ and $f''(x) = -\frac{1}{4}(1+x)^{-3/2}$. For $|x| \leq \frac{1}{2}$ the intermediate point ξ of Taylor's formula satisfies $1 + \xi \geq \frac{1}{2}$, hence $|f''(\xi)| \leq \frac{1}{4} \cdot 2^{3/2} = \frac{\sqrt{2}}{2} \leq 1$ and

$$\left| \sqrt{1+x} - 1 - \frac{x}{2} \right| = \left| \frac{f''(\xi)}{2} x^2 \right| \leq \frac{x^2}{2}.$$

Step 4 — reassembly. From $\rho_i(c) = t\sqrt{1+x_i}$ (the positive root, because $t > 0$) and from Step 3,

$$\rho_i(c) = t \left(1 + \frac{x_i}{2} + e_i\right), \quad |e_i| \leq \frac{x_i^2}{2},$$

and, substituting x_i ,

$$t \cdot \frac{x_i}{2} = -\langle u, w_i \rangle + \frac{\|w_i\|^2}{2t}.$$

Hence $\rho_i(c) = t - \langle u, w_i \rangle + \eta_i$ with $\eta_i = \frac{\|w_i\|^2}{2t} + t e_i$.

Step 5 — estimate of the remainder. From Step 2, $|x_i| \leq \frac{17}{16} \cdot \frac{2M}{t} = \frac{17M}{8t}$, so

$$t|e_i| \leq \frac{t x_i^2}{2} \leq \frac{t}{2} \cdot \frac{289M^2}{64t^2} = \frac{289}{128} \cdot \frac{M^2}{t} \leq \frac{5M^2}{2t},$$

while $\frac{\|w_i\|^2}{2t} \leq \frac{M^2}{2t}$. Adding, $|\eta_i| \leq \frac{M^2}{2t} + \frac{5M^2}{2t} = \frac{3M^2}{t} \leq \frac{4M^2}{t}$. □

Theorem 31.2: Behavior of the objective function at infinity. Let P be a sample with $M = \max_i \|w_i\| > 0$ and let G be the function of Proposition 31.2. Then for every unit vector u and every $t \geq 8M$

$$\left| G(\bar{p} + tu) - u^\top S u \right| \leq \frac{24nM^3}{t}.$$

In particular $G(\bar{p} + tu) \rightarrow u^\top S u$ as $t \rightarrow +\infty$, uniformly in u , and

$$\liminf_{\|c\| \rightarrow +\infty} G(c) \geq \lambda_{\min}(S).$$

Proof. Step 1 — the residuals relative to the mean. Let $c = \bar{p} + tu$ with $t \geq 8M$. By Lemma 31.3, $\rho_i(c) = t - \langle u, w_i \rangle + \eta_i$ with $|\eta_i| \leq 4M^2/t$. Averaging over i and using $\sum_i w_i = \sum_i (p_i - \bar{p}) = n\bar{p} - n\bar{p} = 0$, hence $\frac{1}{n} \sum_i \langle u, w_i \rangle = \langle u, \frac{1}{n} \sum_i w_i \rangle = 0$, we get $\bar{\rho}(c) = t + \bar{\eta}$ with $\bar{\eta} = \frac{1}{n} \sum_i \eta_i$. Therefore

$$\rho_i(c) - \bar{\rho}(c) = -\langle u, w_i \rangle + B_i, \quad B_i = \eta_i - \bar{\eta}, \quad |B_i| \leq |\eta_i| + |\bar{\eta}| \leq \frac{8M^2}{t}.$$

Step 2 — comparison of the sums of squares. Setting $A_i = \langle u, w_i \rangle$, we have $(\rho_i - \bar{\rho})^2 = (B_i - A_i)^2 = A_i^2 - 2A_i B_i + B_i^2$, so

$$\left| G(c) - \sum_i A_i^2 \right| = \left| \sum_i (-2A_i B_i + B_i^2) \right| \leq 2 \sum_i |A_i| |B_i| + \sum_i B_i^2.$$

By Cauchy–Schwarz $|A_i| \leq \|w_i\| \leq M$, and by Step 1 $|B_i| \leq 8M^2/t$; hence

$$\left| G(c) - \sum_i A_i^2 \right| \leq 2nM \cdot \frac{8M^2}{t} + n \cdot \frac{64M^4}{t^2} = \frac{16nM^3}{t} + \frac{64nM^4}{t^2}.$$

Since $t \geq 8M$ implies $M/t \leq \frac{1}{8}$, the second term is $\frac{64nM^3}{t} \cdot \frac{M}{t} \leq \frac{8nM^3}{t}$, and the sum is at most $\frac{24nM^3}{t}$.

Step 3 — identification of the limit. By Lemma 31.2, $\sum_i A_i^2 = \sum_i \langle u, w_i \rangle^2 = u^\top S u$. This proves the inequality of the statement; the right-hand side does not depend on u and tends to 0 as $t \rightarrow +\infty$, so the convergence is uniform in u .

Step 4 — the liminf at infinity. Let c have $\|c - \bar{p}\| = t \geq 8M$ and let $u = (c - \bar{p})/t$, a unit vector. By the previous steps and by Lemma 31.2,

$$G(c) \geq u^\top S u - \frac{24nM^3}{t} \geq \lambda_{\min}(S) - \frac{24nM^3}{t}.$$

Since $\|c\| \rightarrow +\infty$ is equivalent to $t = \|c - \bar{p}\| \rightarrow +\infty$, passing to the liminf gives $\liminf_{\|c\| \rightarrow \infty} G(c) \geq \lambda_{\min}(S)$. $\square$

***Remark 31.5: What $u^\top S u$ is: the limiting line.** The quantity $u^\top S u = \sum_i \langle u, w_i \rangle^2$ is the sum of squared distances of the points p_i from the line $\ell_u = \{q : \langle u, q - \bar{p} \rangle = 0\}$, i.e. from the line through the centroid orthogonal to u : indeed the distance of p_i from ℓ_u equals $|\langle u, p_i - \bar{p} \rangle| = |\langle u, w_i \rangle|$. Theorem 31.2 therefore says that, as the center moves off in the direction u , the optimal circle degenerates into the line through the centroid perpendicular to u , and the objective function tends to the residual of the orthogonal linear fit on that line. By Lemma 31.2 the best of these residuals is $\lambda_{\min}(S)$, obtained by choosing u in the direction of minimum dispersion, i.e. by taking as the limiting line the one of maximum dispersion.*

***Corollary 31.3: The infimum does not exceed the residual of the optimal line.** If $M > 0$, then $\inf_{c \in \mathbb{R}^2} G(c) \leq \lambda_{\min}(S)$, and hence $\inf_{\theta} F(\theta) \leq \lambda_{\min}(S)$.*

Proof. Let u^* be a unit eigenvector of S corresponding to $\lambda_{\min}(S)$, which exists by Lemma 31.2. By Theorem 31.2, for every $t \geq 8M$,

$$G(\bar{p} + t u^*) \leq (u^*)^\top S u^* + \frac{24nM^3}{t} = \lambda_{\min}(S) + \frac{24nM^3}{t}.$$

Hence $\inf_c G(c) \leq \lambda_{\min}(S) + \frac{24nM^3}{t}$ for every $t \geq 8M$; letting $t \rightarrow +\infty$ gives $\inf_c G \leq \lambda_{\min}(S)$. The second claim follows from Proposition 31.2, by which $\inf_{\theta} F = \inf_c G$. $\square$

***Theorem 31.3: Existence of the minimum.** Let P be a sample with $M > 0$. If there exists $c_0 \in \mathbb{R}^2$ with*

$$G(c_0) < \lambda_{\min}(S),$$

then G attains a minimum on $\mathbb{R}^2$ and F attains a minimum on $\mathbb{R}^2 \times [0, +\infty)$; every minimizer of G belongs to the closed disc of center $\bar{p}$ and radius

$$t_0 = \max \left\{ 8M, \frac{24nM^3}{\lambda_{\min}(S) - G(c_0)} \right\}.$$

Proof. Step 1 — G is continuous. Each $\rho_i(c) = \|p_i - c\|$ is continuous in c (the norm is 1-Lipschitz), hence so are $\bar{\rho}$ and, by composition of continuous functions, $G(c) = \sum_i (\rho_i(c) - \bar{\rho}(c))^2$.

Step 2 — outside a disc G is too large. Let $m = G(c_0)$ and $\varepsilon = \lambda_{\min}(S) - m > 0$. Let c have $t = \|c - \bar{p}\| > t_0$. Then $t \geq 8M$ and $\frac{24nM^3}{t} < \frac{24nM^3}{t_0} \leq \varepsilon$, so by Step 4 of the proof of Theorem 31.2

$$G(c) \geq \lambda_{\min}(S) - \frac{24nM^3}{t} > \lambda_{\min}(S) - \varepsilon = m.$$

The inequality $\frac{24nM^3}{t} < \varepsilon$ holds because $t > t_0 \geq \frac{24nM^3}{\varepsilon}$; the condition $t \geq 8M$ holds because $t > t_0 \geq 8M$.

Step 3 — Weierstrass on the disc. Let $K = \{c : \|c - \bar{p}\| \leq t_0\}$, closed and bounded, hence compact; it is nonempty and, by Step 2, contains c_0 (because $G(c_0) = m$ and outside K one has $G > m$). The function G , continuous by Step 1, attains on K a minimum point c^* , with $G(c^*) \leq G(c_0) = m$.

Step 4 — the minimum on K is global. For every $c \notin K$ one has $G(c) > m \geq G(c^*)$ by Step 2; for every $c \in K$ one has $G(c) \geq G(c^*)$ by Step 3. Hence c^* is a global minimizer of G on $\mathbb{R}^2$, and every other global minimizer lies in K for the same reason.

Step 5 — from G to F . Setting $r^* = \bar{\rho}(c^*) \geq 0$ and $\theta^* = (c^*, r^*)$, Proposition 31.2 gives $F(\theta^*) = G(c^*) = \inf_c G = \inf_\theta F$: hence θ^* is a global minimizer of F . $\square$

Corollary 31.4: Collinear points: the minimum does not exist. Let P be a sample whose points all lie on a line ℓ and among which at least three are distinct. Then $\lambda_{\min}(S) = 0$, $\inf_c G(c) = 0$ and $G(c) > 0$ for every $c \in \mathbb{R}^2$: the objective function F has no minimum.

Proof. Step 1 — $\lambda_{\min}(S) = 0$. Let v be a direction unit vector of ℓ and let u be a unit vector orthogonal to v . All the points lie on ℓ , so the centroid $\bar{p} = \frac{1}{n} \sum p_i$ also belongs to it (it is a convex combination of points of a line), and each $w_i = p_i - \bar{p}$ is parallel to v , i.e. $\langle u, w_i \rangle = 0$. By Lemma 31.2, $u^\top S u = \sum_i \langle u, w_i \rangle^2 = 0$; since S is positive semidefinite, $\lambda_{\min}(S) = 0$. Moreover $M > 0$, because at least two points are distinct.

Step 2 — $\inf G = 0$. By Corollary 31.3, $\inf_c G \leq \lambda_{\min}(S) = 0$; and $G \geq 0$ by definition. Hence $\inf_c G = 0$.

Step 3 — G never vanishes. Suppose $G(c) = 0$ for some c . Then all the terms $(\rho_i(c) - \bar{\rho}(c))^2$ vanish, i.e. $\rho_1(c) = \dots = \rho_n(c) =: \varrho$: all the points are at distance ϱ from c . Parametrize ℓ as $q + sv$, $s \in \mathbb{R}$, and let s_1, s_2, s_3 be the parameters of three distinct points of the sample. The function

$$\psi(s) = \|q + sv - c\|^2 = s^2 \|v\|^2 + 2s \langle v, q - c \rangle + \|q - c\|^2 = s^2 + 2s \langle v, q - c \rangle + \|q - c\|^2$$

is a polynomial of degree exactly 2 in s (leading coefficient $\|v\|^2 = 1$). The equation $\psi(s) = \varrho^2$ is thus a quadratic equation, and has at most two solutions; but it is satisfied by s_1, s_2, s_3 , which are three distinct values (distinct points of a line have distinct parameters). Contradiction: hence $G(c) > 0$ for every c .

Step 4 — conclusion. The infimum of G equals 0 (Step 2) but is not attained at any point (Step 3): G has no minimum. By Proposition 31.2, $\inf_\theta F = \inf_c G = 0$, and if F had a minimum at $\theta^* = (c^*, r^*)$ we would have $G(c^*) \leq F(\theta^*) = 0$, absurd. Hence F has no minimum either. $\square$

Example 31.2: Five collinear points: the escape to infinity, in numbers. Let P be the sample $(0, 0), (1, 0), (2, 0), (3, 0), (4, 0)$. The centroid is $\bar{p} = (2, 0)$, the deviations are $w_i = (s_i, 0)$ with $s_i \in \{-2, -1, 0, 1, 2\}$, and

$$S = \sum_i w_i w_i^\top = \begin{pmatrix} \sum_i s_i^2 & 0 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} 10 & 0 \\ 0 & 0 \end{pmatrix}, \quad \lambda_{\min}(S) = 0.$$

Take $c = (2, t)$ with $t > 0$. Then $\rho_i = \sqrt{s_i^2 + t^2}$ and, expanding as in Lemma 31.3 but one order further, $\rho_i = t + \frac{s_i^2}{2t} - \frac{s_i^4}{8t^3} + O(t^{-5})$, whence $\rho_i - \bar{\rho} = \frac{s_i^2 - m_2}{2t} + O(t^{-3})$ with $m_2 = \frac{1}{5} \sum_i s_i^2 = 2$. Therefore

$$\begin{aligned} G(2, t) &= \frac{1}{4t^2} \sum_i (s_i^2 - 2)^2 + O(t^{-4}) = \frac{2^2 + 1^2 + 2^2 + 1^2 + 2^2}{4t^2} + O(t^{-4}) \\ &= \frac{14}{4t^2} + O(t^{-4}) = \frac{3.5}{t^2} + O(t^{-4}). \end{aligned}$$

Independent check (direct evaluation of G in double precision): $G(2, 10) = 3.4244729 \cdot 10^{-2}$ against $3.5/10^2 = 3.5 \cdot 10^{-2}$; $G(2, 100) = 3.4992252 \cdot 10^{-4}$ against $3.5 \cdot 10^{-4}$; $G(2, 1000) = 3.4999922 \cdot 10^{-6}$ against $3.5 \cdot 10^{-6}$. ✓ The ratio of the computed value to the estimate tends to 1 as $1 + O(t^{-2})$, exactly as predicted. The infimum 0 is never attained: the optimal radius $\bar{\rho}(2, t) \approx t + 1/t$ diverges, and the circle degenerates into the line $y = 0$, which is the line of Observation 31.5 for $u = (0, 1)$.

Proposition 31.4: Samples with few points: the minimum exists but is not unique.

- (i) If $n = 1$, then $F(\theta) = 0$ for every $c \in \mathbb{R}^2$ and $r = \|p_1 - c\|$: the set of global minimizers is a two-dimensional surface.
- (ii) If $n = 2$ and $p_1 \neq p_2$, then $F(\theta) = 0$ if and only if c belongs to the perpendicular bisector of the segment $p_1 p_2$ and $r = \|p_1 - c\|$: the set of global minimizers is a curve.
- (iii) If all the points of the sample coincide ($M = 0$), then $F(\theta) = 0$ if and only if $r = \|p_1 - c\|$, for every c .

In all three cases the minimum exists, equals 0, and is not unique.

Proof. (i) For $n = 1$, $F(\theta) = (\rho_1(c) - r)^2$, which is ≥ 0 and vanishes exactly for $r = \rho_1(c) = \|p_1 - c\|$. Since c ranges freely over $\mathbb{R}^2$, the set of minimizers is $\{(c, \|p_1 - c\|) : c \in \mathbb{R}^2\}$, the graph of a continuous function on $\mathbb{R}^2$.

(ii) For $n = 2$, $F(\theta) = (\rho_1 - r)^2 + (\rho_2 - r)^2 \geq 0$ vanishes if and only if $\rho_1(c) = \rho_2(c) = r$. The condition $\|p_1 - c\| = \|p_2 - c\|$ defines, by definition, the perpendicular bisector of the segment $p_1 p_2$, which is a line because $p_1 \neq p_2$; on it $r = \|p_1 - c\|$ is determined by c . The set of minimizers is thus the graph of a continuous function on a line.

(iii) If $p_1 = \dots = p_n =: p$, then $\rho_i(c) = \|p - c\|$ for every i and $F(\theta) = n(\|p - c\| - r)^2$, which vanishes if and only if $r = \|p - c\|$.

In all cases $F \geq 0$ by definition and the value 0 is attained: these are therefore global minima, and the sets described have more than one element. □

Remark 31.6: The existence criterion is verifiable. Theorem 31.3 can be used in practice: one only needs to compute $\lambda_{\min}(S)$ (two eigenvalues of a 2×2 matrix: a closed-form operation) and compare it with the value of G at the center proposed by an algebraic method. If $G(c_0) < \lambda_{\min}(S)$ the minimum exists, lies in the explicit disc of the statement,

and any descent method starting from c_0 that decreases G stays in a compact set. On the two numerical samples of the chapter the margin is enormous: in sample A (Solved exercise 31.4) one has $\lambda_{\min}(S) = 75.7684689$ against $G(c^*) = 0.3463347$; in sample B, which is a short arc (Solved exercise 31.5), one has $\lambda_{\min}(S) = 0.2201842$ against $G(c^*) = 0.0017718$: the ratio is still two orders of magnitude, but one already sees that shortening the arc brings the two numbers closer. In the limit of collinear points they coincide and the minimum disappears (Corollary 31.4).

31.4. The normal equations and their nonlinearity

Proposition 31.5: Regularity of the objective function. Let $\Omega = \{\theta = (c, r) : \rho_i(c) > 0 \text{ for every } i\}$, i.e. the set of parameters whose center does not coincide with any data point. Then Ω is an open subset of $\mathbb{R}^3$ and F is of class C^∞ on Ω , with

$$\frac{\partial \rho_i}{\partial c} = -u_i^\top, \quad u_i = u_i(c) = \frac{p_i - c}{\rho_i(c)} \quad (\|u_i\| = 1).$$

Proof. Step 1 — Ω is open. The function $c \mapsto \min_i \rho_i(c)$ is continuous (finite minimum of continuous functions) and Ω is the preimage of the open set $(0, +\infty)$ multiplied by $\mathbb{R}$ in the variable r : it is therefore open in $\mathbb{R}^3$.

Step 2 — derivative of ρ_i . On Ω one has $\rho_i(c) = \sqrt{g_i(c)}$ with $g_i(c) = (x_i - a)^2 + (y_i - b)^2 > 0$; g_i is a polynomial and $s \mapsto \sqrt{s}$ is C^∞ on $(0, +\infty)$, hence $\rho_i \in C^\infty(\Omega)$. Differentiating,

$$\frac{\partial \rho_i}{\partial a} = \frac{-2(x_i - a)}{2\sqrt{g_i}} = -\frac{x_i - a}{\rho_i}, \quad \frac{\partial \rho_i}{\partial b} = -\frac{y_i - b}{\rho_i},$$

i.e. $\partial \rho_i / \partial c = -u_i^\top$ with $u_i = (p_i - c) / \rho_i$. That u_i is a unit vector follows from $\|p_i - c\| = \rho_i$.

Step 3 — F . $d_i(\theta) = \rho_i(c) - r$ is C^∞ on Ω and $F = \sum_i d_i^2$ is a sum of squares of C^∞ functions: it is C^∞ . $\square$

Proposition 31.6: Gradient of the objective function. On Ω one has

$$\frac{\partial F}{\partial c} = -2 \sum_{i=1}^n d_i u_i^\top, \quad \frac{\partial F}{\partial r} = -2 \sum_{i=1}^n d_i,$$

$$\text{i.e. } \nabla F(\theta) = -2 \sum_{i=1}^n d_i \begin{pmatrix} u_i \\ 1 \end{pmatrix}.$$

Proof. By Proposition 31.5, $F = \sum_i d_i^2$ is differentiable on Ω and $\partial F / \partial \theta = 2 \sum_i d_i \partial d_i / \partial \theta$. Now $\partial d_i / \partial c = \partial \rho_i / \partial c = -u_i^\top$ (the term $-r$ does not depend on c) and $\partial d_i / \partial r = -1$ (the term ρ_i does not depend on r). Substituting gives the two formulas, which collected into a single column vector give the final expression. $\square$

Theorem 31.4: Normal equations of the geometric fit. Let $\theta^* = (c^*, r^*) \in \Omega$ with $r^* > 0$ be a local minimizer of F . Then the three equations

$$\sum_{i=1}^n d_i = 0, \quad \sum_{i=1}^n d_i u_i = 0 \in \mathbb{R}^2, \quad (31.2)$$

hold, equivalent to the system

$$r^* = \bar{\rho}(c^*) = \frac{1}{n} \sum_{i=1}^n \rho_i(c^*), \quad c^* = \bar{p} - \frac{r^*}{n} \sum_{i=1}^n u_i(c^*). \quad (31.3)$$

Conversely, every $\theta \in \Omega$ satisfying (31.2) is a stationary point of F .

Proof. Step 1 — first-order necessary condition. θ^* is interior to the domain $\mathbb{R}^2 \times (0, +\infty)$ (because $r^* > 0$) and F is differentiable in a neighborhood (Proposition 31.5); hence $\nabla F(\theta^*) = 0$. By Proposition 31.6 this is equivalent to $\sum_i d_i = 0$ and $\sum_i d_i u_i = 0$, i.e. to (31.2).

Step 2 — the first equation gives the radius. $\sum_i d_i = \sum_i \rho_i - nr = 0$ is equivalent to $r = \frac{1}{n} \sum_i \rho_i = \bar{\rho}(c)$: this is the first equation of (31.3), and coincides with Proposition 31.2.

Step 3 — the second equation gives the center. Since $\rho_i u_i = p_i - c$ by definition of u_i , we have

$$0 = \sum_{i=1}^n d_i u_i = \sum_{i=1}^n (\rho_i - r) u_i = \sum_{i=1}^n \rho_i u_i - r \sum_{i=1}^n u_i = \sum_{i=1}^n (p_i - c) - r \sum_{i=1}^n u_i = n(\bar{p} - c) - r \sum_{i=1}^n u_i.$$

Dividing by n and isolating c gives $c = \bar{p} - \frac{r}{n} \sum_i u_i$, i.e. the second equation of (31.3). The steps are reversible, so the two formulations are equivalent.

Step 4 — converse. If $\theta \in \Omega$ satisfies (31.2), then $\nabla F(\theta) = 0$ by Proposition 31.6: θ is stationary. $\square$

Remark 31.7: A fixed-point system, not a linear system. Form (31.3) is instructive: the optimal center is the centroid of the data corrected by a vector proportional to the mean of the radial unit vectors. If the data are distributed symmetrically around the center, that mean vanishes and the optimal center coincides with the centroid; on a short arc, however, all the unit vectors u_i point roughly in the same direction, the mean has norm close to 1 and the correction is nearly r : the optimal center is very far from the centroid. The unknowns, however, also appear on the right-hand side, inside $u_i(c)$ and $\bar{\rho}(c)$: (31.3) is a fixed-point equation, not a linear system, and this is why an iteration is needed.

Proposition 31.7: Hessian matrix. On Ω the Hessian matrix of F , written in blocks with respect to the decomposition $\theta = (c, r)$, is

$$\nabla^2 F(\theta) = 2 \begin{pmatrix} \sum_i u_i u_i^\top & \sum_i u_i \\ \sum_i u_i^\top & n \end{pmatrix} + 2 \begin{pmatrix} \sum_i \frac{d_i}{\rho_i} (I - u_i u_i^\top) & 0 \\ 0 & 0 \end{pmatrix}.$$

Proof. Step 1 — derivative of the radial unit vector. On Ω , $u_i = (p_i - c)/\rho_i$. Differentiating the product and using $\partial \rho_i / \partial c = -u_i^\top$ (Proposition 31.5),

$$\frac{\partial u_i}{\partial c} = \frac{\partial(p_i - c)}{\partial c} \cdot \frac{1}{\rho_i} + (p_i - c) \frac{\partial}{\partial c} \left(\frac{1}{\rho_i} \right) = -\frac{I}{\rho_i} + (p_i - c) \cdot \frac{u_i^\top}{\rho_i^2} = \frac{-I + u_i u_i^\top}{\rho_i},$$

where we used $\partial(1/\rho_i)/\partial c = -\rho_i^{-2} \partial \rho_i / \partial c = \rho_i^{-2} u_i^\top$ and $p_i - c = \rho_i u_i$.

Step 2 — the cc block. Differentiating $\partial F / \partial c = -2 \sum_i d_i u_i^\top$ (Proposition 31.6) with respect to c , with the product rule and with $\partial d_i / \partial c = -u_i^\top$,

$$\frac{\partial^2 F}{\partial c^2} = -2 \sum_i \left[u_i \frac{\partial d_i}{\partial c} + d_i \frac{\partial u_i}{\partial c} \right] = -2 \sum_i \left[-u_i u_i^\top + d_i \frac{-I + u_i u_i^\top}{\rho_i} \right]$$

$$= 2 \sum_i \left[u_i u_i^\top + \frac{d_i}{\rho_i} (I - u_i u_i^\top) \right].$$

Step 3 — the mixed block and the rr block. Differentiating $\partial F / \partial c = -2 \sum_i d_i u_i^\top$ with respect to r , and recalling that u_i does not depend on r while $\partial d_i / \partial r = -1$, we get $\partial^2 F / \partial c \partial r = -2 \sum_i (-1) u_i = 2 \sum_i u_i$. Differentiating $\partial F / \partial r = -2 \sum_i d_i$ with respect to r gives $\partial^2 F / \partial r^2 = -2 \sum_i (-1) = 2n$.

Step 4 — reassembly. Putting together the three blocks and separating the term with d_i / ρ_i from the rest gives the formula of the statement. $\square$

Proposition 31.8: The objective function is not quadratic. *There is a sample P for which $\nabla^2 F$ is not constant on Ω ; in particular F is not a second-degree polynomial in (a, b, r) and the normal equations (31.2) are not a linear system.*

Proof. Take the sample with a single point $p_1 = (1, 0)$ (or, if one prefers a sample with $n \geq 3$, the three points $(1, 0), (1, 0), (1, 0)$, for which everything is multiplied by 3). For $c = (a, 0)$ with $a < 1$ one has $\rho_1 = 1 - a$, $u_1 = (1, 0)$, and by Proposition 31.7 the cc block of the Hessian equals

$$2 \left[\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} + \frac{(1-a)-r}{1-a} \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \right] = 2 \begin{pmatrix} 1 & 0 \\ 0 & 1 - \frac{r}{1-a} \end{pmatrix}.$$

The $(2, 2)$ entry equals $2(1 - \frac{r}{1-a})$, which depends on a : for $r = 1$ it equals 0 at $a = 0$ and -2 at $a = \frac{1}{2}$. Hence $\nabla^2 F$ is not constant.

If F were a polynomial of degree ≤ 2 in the three variables, its Hessian would be the constant matrix of the second-degree coefficients; and the gradient of such a polynomial is affine, so that $\nabla F = 0$ would be a linear system. Since the Hessian is not constant, F is not quadratic and $\nabla F = 0$ is not a linear system. $\square$

Remark 31.8: Where the nonlinearity exactly lies. *The comparison with Volume I, Chapter 10 is sharp. There one minimizes $\sum_i (\rho_i^2 - r^2)^2$: setting $u = 2a$, $v = 2b$, $w = r^2 - a^2 - b^2$ and $z_i = x_i^2 + y_i^2$, the residual becomes $z_i - ux_i - vy_i - w$, i.e. an affine function of the new parameters, and the minimization is a linear least-squares problem with a closed-form solution. Here instead the residual is $\sqrt{(x_i - a)^2 + (y_i - b)^2} - r$, and the square root cannot be absorbed by any change of variables of the three parameters: the term $\frac{d_i}{\rho_i} (I - u_i u_i^\top)$ of the Hessian — which is exactly the piece depending on the curvature of the residual — is not constant. This is the technical reason why the geometric fit requires an iteration and the algebraic fit does not; and it is also the reason why the algebraic fit does not solve the same problem (Section 31.8).*

Example 31.3: A symmetric sample with an exact solution. Let P be the sample $p_1 = (1, 0)$, $p_2 = (-1, 0)$, $p_3 = (0, 2)$, $p_4 = (0, -2)$, and let $\theta^* = (0, 0, \frac{3}{2})$.

The normal equations. One has $\rho_1 = \rho_2 = 1$, $\rho_3 = \rho_4 = 2$, so $\bar{\rho} = \frac{1+1+2+2}{4} = \frac{3}{2} = r^*$: the first normal equation is satisfied, and the residuals are $d_1 = d_2 = -\frac{1}{2}$, $d_3 = d_4 = +\frac{1}{2}$. The radial unit vectors are $u_1 = (1, 0)$, $u_2 = (-1, 0)$, $u_3 = (0, 1)$, $u_4 = (0, -1)$, and

$$\sum_i d_i u_i = -\frac{1}{2}(1, 0) - \frac{1}{2}(-1, 0) + \frac{1}{2}(0, 1) + \frac{1}{2}(0, -1) = (0, 0) :$$

the second equation is satisfied as well. By Theorem 31.4, θ^* is stationary, and

$$F(\theta^*) = 4 \cdot \left(\frac{1}{2}\right)^2 = 1.$$

It is a minimum. By Proposition 31.7, since $\sum_i u_i u_i^\top = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix}$ and $\sum_i u_i = 0$,

$$\sum_i \frac{d_i}{\rho_i} (I - u_i u_i^\top) = 2 \cdot \left(-\frac{1}{2}\right) \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} + 2 \cdot \left(\frac{1}{4}\right) \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} \frac{1}{2} & 0 \\ 0 & -1 \end{pmatrix},$$

whence

$$\nabla^2 F(\theta^*) = 2 \begin{pmatrix} 2 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 4 \end{pmatrix} + 2 \begin{pmatrix} \frac{1}{2} & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix} = \begin{pmatrix} 5 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 8 \end{pmatrix}.$$

The eigenvalues are 2, 5, 8, all positive: by the second-order sufficient condition θ^* is a strict local minimum.

Independent check 1 (grid). Evaluating G of Proposition 31.2 on a 401×401 grid of the square $[-1, 1]^2$ one finds the minimum 1.0000000 at $(0.00000; 0.00000)$ with $\bar{\rho} = 1.500000$. ✓

Independent check 2 (direct method). A Nelder–Mead iteration on the variable c alone, started at $(0.3; 0.4)$, converges in 57 steps to $c = (6.0 \cdot 10^{-8}, 6.3 \cdot 10^{-8})$ with $G = 1.0000000$ and $\bar{\rho} = 1.5000000$. ✓

Remark. The algebraic fit of the same sample gives the same center but radius $\sqrt{\frac{1+1+4+4}{4}} = \sqrt{2.5} = 1.5811388$, larger than 1.5: this is the inequality of Proposition 31.14, verified here in exact form, with gap $\sqrt{2.5} - \frac{3}{2} = 0.0811388$ and $\frac{\text{Var}(\rho)}{\sqrt{2.5} + \frac{3}{2}} = \frac{0.25}{3.0811388} = 0.0811388$. ✓

31.5. Gauss–Newton: Jacobian, step, descent direction

Definition 31.5: Residual vector and Jacobian. For $\theta \in \Omega$ set

$$d(\theta) = (d_1(\theta), \dots, d_n(\theta))^\top \in \mathbb{R}^n, \quad J(\theta) = \frac{\partial d}{\partial \theta} \in \mathbb{R}^{n \times 3}.$$

Then $F(\theta) = \|d(\theta)\|^2 = d^\top d$.

Proposition 31.9: The rows of the Jacobian are the radial unit vectors. For $\theta \in \Omega$, the i -th row of $J(\theta)$ is

$$J_{i\bullet} = -\begin{pmatrix} u_i^\top & 1 \end{pmatrix} = \begin{pmatrix} -\frac{x_i - a}{\rho_i} & -\frac{y_i - b}{\rho_i} & -1 \end{pmatrix},$$

and

$$\nabla F(\theta) = 2J^\top d, \quad J^\top J = \begin{pmatrix} \sum_i u_i u_i^\top & \sum_i u_i \\ \sum_i u_i^\top & n \end{pmatrix}.$$

In particular every entry of J has modulus ≤ 1 and J is dimensionless.

Proof. Step 1 — the rows. $d_i(\theta) = \rho_i(c) - r$, so by Proposition 31.5 $\partial d_i / \partial c = -u_i^\top$ and $\partial d_i / \partial r = -1$: the i -th row of J is $(-u_i^\top, -1)$.

Step 2 — the gradient. Differentiating $F = \sum_i d_i^2$, $\nabla F = 2 \sum_i d_i \nabla d_i = 2J^\top d$, where we used that ∇d_i is the transpose of the i -th row of J . The result coincides with Proposition 31.6, since $2J^\top d = 2 \sum_i d_i \cdot (- (u_i^\top, 1))^\top = -2 \sum_i d_i (u_i, 1)^\top$.

Step 3 — $J^\top J$. By definition of matrix product, $J^\top J = \sum_i J_{i\bullet}^\top J_{i\bullet} = \sum_i \begin{pmatrix} u_i \\ 1 \end{pmatrix} \begin{pmatrix} u_i^\top & 1 \end{pmatrix}$ (the two minus signs cancel), i.e. the block matrix of the statement.

Step 4 — **boundedness**. The components of u_i have modulus $\leq \|u_i\| = 1$, and the third column is the constant -1 . Since every entry is either a component of a unit vector or -1 , J has no physical dimensions: the three parameters a, b, r are all lengths and so are the residuals, hence the derivatives are pure numbers. This is what makes it meaningful to speak of the condition number of J without having to rescale the columns. $\square$

Lemma 31.4: Full rank of the Jacobian. Let $\theta \in \Omega$. Then $\text{rank } J(\theta) = 3$ if and only if the unit vectors $u_1, \dots, u_n$ take at least three distinct values. In particular $n \geq 3$ is necessary, and the rank is not full exactly when all the data lie on at most two rays issuing from the center c .

Proof. **Step 1** — **reformulation**. Set $v_i = (u_i^\top, 1)^\top \in \mathbb{R}^3$; the rows of J are $-v_i^\top$, hence $\text{rank } J = \dim \text{span}\{v_1, \dots, v_n\}$, and $\text{rank } J < 3$ if and only if there is a nonzero $(z, \gamma) \in \mathbb{R}^2 \times \mathbb{R}$ with $\langle z, u_i \rangle + \gamma = 0$ for every i .

Step 2 — **necessarily** $z \neq 0$. If $z = 0$, the condition would give $\gamma = 0$ and hence $(z, \gamma) = 0$, excluded. Hence $z \neq 0$ and the condition says that all the u_i belong to the line $L = \{u \in \mathbb{R}^2 : \langle z, u \rangle = -\gamma\}$.

Step 3 — **a line meets the unit circle in at most two points**. Parametrizing L as $q + s \hat{z}^\perp$ with $\hat{z}^\perp$ a unit vector orthogonal to z and $q \in L$, the condition $\|q + s \hat{z}^\perp\| = 1$ becomes $s^2 + 2s\langle q, \hat{z}^\perp \rangle + \|q\|^2 - 1 = 0$, a quadratic equation in s with leading coefficient $1 \neq 0$: it has at most two solutions. Since $\|u_i\| = 1$ for every i , the u_i take at most two distinct values.

Step 4 — **converse**. Suppose the u_i take at most two distinct values, say u and u' (possibly equal). If $u \neq u'$, let $z \neq 0$ be a vector orthogonal to $u - u'$ and let $\gamma = -\langle z, u \rangle$: then $\langle z, u \rangle + \gamma = 0$ and $\langle z, u' \rangle + \gamma = \langle z, u' - u \rangle = 0$. If $u = u'$, take $z = u \neq 0$ and $\gamma = -1$: $\langle u, u \rangle - 1 = 0$. In both cases $(z, \gamma) \neq 0$ satisfies the condition of Step 1, hence $\text{rank } J < 3$.

Step 5 — **geometric reading**. $u_i = (p_i - c)/\rho_i$ is the direction of the ray from c toward p_i ; two points have the same unit vector if and only if they lie on the same ray issuing from c . Hence "the u_i take at most two values" means "the data lie on at most two rays issuing from c ". Finally three distinct values require at least three points. $\square$

Definition 31.6: Gauss–Newton step. Let $\theta \in \Omega$ with $J = J(\theta)$ of rank 3. The **Gauss–Newton step** at θ is the vector $\delta_{\text{GN}} \in \mathbb{R}^3$ defined by

$$J^\top J \delta_{\text{GN}} = -J^\top d, \quad \text{i.e.} \quad \delta_{\text{GN}} = -(J^\top J)^{-1} J^\top d,$$

and the **Gauss–Newton iteration** is $\theta^{(k+1)} = \theta^{(k)} + \delta_{\text{GN}}(\theta^{(k)})$.

Lemma 31.5: The step minimizes the linear model of the residual. Let J have rank 3. Then δ_{GN} is the unique minimizer of the function $\delta \mapsto \|d + J\delta\|^2$, and is well defined because $J^\top J$ is invertible.

Proof. **Step 1** — **$J^\top J$ is positive definite**. For every $\delta \in \mathbb{R}^3$, $\delta^\top J^\top J \delta = \|J\delta\|^2 \geq 0$, with equality if and only if $J\delta = 0$; since $\text{rank } J = 3$ and J has three columns, the kernel of J is $\{0\}$, hence $\delta^\top J^\top J \delta > 0$ for $\delta \neq 0$. A symmetric positive definite matrix is invertible.

Step 2 — **minimum of the model**. The function $q(\delta) = \|d + J\delta\|^2 = d^\top d + 2d^\top J\delta + \delta^\top J^\top J \delta$ is a second-degree polynomial in δ whose quadratic part is positive definite (Step 1): it is thus strictly convex and has a unique minimizer, which is its only stationary point. From $\nabla q(\delta) = 2J^\top d + 2J^\top J \delta = 0$ it follows that $\delta = -(J^\top J)^{-1} J^\top d = \delta_{\text{GN}}$. $\square$

Theorem 31.5: The Gauss–Newton step is a descent direction. Let $\theta \in \Omega$ with $J = J(\theta)$ of rank 3 and $J^\top d \neq 0$. Then

$$\langle \nabla F(\theta), \delta_{\text{GN}} \rangle = -2 (J^\top d)^\top (J^\top J)^{-1} (J^\top d) < 0,$$

and consequently there exists $\tau_0 > 0$ such that $F(\theta + \tau \delta_{\text{GN}}) < F(\theta)$ for every $\tau \in (0, \tau_0)$. If instead $J^\top d = 0$, then $\delta_{\text{GN}} = 0$ and θ is a stationary point of F .

Proof. Step 1 — the scalar product. By Proposition 31.9, $\nabla F = 2J^\top d$. Setting $g = J^\top d \in \mathbb{R}^3$ and $A = J^\top J$, we have $\delta_{\text{GN}} = -A^{-1}g$ and

$$\langle \nabla F, \delta_{\text{GN}} \rangle = \langle 2g, -A^{-1}g \rangle = -2g^\top A^{-1}g.$$

Step 2 — the sign. A is symmetric positive definite (Step 1 of Lemma 31.5); hence so is A^{-1} : if $Av = \mu v$ with $\mu > 0$ and $v \neq 0$, then $A^{-1}v = \mu^{-1}v$, and the eigenvalues of A^{-1} are the reciprocals of those of A , all positive. Hence $g^\top A^{-1}g > 0$ for $g \neq 0$, and $\langle \nabla F, \delta_{\text{GN}} \rangle < 0$.

Step 3 — actual decrease. F is differentiable at $\theta \in \Omega$ (Proposition 31.5) and Ω is open, so the function $\varphi(\tau) = F(\theta + \tau \delta_{\text{GN}})$ is defined and differentiable in a neighborhood of $\tau = 0$, with $\varphi'(0) = \langle \nabla F(\theta), \delta_{\text{GN}} \rangle < 0$. By definition of derivative there exists $\tau_0 > 0$ such that $\frac{\varphi(\tau) - \varphi(0)}{\tau} < 0$ for $0 < \tau < \tau_0$, i.e. $\varphi(\tau) < \varphi(0) = F(\theta)$.

Step 4 — the case $J^\top d = 0$. Then $\delta_{\text{GN}} = -A^{-1} \cdot 0 = 0$ and $\nabla F = 2J^\top d = 0$: θ is stationary, and the iteration stops. $\square$

Corollary 31.5: Fixed points of the iteration and stationary points. If $J(\theta)$ has rank 3, then θ is a fixed point of the Gauss–Newton iteration if and only if θ satisfies the normal equations (31.2).

Proof. θ is a fixed point if and only if $\delta_{\text{GN}}(\theta) = 0$, i.e., since $J^\top J$ is invertible (Lemma 31.5), if and only if $J^\top d = 0$, i.e. $\nabla F(\theta) = 0$ (Proposition 31.9), i.e., by Theorem 31.4, if and only if (31.2) holds. $\square$

Remark 31.9: What Gauss–Newton discards. Comparing Proposition 31.7 with Proposition 31.9 one sees that

$$\nabla^2 F(\theta) = 2J^\top J + 2 \begin{pmatrix} \sum_i \frac{d_i}{\rho_i} (I - u_i u_i^\top) & 0 \\ 0 & 0 \end{pmatrix} :$$

the Gauss–Newton method replaces the exact Hessian with only the part $2J^\top J$, discarding the term proportional to the residuals. The substitution is the more harmless the smaller the residuals d_i are compared with the radial distances ρ_i : on the data of Solved exercise 31.4 the ratio $\max_i |d_i| / \min_i \rho_i$ equals $0.2875391 / 4.8294136 = 0.0595391$, and indeed the iteration converges in three steps. On very noisy data, or on a fit that starts far from the minimum, the discarded term is not small and Gauss–Newton may diverge: this is the problem that the damping of Section 31.6 solves.

Remark 31.10: What we import about convergence. The convergence rate of the Gauss–Newton iteration — local quadratic convergence in the case of zero residual, linear with a factor proportional to the norm of the discarded term in the case of nonzero residual, and possible divergence without a line search — is a result of numerical analysis that here is **imported** and not proved: see Nocedal–Wright, *Numerical Optimization*, 2nd ed.,

Chapter 10 "Least-Squares Problems", pp. 245–269. What exactly is missing: the estimate $\|\theta^{(k+1)} - \theta^*\| \leq C\|\theta^{(k)} - \theta^*\|^2 + L\|\theta^{(k)} - \theta^*\|$ with L tied to the term $\sum_i \frac{d_i}{\rho_i}(I - u_i u_i^\top)$ of Proposition 31.7, and the Lipschitz regularity hypotheses on the Jacobian in a neighborhood of the minimum that support it. In this chapter we prove only that the step is one of descent (Theorem 31.5) and that the fixed points are exactly the stationary points (Corollary 31.5): these are the two facts needed to guarantee the correctness of the algorithm with a line search, not its speed.

31.6. Levenberg–Marquardt: damping and its two limits

The Gauss–Newton step has two twin defects: it is undefined when the Jacobian loses rank (Lemma 31.4), and when the rank is nearly lost the step is enormous, so much so that it leaves the region where the linear model of the residual is credible. Levenberg–Marquardt damping repairs both with a single parameter.

Definition 31.7: Damped Levenberg–Marquardt step. Let $\theta \in \Omega$, $J = J(\theta)$, $d = d(\theta)$ and $\lambda > 0$ the **damping parameter**. The **Levenberg–Marquardt step** is the vector $\delta(\lambda) \in \mathbb{R}^3$ defined by

$$(J^\top J + \lambda I) \delta(\lambda) = -J^\top d.$$

Theorem 31.6: The damped step is always well defined and is one of descent. Let $\theta \in \Omega$ and $\lambda > 0$. Then:

- (i) $J^\top J + \lambda I$ is symmetric positive definite, whatever the rank of J ; in particular it is invertible and $\delta(\lambda)$ exists and is unique;
- (ii) $\delta(\lambda)$ is the unique minimizer of the function $\delta \mapsto \|d + J\delta\|^2 + \lambda\|\delta\|^2$;
- (iii) if $J^\top d \neq 0$, then $\langle \nabla F(\theta), \delta(\lambda) \rangle < 0$, and hence there exists $\tau_0 > 0$ with $F(\theta + \tau\delta(\lambda)) < F(\theta)$ for every $\tau \in (0, \tau_0)$.

Proof. (i) The matrix $J^\top J$ is symmetric and positive semidefinite, because $\delta^\top J^\top J \delta = \|J\delta\|^2 \geq 0$. Hence for $\delta \neq 0$

$$\delta^\top (J^\top J + \lambda I) \delta = \|J\delta\|^2 + \lambda\|\delta\|^2 \geq \lambda\|\delta\|^2 > 0,$$

and the matrix is positive definite; it is symmetric because it is a sum of symmetric matrices. A positive definite matrix has trivial kernel, hence it is invertible.

(ii) The function $q_\lambda(\delta) = \|d + J\delta\|^2 + \lambda\|\delta\|^2 = d^\top d + 2d^\top J\delta + \delta^\top (J^\top J + \lambda I)\delta$ is a second-degree polynomial whose quadratic part is positive definite by (i): it is thus strictly convex and has a unique minimum, its only stationary point. From $\nabla q_\lambda = 2J^\top d + 2(J^\top J + \lambda I)\delta = 0$ it follows that $\delta = \delta(\lambda)$.

(iii) Setting $g = J^\top d$ and $A_\lambda = J^\top J + \lambda I$, we have $\nabla F = 2g$ (Proposition 31.9) and $\delta(\lambda) = -A_\lambda^{-1}g$, hence

$$\langle \nabla F, \delta(\lambda) \rangle = -2g^\top A_\lambda^{-1}g < 0,$$

because A_λ^{-1} is positive definite (the inverse of a symmetric positive definite matrix has as eigenvalues the reciprocals, all positive) and $g \neq 0$. The decrease for small steps follows as in Step 3 of the proof of Theorem 31.5. $\square$

Theorem 31.7: The two limits of the damping. Let $\theta \in \Omega$ and $g = J^\top d$.

- (i) If $\text{rank } J = 3$, then $\lim_{\lambda \rightarrow 0^+} \delta(\lambda) = \delta_{\text{GN}}$.
- (ii) $\lim_{\lambda \rightarrow +\infty} \lambda \delta(\lambda) = -g = -\frac{1}{2} \nabla F(\theta)$. In particular, if $g \neq 0$, the unit vector of the step

tends to the unit vector of the steepest-descent direction:

$$\lim_{\lambda \rightarrow +\infty} \frac{\delta(\lambda)}{\|\delta(\lambda)\|} = -\frac{\nabla F(\theta)}{\|\nabla F(\theta)\|}.$$

Proof. (i) If $\text{rank } J = 3$ then $J^\top J$ is invertible (Step 1 of Lemma 31.5). The map $A \mapsto A^{-1}$ is continuous on the open set of invertible matrices (the entries of the inverse are, by Cramer's rule, rational functions of the entries with denominator $\det A \neq 0$), and $\lambda \mapsto J^\top J + \lambda I$ is continuous with value $J^\top J$ at $\lambda = 0$; for λ small enough the matrix remains invertible. Hence

$$\lim_{\lambda \rightarrow 0^+} \delta(\lambda) = \lim_{\lambda \rightarrow 0^+} -(J^\top J + \lambda I)^{-1} g = -(J^\top J)^{-1} g = \delta_{\text{GN}}.$$

(ii) For $\lambda > 0$,

$$\lambda \delta(\lambda) = -\lambda (J^\top J + \lambda I)^{-1} g = -\left(\frac{J^\top J}{\lambda} + I\right)^{-1} g,$$

where we used $\lambda(B + \lambda I)^{-1} = (\lambda^{-1}B + I)^{-1}$, valid because $\lambda(B + \lambda I)^{-1} \cdot (\lambda^{-1}B + I) = \lambda(B + \lambda I)^{-1} \cdot \lambda^{-1}(B + \lambda I) = I$. Now $\lambda^{-1}J^\top J \rightarrow 0$ as $\lambda \rightarrow +\infty$, hence $\lambda^{-1}J^\top J + I \rightarrow I$, which is invertible; by the continuity of inversion (Part (i)) we get $\lambda \delta(\lambda) \rightarrow -I^{-1}g = -g$. Since $\nabla F = 2g$, the limit is $-\frac{1}{2}\nabla F$.

Unit vectors. If $g \neq 0$, by what we just showed $\|\lambda \delta(\lambda)\| \rightarrow \|g\| > 0$, hence $\lambda \delta(\lambda) \neq 0$ for large λ and

$$\frac{\delta(\lambda)}{\|\delta(\lambda)\|} = \frac{\lambda \delta(\lambda)}{\|\lambda \delta(\lambda)\|} \rightarrow \frac{-g}{\|g\|} = -\frac{\nabla F}{\|\nabla F\|},$$

by continuity of the map $v \mapsto v/\|v\|$ away from the origin. $\square$

Proposition 31.10: The step length decreases with the damping. Let $\theta \in \Omega$ with $g = J^\top d \neq 0$. Then the function $\lambda \mapsto \|\delta(\lambda)\|$ is strictly decreasing on $(0, +\infty)$, with $\lim_{\lambda \rightarrow +\infty} \|\delta(\lambda)\| = 0$; if moreover $\text{rank } J = 3$, then $\lim_{\lambda \rightarrow 0^+} \|\delta(\lambda)\| = \|\delta_{\text{GN}}\|$ and $\|\delta(\lambda)\| < \|\delta_{\text{GN}}\|$ for every $\lambda > 0$.

Proof. **Step 1 — singular value decomposition.** Let $J = U\Sigma V^\top$ be a reduced singular value decomposition, with $U \in \mathbb{R}^{n \times 3}$ having orthonormal columns, $V \in \mathbb{R}^{3 \times 3}$ orthogonal and $\Sigma = \text{diag}(\sigma_1, \sigma_2, \sigma_3)$, $\sigma_j \geq 0$. Then $J^\top J = V\Sigma^2 V^\top$ and

$$J^\top J + \lambda I = V(\Sigma^2 + \lambda I)V^\top, \quad g = J^\top d = V\Sigma U^\top d.$$

Step 2 — explicit form of the step. Setting $h = U^\top d \in \mathbb{R}^3$ with components h_1, h_2, h_3 ,

$$\delta(\lambda) = -V(\Sigma^2 + \lambda I)^{-1}\Sigma h, \quad \text{i.e.} \quad V^\top \delta(\lambda) = \left(-\frac{\sigma_1 h_1}{\sigma_1^2 + \lambda}, -\frac{\sigma_2 h_2}{\sigma_2^2 + \lambda}, -\frac{\sigma_3 h_3}{\sigma_3^2 + \lambda}\right)^\top.$$

Since V is orthogonal, $\|\delta(\lambda)\| = \|V^\top \delta(\lambda)\|$ and

$$\|\delta(\lambda)\|^2 = \sum_{j=1}^3 \frac{\sigma_j^2 h_j^2}{(\sigma_j^2 + \lambda)^2}.$$

Step 3 — monotonicity. Each term is a nonincreasing function of $\lambda > 0$, because the numerator is constant and the denominator grows; and it is *strictly* decreasing if $\sigma_j h_j \neq 0$. Since $g = V\Sigma h \neq 0$ and V is invertible, $\Sigma h \neq 0$, i.e. at least one $\sigma_j h_j \neq 0$: the sum is strictly decreasing.

Step 4 — the limits. Each term tends to 0 as $\lambda \rightarrow +\infty$, hence $\|\delta(\lambda)\| \rightarrow 0$. If $\text{rank } J = 3$ all the σ_j are positive and each term tends to h_j^2/σ_j^2 as $\lambda \rightarrow 0^+$; the sum is $\|\Sigma^{-1}h\|^2 = \|\delta_{\text{GN}}\|^2$,

consistent with Theorem 31.7(i). The strict inequality for $\lambda > 0$ follows from the strict monotonicity of Step 3. $\square$

Remark 31.11: Damping as a trust region. Proposition 31.10 says that λ controls the length of the step monotonically: increasing λ shortens the step and rotates it toward the gradient. The fact that $\delta(\lambda)$ is exactly the solution of the constrained problem

$$\min_{\|\delta\| \leq \Delta} \|d + J\delta\|^2$$

for a suitable $\Delta = \Delta(\lambda)$ — i.e. that Levenberg–Marquardt is a trust-region method — is a result that here is **imported** and not proved: see Nocedal–Wright, *Numerical Optimization*, 2nd ed., Chapter 4 "Trust-Region Methods", pp. 66–100, and Chapter 10, pp. 245–269. What is missing: the first-order optimality conditions for the constrained problem with Lagrange multiplier λ and the discussion of the so-called hard case, in which the minimum of the model falls on the boundary of the region without the multiplier being determined by the equation $\|\delta(\lambda)\| = \Delta$ alone. Here we prove only well-posedness (Theorem 31.6), the two limits (Theorem 31.7) and the monotonicity of the length (Proposition 31.10), which are the facts on which the practical update rule for λ rests.

Figure 31.2: The Levenberg–Marquardt "fan" in the model case $J^\top J = \text{diag}(4; 0.25)$, $J^\top d = (1; 1)$, for which $\delta(\lambda) = -(\frac{1}{4+\lambda}; \frac{1}{0.25+\lambda})$. The directions drawn correspond to $\lambda = 0$ (-93.5763°), 0.25 (-96.7098°), 1 (-104.0362°), 4 (-117.9795°), 16 (-129.0939°) and $\lambda \rightarrow \infty$ (-135° , i.e. the direction of $-\nabla F = -2(1; 1)$). Check of the limiting case: as $\lambda \rightarrow \infty$ the two components of $\lambda\delta(\lambda)$ both tend to -1 , hence the angle tends to $\arctan(-1/-1)$ in the third quadrant, i.e. -135° , as in Theorem 31.7(ii). $\checkmark$

Best practice. Damping update rule. At each iteration one computes $\delta(\lambda)$ and compares $F(\theta + \delta(\lambda))$ with $F(\theta)$:

- if F has decreased, the step is accepted and λ is *reduced* (typically $\lambda \leftarrow \lambda/10$), moving closer to Gauss–Newton;
- if F has not decreased, the step is rejected and λ is *increased* (typically $\lambda \leftarrow 10\lambda$), shortening the step and rotating it toward the gradient.

Theorem 31.6(iii) guarantees that, for λ large enough, an acceptable step always exists, provided $\nabla F(\theta) \neq 0$: indeed $\delta(\lambda)$ is one of descent and its length tends to 0 (Proposition 31.10), so it eventually falls in the interval $(0, \tau_0)$ of the theorem. The loop can therefore never get stuck at a nonstationary point.

31.7. Conditioning, short arcs and stopping criteria

Definition 31.8: Condition number of the Jacobian. Let $\sigma_1 \geq \sigma_2 \geq \sigma_3 \geq 0$ be the singular values of $J(\theta)$. If $\sigma_3 > 0$ set

$$\kappa_2(J) = \frac{\sigma_1}{\sigma_3} \geq 1,$$

the **spectral condition number** of J ; if $\sigma_3 = 0$ set $\kappa_2(J) = +\infty$. Since the eigenvalues of $J^\top J$ are the σ_j^2 , one has $\kappa_2(J)^2 = \kappa_2(J^\top J)$.

Proposition 31.11: Sensitivity of the step to the data. Let J have rank 3 and let δ_{GN} and $\tilde{\delta}_{\text{GN}}$ be the Gauss–Newton steps computed with the residual vectors d and $d + e$ respectively (same J). Then

$$\|\tilde{\delta}_{\text{GN}} - \delta_{\text{GN}}\| \leq \frac{\|e\|}{\sigma_3}, \quad \text{and, if } \delta_{\text{GN}} \neq 0, \quad \frac{\|\tilde{\delta}_{\text{GN}} - \delta_{\text{GN}}\|}{\|\delta_{\text{GN}}\|} \leq \kappa_2(J) \frac{\|e\|}{\|J\delta_{\text{GN}}\|}.$$

Proof. Step 1 — the difference. By linearity, $\tilde{\delta}_{\text{GN}} - \delta_{\text{GN}} = -(J^\top J)^{-1} J^\top e$.

Step 2 — norm of the pseudoinverse. With $J = U\Sigma V^\top$ as in Step 1 of the proof of Proposition 31.10, and Σ invertible because the rank is 3,

$$(J^\top J)^{-1} J^\top = (V\Sigma^2 V^\top)^{-1} V\Sigma U^\top = V\Sigma^{-2} \Sigma U^\top = V\Sigma^{-1} U^\top.$$

For every $e \in \mathbb{R}^n$, since U has orthonormal columns and V is orthogonal, $\|V\Sigma^{-1} U^\top e\| = \|\Sigma^{-1} U^\top e\| \leq \sigma_3^{-1} \|U^\top e\| \leq \sigma_3^{-1} \|e\|$. This proves the first estimate.

Step 3 — the relative form. Since $\|J\delta_{\text{GN}}\| \leq \sigma_1 \|\delta_{\text{GN}}\|$ (the largest singular value is the spectral norm), one has $\|\delta_{\text{GN}}\| \geq \|J\delta_{\text{GN}}\|/\sigma_1$ and hence

$$\frac{\|\tilde{\delta}_{\text{GN}} - \delta_{\text{GN}}\|}{\|\delta_{\text{GN}}\|} \leq \frac{\|e\|/\sigma_3}{\|J\delta_{\text{GN}}\|/\sigma_1} = \frac{\sigma_1}{\sigma_3} \cdot \frac{\|e\|}{\|J\delta_{\text{GN}}\|} = \kappa_2(J) \frac{\|e\|}{\|J\delta_{\text{GN}}\|}.$$

□

Theorem 31.8: Conditioning on a symmetric arc. Let $c \in \mathbb{R}^2$, $r > 0$ and $\varphi_1, \dots, \varphi_n$ be angles such that the list $(\varphi_1, \dots, \varphi_n)$ is symmetric about 0 (i.e. counted with multiplicity, $-\varphi$ occurs as many times as φ). Let $p_i = c + r(\cos \varphi_i, \sin \varphi_i)$ and $\theta = (c, r)$. Setting

$$C_1 = \frac{1}{n} \sum_{i=1}^n \cos \varphi_i, \quad C_2 = \frac{1}{n} \sum_{i=1}^n \cos^2 \varphi_i,$$

one has

$$J(\theta)^\top J(\theta) = n M, \quad M = \begin{pmatrix} C_2 & 0 & C_1 \\ 0 & 1 - C_2 & 0 \\ C_1 & 0 & 1 \end{pmatrix},$$

and the eigenvalues of M are

$$\mu_0 = 1 - C_2, \quad \mu_{\pm} = \frac{(1 + C_2) \pm \sqrt{(1 - C_2)^2 + 4C_1^2}}{2},$$

all nonnegative. Consequently $\kappa_2(J(\theta))^2 = \frac{\max\{\mu_0, \mu_+, \mu_-\}}{\min\{\mu_0, \mu_+, \mu_-\}}$.

Proof. Step 1 — the radial unit vectors. By construction $p_i - c = r(\cos \varphi_i, \sin \varphi_i)$ and $\rho_i = \|p_i - c\| = r$, hence $u_i = (\cos \varphi_i, \sin \varphi_i)$ and $\theta \in \Omega$ because $r > 0$.

Step 2 — the sums. By Proposition 31.9,

$$J^\top J = \begin{pmatrix} \sum_i \cos^2 \varphi_i & \sum_i \cos \varphi_i \sin \varphi_i & \sum_i \cos \varphi_i \\ \sum_i \cos \varphi_i \sin \varphi_i & \sum_i \sin^2 \varphi_i & \sum_i \sin \varphi_i \\ \sum_i \cos \varphi_i & \sum_i \sin \varphi_i & n \end{pmatrix}.$$

The function $\varphi \mapsto \sin \varphi$ is odd, and the list of angles is symmetric: pairing φ with $-\varphi$ gives $\sum_i \sin \varphi_i = 0$. Also $\varphi \mapsto \cos \varphi \sin \varphi = \frac{1}{2} \sin 2\varphi$ is odd, hence $\sum_i \cos \varphi_i \sin \varphi_i = 0$. Finally $\sum_i \cos^2 \varphi_i = nC_2$, $\sum_i \sin^2 \varphi_i = \sum_i (1 - \cos^2 \varphi_i) = n(1 - C_2)$ and $\sum_i \cos \varphi_i = nC_1$. Substituting gives $J^\top J = nM$.

Step 3 — the eigenvalues. The vector $e_2 = (0, 1, 0)^\top$ satisfies $Me_2 = (1 - C_2)e_2$, hence $\mu_0 = 1 - C_2$ is an eigenvalue. The orthogonal complement $\text{span}\{e_1, e_3\}$ is invariant under M (the entries $(1, 2)$, $(2, 1)$, $(2, 3)$, $(3, 2)$ are zero), and the restriction has matrix $N = \begin{pmatrix} C_2 & C_1 \\ C_1 & 1 \end{pmatrix}$, with trace $1 + C_2$ and determinant $C_2 - C_1^2$. The eigenvalues of a 2×2 matrix are the roots of $\mu^2 - (\text{tr } N)\mu + \det N = 0$, i.e.

$$\mu_{\pm} = \frac{(1 + C_2) \pm \sqrt{(1 + C_2)^2 - 4(C_2 - C_1^2)}}{2} = \frac{(1 + C_2) \pm \sqrt{(1 - C_2)^2 + 4C_1^2}}{2},$$

having used $(1 + C_2)^2 - 4C_2 = (1 - C_2)^2$.

Step 4 — nonnegativity. $C_2 \leq 1$ because $\cos^2 \leq 1$, hence $\mu_0 \geq 0$. By the Cauchy–Schwarz inequality applied to the vectors $(\cos \varphi_1, \dots, \cos \varphi_n)$ and $(1, \dots, 1)$, $(\sum_i \cos \varphi_i)^2 \leq n \sum_i \cos^2 \varphi_i$, i.e. $C_1^2 \leq C_2$: hence $\det N = C_2 - C_1^2 \geq 0$ and, since also $\text{tr } N = 1 + C_2 \geq 0$, both eigenvalues $\mu_{\pm}$ are ≥ 0 .

Step 5 — the condition number. The eigenvalues of $J^\top J = nM$ are $n\mu_0$, $n\mu_{\pm}$, and coincide with the squares of the singular values of J . The ratio between the largest and the smallest is thus $\kappa_2(J)^2$, and the factor n cancels. $\square$

Corollary 31.6: Degradation on short arcs. Replace in Theorem 31.8 the sample averages with the continuous averages on $[-\alpha, \alpha]$, i.e.

$$C_1 = \frac{1}{2\alpha} \int_{-\alpha}^{\alpha} \cos \varphi \, d\varphi = \frac{\sin \alpha}{\alpha}, \quad C_2 = \frac{1}{2\alpha} \int_{-\alpha}^{\alpha} \cos^2 \varphi \, d\varphi = \frac{1}{2} + \frac{\sin 2\alpha}{4\alpha}.$$

Then, as $\alpha \rightarrow 0^+$,

$$\mu_+ = 2 - \frac{\alpha^2}{3} + O(\alpha^4), \quad \mu_0 = \frac{\alpha^2}{3} + O(\alpha^4), \quad \mu_- = \frac{\alpha^4}{90}(1 + O(\alpha^2)),$$

and hence

$$\kappa_2(J) = \frac{\sqrt{180}}{\alpha^2}(1 + O(\alpha^2)) = \frac{13.4164079}{\alpha^2}(1 + O(\alpha^2)).$$

Proof. Step 1 — the two integrals. $\int_{-\alpha}^{\alpha} \cos \varphi \, d\varphi = 2 \sin \alpha$, whence $C_1 = \sin \alpha / \alpha$. With $\cos^2 \varphi = \frac{1 + \cos 2\varphi}{2}$, $\int_{-\alpha}^{\alpha} \cos^2 \varphi \, d\varphi = \alpha + \frac{\sin 2\alpha}{2}$, whence $C_2 = \frac{1}{2} + \frac{\sin 2\alpha}{4\alpha}$.

Step 2 — Taylor expansions. From $\sin s = s - \frac{s^3}{6} + \frac{s^5}{120} + O(s^7)$ it follows that $\frac{\sin s}{s} = 1 - \frac{s^2}{6} + \frac{s^4}{120} + O(s^6)$. Hence

$$C_1 = 1 - \frac{\alpha^2}{6} + \frac{\alpha^4}{120} + O(\alpha^6),$$

and, with $s = 2\alpha$,

$$C_2 = \frac{1}{2} + \frac{1}{2} \cdot \frac{\sin 2\alpha}{2\alpha} = \frac{1}{2} + \frac{1}{2} \left(1 - \frac{4\alpha^2}{6} + \frac{16\alpha^4}{120} \right) + O(\alpha^6) = 1 - \frac{\alpha^2}{3} + \frac{\alpha^4}{15} + O(\alpha^6).$$

Step 3 — trace and determinant. It follows immediately that $\mu_0 = 1 - C_2 = \frac{\alpha^2}{3} - \frac{\alpha^4}{15} + O(\alpha^6)$ and $\text{tr } N = 1 + C_2 = 2 - \frac{\alpha^2}{3} + O(\alpha^4)$. For the determinant,

$$C_1^2 = \left(1 - \frac{\alpha^2}{6} + \frac{\alpha^4}{120} \right)^2 + O(\alpha^6) = 1 - \frac{\alpha^2}{3} + \left(\frac{1}{60} + \frac{1}{36} \right) \alpha^4 + O(\alpha^6) = 1 - \frac{\alpha^2}{3} + \frac{2\alpha^4}{45} + O(\alpha^6),$$

where $\frac{1}{60} + \frac{1}{36} = \frac{3+5}{180} = \frac{2}{45}$; hence

$$\det N = C_2 - C_1^2 = \frac{\alpha^4}{15} - \frac{2\alpha^4}{45} + O(\alpha^6) = \frac{\alpha^4}{45} + O(\alpha^6).$$

Step 4 — the two eigenvalues of the block. Let $T = \text{tr } N$ and $D = \det N$. Since $T \rightarrow 2$ and $D = O(\alpha^4)$, for small α $4D/T^2 = O(\alpha^4)$ and

$$\sqrt{T^2 - 4D} = T \sqrt{1 - \frac{4D}{T^2}} = T \left(1 - \frac{2D}{T^2} + O(\alpha^8) \right) = T - \frac{2D}{T} + O(\alpha^8).$$

Hence

$$\begin{aligned} \mu_+ &= \frac{T + \sqrt{T^2 - 4D}}{2} = T - \frac{D}{T} + O(\alpha^8) = 2 - \frac{\alpha^2}{3} + O(\alpha^4), \\ \mu_- &= \frac{T - \sqrt{T^2 - 4D}}{2} = \frac{D}{T} + O(\alpha^8). \end{aligned}$$

Substituting $D = \frac{\alpha^4}{45}(1 + O(\alpha^2))$ and $T = 2(1 + O(\alpha^2))$ gives $\mu_- = \frac{\alpha^4}{90}(1 + O(\alpha^2))$.

Step 5 — ordering and condition number. For α small enough $\mu_+ \approx 2$, $\mu_0 \approx \alpha^2/3$ and $\mu_- \approx \alpha^4/90$ are in strictly decreasing order; hence by Theorem 31.8

$$\kappa_2(J)^2 = \frac{\mu_+}{\mu_-} = \frac{2(1 + O(\alpha^2))}{\frac{\alpha^4}{90}(1 + O(\alpha^2))} = \frac{180}{\alpha^4}(1 + O(\alpha^2)),$$

and taking the square root (which preserves expansions of the type $1 + O(\alpha^2)$) $\kappa_2(J) = \frac{\sqrt{180}}{\alpha^2}(1 + O(\alpha^2))$. Finally $\sqrt{180} = 6\sqrt{5} = 13.4164079$. $\square$

Example 31.4: Numerical check of the estimate $\kappa \sim \sqrt{180}\alpha^{-2}$. Three quantities are compared: the *exact* condition number computed with the singular value decomposition of J for $n = 201$ equally spaced points in $[-\alpha, \alpha]$ on a unit circle; the condition number obtained from the formula of Theorem 31.8 with the *continuous* moments of Corollary 31.6; and the asymptotic estimate $\sqrt{180}/\alpha^2$.

α	$\kappa_2(J), n = 201$	$\kappa_2, \text{continuous moments}$	$\sqrt{180}/\alpha^2$	ratio
1.00	12.2382	12.3685	13.4164	0.92189
0.50	51.9205	52.4494	53.6656	0.97734
0.30	146.3455	147.8159	149.0712	0.99158
0.20	330.8339	334.1425	335.4102	0.99622
0.10	1327.1312	1340.3655	1341.6408	0.99905
0.05	5312.3489	5365.2860	5366.5631	0.99976

The last column is the ratio between the third and the fourth: it tends to 1 as $1 + O(\alpha^2)$,

exactly as predicted by Corollary 31.6 (the gap from unity shrinks by a factor of four every time α is halved, from 0.2 downward: 0.00378, 0.00095, 0.00024, in ratio 3.98 and 3.96, i.e. ≈ 4 , as it must be for a term of order α^2). ✓

Independent check. The eigenvalues were computed twice: once with the singular value decomposition routine applied directly to J , the other with the closed-form formulas $\mu_0 = 1 - C_2$ and $\mu_{\pm}$ of Theorem 31.8. For $\alpha = 0.30$ and $n = 201$ the two computations give $\mu_+ = 1.9701541$, $\mu_0 = 0.0297539$, $\mu_- = 9.1990 \cdot 10^{-5}$ with agreement down to the last printed digit; and $\det N = 1.812347 \cdot 10^{-4}$ against $\alpha^4/45 = 1.8 \cdot 10^{-4}$. ✓

Remark 31.12: What $\kappa \approx 1000$ means. For an arc of half-aperture $\alpha = 0.1$ radians (a little less than 6°) the condition number is about $1.3 \cdot 10^3$: by Proposition 31.11, a relative error of 10^{-3} on the residuals can produce a relative error of order unity on the parameters. In double precision this is not yet a problem of arithmetic, but it is a statistical problem: measurement noise, not rounding, is amplified. On sample B of Solved exercise 31.5, with measured half-aperture 0.2828 radians, one has $\kappa_2(J) = 134.9473$, and shifting the ordinate of the endpoint by 0.010 changes the estimated radius by 0.0367: an amplification factor of 3.7 on the radius alone, which becomes much larger on the coordinates of the center.

Proposition 31.12: Stopping criteria: from the gradient to the residual step. Let $\theta \in \Omega$ with $J = J(\theta)$ of rank 3 and singular values $\sigma_1 \geq \sigma_2 \geq \sigma_3 > 0$. Then

$$\|\delta_{\text{GN}}\| \leq \frac{\|J^\top d\|}{\sigma_3^2} = \frac{\|\nabla F(\theta)\|}{2\sigma_3^2}, \quad \|\nabla F(\theta)\| \leq 2\sigma_1 \|d\|.$$

In particular a stopping criterion on the gradient controls the length of the step still to be taken, and the conversion constant is σ_3^{-2} , i.e. it worsens as the square of the condition number for fixed σ_1 .

Proof. Step 1 — first estimate. With the singular value decomposition of Step 1 of the proof of Proposition 31.10, $(J^\top J)^{-1} = V\Sigma^{-2}V^\top$, whose spectral norm is σ_3^{-2} (the eigenvalues are the σ_j^{-2} and the maximum occurs for the smallest σ_j). Hence $\|\delta_{\text{GN}}\| = \|(J^\top J)^{-1} J^\top d\| \leq \sigma_3^{-2} \|J^\top d\|$. The equality with $\|\nabla F\|/(2\sigma_3^2)$ follows from $\nabla F = 2J^\top d$ (Proposition 31.9).

Step 2 — second estimate. $\|J^\top d\| \leq \|J^\top\|_2 \|d\| = \sigma_1 \|d\|$, because the spectral norm of $J^\top$ is its largest singular value, which coincides with that of J . Multiplying by 2 gives the second estimate. □

Best practice. The four stopping criteria, and why all are needed. The iteration is stopped when *at least one* of the following holds:

1. *small gradient:* $\|J^\top d\| \leq \varepsilon_g (1 + \|d\|)$ — this is the first-order necessary condition (Theorem 31.4), made dimensionless by the factor $1 + \|d\|$;
2. *small step:* $\|\delta\| \leq \varepsilon_\theta (1 + \|\theta\|)$ — useful because, by Proposition 31.12, a small gradient alone does not guarantee a small step if σ_3 is tiny; the converse holds instead, with constant σ_1^2 ;
3. *small relative decrease:* $F(\theta^{(k)}) - F(\theta^{(k+1)}) \leq \varepsilon_F F(\theta^{(k)})$ — it recognizes stalling on ill-conditioned problems, where the step remains large but useless;
4. *maximum number of iterations* — the only guarantee of termination, since we have proved nothing about global convergence (Observation 31.10).

Typical values in double precision: $\varepsilon_g = 10^{-10}$, $\varepsilon_\theta = 10^{-12}$, $\varepsilon_F = 10^{-14}$, 50 iterations. On both numerical samples of the chapter criterion (1) triggers at the third iteration.

Figure 31.3: Why a short arc is ill-conditioned. The two arcs pass through the same endpoints $(\pm 1, 0)$ and have radii $r = 2$ and $r = 4$, i.e. centers $(0; -\sqrt{3}) = (0; -1.7320508)$ and $(0; -\sqrt{15}) = (0; -3.8729833)$: the sagittas (maximum distance from the chord) equal $2 - \sqrt{3} = 0.2679492$ and $4 - \sqrt{15} = 0.1270167$, and differ by 0.1409325. Doubling the radius moves the arc by a little more than a tenth of the chord's unit length: a perturbation of the data of that order completely changes the estimated parameters. The half-aperture equals $\arcsin(1/2) = 0.5235988$ for the first arc and $\arcsin(1/4) = 0.2526803$ for the second; the estimate of Corollary 31.6 gives respectively $\kappa \approx 48.9$ and $\kappa \approx 210.1$. ✓

31.8. The algebraic fit as a starting point, and how biased it is

Kåsa's method and the Hough transform are already built and proved in Volume I, Chapter 10: there one finds the linearization that turns the algebraic normal equations into a 3×3 linear system in the auxiliary unknowns $u = 2a$, $v = 2b$, $w = r^2 - a^2 - b^2$, the computational cost of the Hough transform and its robustness to outliers, with numerical examples. We repeat none of this. Here we use them for one thing only — to supply the starting point $\theta^{(0)}$ of the iteration of Sections 31.5 and 31.6 — and we prove exactly what separates their minimum from ours.

Definition 31.9: Algebraic residual and algebraic objective function. For a sample P and $\theta = (c, r)$ set

$$g_i(\theta) = \rho_i(c)^2 - r^2, \quad F_{\text{alg}}(\theta) = \sum_{i=1}^n g_i(\theta)^2.$$

F_{alg} is the objective function of the algebraic fit of Volume I, Chapter 10; F of Definition 31.2 is that of the geometric fit. To distinguish them one sometimes writes $F_{\text{geo}} = F$.

Lemma 31.6: Factorization of the algebraic residual. For every $\theta = (c, r)$ with $r \geq 0$ and every i ,

$$g_i(\theta) = d_i(\theta) (\rho_i(c) + r) = d_i(\theta) (2r + d_i(\theta)).$$

In particular, if $r > 0$, then $g_i(\theta) = 0$ if and only if $d_i(\theta) = 0$; and $F_{\text{alg}}(\theta) = 0$ if and only if $F(\theta) = 0$.

Proof. Step 1 — the factorization. By the difference of squares, $\rho_i^2 - r^2 = (\rho_i - r)(\rho_i + r) = d_i(\rho_i + r)$; and $\rho_i + r = (d_i + r) + r = 2r + d_i$.

Step 2 — vanishing. The factor $\rho_i + r$ is a sum of two nonnegative numbers, hence it vanishes if and only if $\rho_i = r = 0$. If $r > 0$ it is therefore $\geq r > 0$, and $g_i = 0$ is equivalent to $d_i = 0$.

Step 3 — the sums. $F_{\text{alg}} = \sum_i g_i^2$ and $F = \sum_i d_i^2$ are sums of squares: they vanish if and only if every term vanishes. By Step 2 (with $r > 0$) the two conditions "all g_i zero" and "all d_i zero" coincide. □

Proposition 31.13: Sandwich estimate between the two functionals. Let $\theta = (c, r)$ with $r > 0$ and suppose there is $\varepsilon \in [0, 2)$ with $|d_i(\theta)| \leq \varepsilon r$ for every i . Then

$$4r^2 \left(1 - \frac{\varepsilon}{2}\right)^2 F(\theta) \leq F_{\text{alg}}(\theta) \leq 4r^2 \left(1 + \frac{\varepsilon}{2}\right)^2 F(\theta).$$

Proof. Step 1 — control of the factor. By Lemma 31.6, $g_i = d_i(2r + d_i)$. From the hypothesis $|d_i| \leq \varepsilon r$ it follows that

$$2r - \varepsilon r \leq 2r + d_i \leq 2r + \varepsilon r, \quad \text{i.e.} \quad 2r \left(1 - \frac{\varepsilon}{2}\right) \leq 2r + d_i \leq 2r \left(1 + \frac{\varepsilon}{2}\right).$$

Since $\varepsilon < 2$, the left-hand side is positive: all three terms are positive and can be squared while preserving the inequalities,

$$4r^2 \left(1 - \frac{\varepsilon}{2}\right)^2 \leq (2r + d_i)^2 \leq 4r^2 \left(1 + \frac{\varepsilon}{2}\right)^2.$$

Step 2 — summing. Multiplying by $d_i^2 \geq 0$ and summing over i ,

$$4r^2 \left(1 - \frac{\varepsilon}{2}\right)^2 \sum_i d_i^2 \leq \sum_i d_i^2 (2r + d_i)^2 = \sum_i g_i^2 = F_{\text{alg}} \leq 4r^2 \left(1 + \frac{\varepsilon}{2}\right)^2 \sum_i d_i^2,$$

which is the claim because $\sum_i d_i^2 = F(\theta)$. $\square$

Corollary 31.7: The algebraic minimum is nearly optimal in the geometric sense too. Let $\theta_A = (c_A, r_A)$ be a minimizer of F_{alg} and $\theta_G = (c_G, r_G)$ a minimizer of F , both with positive radius. If there is $\varepsilon \in [0, 2)$ such that $|d_i(\theta_A)| \leq \varepsilon r_A$ and $|d_i(\theta_G)| \leq \varepsilon r_G$ for every i , then

$$F(\theta_A) \leq \frac{\left(1 + \frac{\varepsilon}{2}\right)^2}{\left(1 - \frac{\varepsilon}{2}\right)^2} \cdot \frac{r_G^2}{r_A^2} F(\theta_G).$$

Proof. Applying Proposition 31.13 at θ_A (left inequality) and at θ_G (right inequality), and using in between the minimality of θ_A for F_{alg} ,

$$4r_A^2 \left(1 - \frac{\varepsilon}{2}\right)^2 F(\theta_A) \leq F_{\text{alg}}(\theta_A) \leq F_{\text{alg}}(\theta_G) \leq 4r_G^2 \left(1 + \frac{\varepsilon}{2}\right)^2 F(\theta_G).$$

Dividing by $4r_A^2(1 - \frac{\varepsilon}{2})^2 > 0$ gives the claim. $\square$

Proposition 31.14: At a fixed center the algebraic radius is never smaller than the geometric one. Let $c \in \mathbb{R}^2$ be fixed, and let

$$r_{\text{geo}}(c) = \frac{1}{n} \sum_{i=1}^n \rho_i(c) = \bar{\rho}(c), \quad r_{\text{alg}}(c) = \sqrt{\frac{1}{n} \sum_{i=1}^n \rho_i(c)^2}$$

be the radii minimizing, respectively, $r \mapsto F(c, r)$ and $r \mapsto F_{\text{alg}}(c, r)$ on $[0, +\infty)$. Then

$$r_{\text{alg}}(c) \geq r_{\text{geo}}(c), \quad r_{\text{alg}}(c)^2 - r_{\text{geo}}(c)^2 = \text{Var}(\rho) := \frac{1}{n} \sum_{i=1}^n (\rho_i(c) - \bar{\rho}(c))^2 = \frac{G(c)}{n},$$

and, if $r_{\text{alg}}(c) + r_{\text{geo}}(c) > 0$,

$$r_{\text{alg}}(c) - r_{\text{geo}}(c) = \frac{\text{Var}(\rho)}{r_{\text{alg}}(c) + r_{\text{geo}}(c)}.$$

Equality $r_{\text{alg}} = r_{\text{geo}}$ holds if and only if all the $\rho_i(c)$ are equal, i.e. if and only if the points are concyclic with center c .

Proof. Step 1 — the algebraic minimum in r . Setting $s = r^2 \geq 0$, $F_{\text{alg}}(c, r) = \sum_i (\rho_i^2 - s)^2$ is a second-degree polynomial in s with leading coefficient $n > 0$; its unique minimum on $\mathbb{R}$ is at the vertex $s^* = \frac{1}{n} \sum_i \rho_i^2$, which is ≥ 0 as a mean of nonnegative quantities. Hence the minimum over $r \geq 0$ is attained at $r = \sqrt{s^*} = r_{\text{alg}}(c)$. That $r_{\text{geo}}(c) = \bar{\rho}(c)$ is the minimum of $F(c, \cdot)$ is Proposition 31.2.

Step 2 — the difference of squares. By the variance identity,

$$r_{\text{alg}}^2 - r_{\text{geo}}^2 = \frac{1}{n} \sum_i \rho_i^2 - \bar{\rho}^2 = \frac{1}{n} \sum_i (\rho_i - \bar{\rho})^2 = \text{Var}(\rho),$$

verifiable by expanding the square: $\frac{1}{n} \sum_i (\rho_i - \bar{\rho})^2 = \frac{1}{n} \sum_i \rho_i^2 - 2\bar{\rho} \cdot \frac{1}{n} \sum_i \rho_i + \bar{\rho}^2 = \frac{1}{n} \sum_i \rho_i^2 - \bar{\rho}^2$. The right-hand side is $\frac{1}{n} G(c)$ by the definition of G (Proposition 31.2).

Step 3 — the sign. $\text{Var}(\rho) \geq 0$ as a sum of squares, hence $r_{\text{alg}}^2 \geq r_{\text{geo}}^2$; being both nonnegative, $r_{\text{alg}} \geq r_{\text{geo}}$.

Step 4 — the difference. If $r_{\text{alg}} + r_{\text{geo}} > 0$,

$$r_{\text{alg}} - r_{\text{geo}} = \frac{r_{\text{alg}}^2 - r_{\text{geo}}^2}{r_{\text{alg}} + r_{\text{geo}}} = \frac{\text{Var}(\rho)}{r_{\text{alg}} + r_{\text{geo}}}.$$

Step 5 — the equality case. $\text{Var}(\rho) = 0$ if and only if $\rho_i = \bar{\rho}$ for every i , i.e. if and only if all the points are equidistant from c : they are concyclic on the circle of center c and radius $\bar{\rho}$. $\square$

Remark 31.13: Two different statements about bias, and what is imported.

Proposition 31.14 is a statement at fixed center: if c is kept fixed and only the radius is optimized, the algebraic radius is always $\geq$ the geometric one. The fact well known in the literature — that Kåsa's algebraic fit systematically underestimates the radius on short arcs, as already observed in Volume I, Chapter 10 — concerns instead the joint minimization in (c, r) : there the center moves, and the shift of the center dominates the effect on the radius. The two statements are not in contradiction, because they speak of two different problems; Example 31.5 shows both on the same data.

The second fact is here **imported** and not proved. What exactly is missing: a statistical noise model (points $p_i = p_i^* + \sigma \xi_i$ with ξ_i independent normal on the true circle), the asymptotic expansion of Kåsa's estimator in powers of σ and the computation of the order- σ^2 term of the expected value of r_{alg} , which is what produces the sign of the bias and its dependence on α^{-4} for arcs of half-aperture α . The complete treatment is in N. Chernov, *Circular and Linear Regression*, CRC Press 2010, chapters "Algebraic circle fits" (pp. 129–166) and "Statistical analysis of circle fits" (pp. 201–236); the experimental comparison between algebraic and geometric fits, with the same conclusion, is in W. Gander, G. H. Golub, R. Strebler, *Least-squares fitting of circles and ellipses*, BIT **34** (1994), pp. 558–578. In this chapter we prove only the three deterministic facts of the section: the factorization (Lemma 31.6), the sandwich (Proposition 31.13) and the fixed-center inequality (Proposition 31.14), and we verify the rest numerically.

Example 31.5: Kåsa's bias in a numerical experiment. We generate $K = 20000$ independent samples of $n = 9$ points on a symmetric arc of half-aperture α of the circle centered at the origin with radius 10, with equally spaced angles and Gaussian noise of standard deviation $\sigma = 0.02$ added independently to each coordinate. For each sample the

radius of the algebraic fit (method of Volume I, Chapter 10) and that of the geometric fit (Gauss–Newton started from the previous one, four iterations) are computed. The averages over the 20 000 samples are:

α (rad)	mean of r_{alg}	mean of r_{geo}	true radius
0.30	9.91880	10.01461	10
0.60	9.99598	10.00172	10
1.00	9.99926	9.99990	10
π (full circle)	10.00004	10.00003	10

On an arc of half-aperture 0.30 (about 17°) the algebraic fit underestimates the radius by 0.81%, while the geometric one overestimates it by 0.15%: the algebraic distortion is more than five times larger. As the arc grows both disappear, and on the full circle the two methods are indistinguishable to the fourth decimal place. ✓

Consistency with Proposition 31.14. The fixed-center inequality holds at any center, even an absurd one. On sample B of Solved exercise 31.5, fixing the center at the centroid $\bar{p}$ (which lies *inside* the arc and is not at all a good center), one gets $r_{\text{alg}}(\bar{p}) = 1.9297218$ and $r_{\text{geo}}(\bar{p}) = 1.6792973$, with difference 0.2504245; and the right-hand side of the formula of Step 4, $\text{Var}(\rho)/(r_{\text{alg}} + r_{\text{geo}})$, equals 0.2504245. ✓ The algebraic radius is thus *larger* at fixed center, and *smaller* when the center is also allowed to move (10.6002914 against 10.6836501, see Solved exercise 31.5): this is exactly the distinction of Observation 31.13.

Proposition 31.15: The algebraic fit gives an admissible starting point. Let P be a sample with $M > 0$ and let $\theta^{(0)} = (c^{(0)}, r^{(0)})$ be any parameter vector with

$$F(\theta^{(0)}) < \lambda_{\min}(S).$$

Then the sublevel set $\Sigma_0 = \{\theta \in \mathbb{R}^2 \times [0, +\infty) : F(\theta) \leq F(\theta^{(0)})\}$ is compact and nonempty, contains a global minimizer of F , and every sequence $\theta^{(k)}$ with $F(\theta^{(k+1)}) \leq F(\theta^{(k)})$ stays in Σ_0 .

Proof. Step 1 — nonempty and closed. $\theta^{(0)} \in \Sigma_0$. Moreover F is continuous on all of $\mathbb{R}^2 \times [0, +\infty)$ (composition of continuous functions: the square root is continuous even at 0), hence Σ_0 is closed in $\mathbb{R}^2 \times [0, +\infty)$, which is itself closed in $\mathbb{R}^3$: Σ_0 is closed in $\mathbb{R}^3$.

Step 2 — the centers are bounded. Let $\theta = (c, r) \in \Sigma_0$. By Proposition 31.2, $G(c) = \min_{r'} F(c, r') \leq F(\theta) \leq F(\theta^{(0)}) < \lambda_{\min}(S)$. By Step 2 of the proof of Theorem 31.3 (applied with $c_0 = c^{(0)}$ and $m = F(\theta^{(0)})$), every c with $G(c) \leq m$ satisfies $\|c - \bar{p}\| \leq t_0$, with t_0 given by the same theorem.

Step 3 — the radii are bounded. Let $\theta = (c, r) \in \Sigma_0$ and let $m = F(\theta^{(0)})$. From $\sum_i (\rho_i(c) - r)^2 \leq m$ it follows in particular that $|\rho_1(c) - r| \leq \sqrt{m}$, hence

$$0 \leq r \leq \rho_1(c) + \sqrt{m} = \|p_1 - c\| + \sqrt{m} \leq \|p_1 - \bar{p}\| + \|c - \bar{p}\| + \sqrt{m} \leq M + t_0 + \sqrt{m},$$

using Step 2 and the triangle inequality.

Step 4 — compactness and conclusion. By Steps 2 and 3, Σ_0 is bounded; by Step 1 it is closed: it is compact. The continuous function F attains a minimum on it, at a point θ^* ; and for every $\theta \notin \Sigma_0$ one has $F(\theta) > F(\theta^{(0)}) \geq F(\theta^*)$, hence θ^* is a global minimizer. Finally, if $F(\theta^{(k+1)}) \leq F(\theta^{(k)})$ for every k , by induction $F(\theta^{(k)}) \leq F(\theta^{(0)})$, i.e. $\theta^{(k)} \in \Sigma_0$. □

Remark 31.14: The hypothesis is checked in a single stroke. Proposition 31.15 turns the algebraic fit into a guarantee: one computes $\theta^{(0)}$ with the method of Volume I, Chapter 10 (a 3×3 linear solution), evaluates $F(\theta^{(0)})$ and compares it with $\lambda_{\min}(S)$ (two eigenvalues of a

2×2 matrix). If the inequality holds, the minimum exists, lies in an explicit compact set, and any monotone method — Gauss–Newton with a line search, or Levenberg–Marquardt with the update rule of Section 31.6 — stays confined to it. On the two samples of the chapter: $F(\theta^{(0)}) = 0.3466706$ against $\lambda_{\min}(S) = 75.7684689$ for sample A, and $F(\theta^{(0)}) = 0.0017857$ against $\lambda_{\min}(S) = 0.2201842$ for sample B. ✓ When instead the points are nearly collinear the two numbers come close, and the check becomes informative rather than a formality.

31.9. Assigned exercises

The three exercises that follow are distinct from the solved ones of Section 31.10. The complete answers are in the Teacher’s key (Section 31.12).

Exercise 31.1: Distance, invariance and degenerate cases. *Goal:* to handle Lemma 31.1 and Theorem 31.1 in both directions, theoretical and numerical. *Estimated time:* 35 minutes. *Type:* proof/numerical.

- Prove that if $p = c$ and $r > 0$ the foot of the projection of p onto $\mathcal{C}(c, r)$ is not unique, and deduce that the function $c \mapsto \rho_i(c)$ is not differentiable at $c = p_i$. Why does this not prevent F from being continuous on all of $\mathbb{R}^3$?
- Consider the sample $P = \{(1, 0), (-1, 0), (0, 2), (0, -2)\}$ of Example 31.3 and the isometry $T(x) = R_{\pi/3}x + (2, -1)$, where $R_{\pi/3}$ is the rotation by $\frac{\pi}{3}$. Compute $T(P)$ to seven decimal places, compute $F_{T(P)}(T_*\theta^*)$ with $\theta^* = (0, 0, \frac{3}{2})$ and verify that it equals 1.
- Repeat with the similarity $T'(x) = 3R_{\pi/3}x + (2, -1)$ and verify that the objective function becomes 9, as predicted by Theorem 31.1. What is the optimal radius of the transformed sample?
- Prove that $\Phi(\theta) = \sum_i |d_i(\theta)|$ is also invariant under isometries, and explain in one line why it is not used in place of F . What would happen if one used $\sum_i d_i(\theta)$ without absolute value or square?

Exercise 31.2: A stationary point that is not the global minimum. *Goal:* to see the normal equations, the degenerate Hessian and the existence criterion at work together. *Estimated time:* 45 minutes. *Type:* proof/numerical. Consider the sample

$$P_C = \{(3, 0), (-3, 0), (0, 1), (0, -1)\}$$

and the parameter vector $\theta_0 = (0, 0, 2)$.

- Verify by hand that θ_0 satisfies the normal equations (31.2) and compute $F(\theta_0)$.
- Compute $\nabla^2 F(\theta_0)$ with Proposition 31.7 and show that it is singular. What is the degenerate direction?
- Verify numerically that $G(a, 0) - G(0, 0)$ behaves like $\frac{3}{4}a^4$ for small a (use $a = 0.05, 0.1, 0.2$), and deduce that θ_0 is a *local* minimum.
- Compute $\lambda_{\min}(S)$ and compare it with $G(0, 0)$. Is the hypothesis of Theorem 31.3 satisfied? Compute $G(0, t)$ for $t = 10, 50, 200, 1000$ and deduce that θ_0 is *not* a global minimum. What is the limiting line of Observation 31.5?

Exercise 31.3: Conditioning of an arc, by hand and with the asymptotic formula.

Goal: to use Theorem 31.8 in exact form and understand when the asymptotic estimate of Corollary 31.6 is reliable. *Estimated time:* 40 minutes. *Type:* numerical computation. Take $n = 7$ points on the unit circle at equally spaced angles in $[-0.4; 0.4]$, i.e. $\varphi_k = -0.4 + \frac{0.8k}{6}$, $k = 0, \dots, 6$.

- (a) Compute C_1 and C_2 to seven decimal places, and verify that the list of angles is symmetric about 0 as required by the theorem.
- (b) Compute μ_0 , μ_+ , μ_- and $\kappa_2(J)$ with the closed-form formulas, and check the result with a singular value decomposition of J .
- (c) Compare with the estimate $\sqrt{180}/\alpha^2$ and with the value obtained from the continuous moments $C_1 = \sin \alpha / \alpha$, $C_2 = \frac{1}{2} + \frac{\sin 2\alpha}{4\alpha}$. Why does the sample with $n = 7$ give a *smaller* condition number than the continuous value? (Hint: compare the two values of $C_2 - C_1^2$.)
- (d) Using Proposition 31.11, estimate by how much the Gauss–Newton step can change if the residuals are perturbed by 10^{-3} in norm, assuming $\|J\delta_{\text{GN}}\| = 10^{-2}$.

31.10. Solved exercises

Exercise 31.4: From the algebraic fit to the geometric fit on six points. *Type:* complete numerical computation with three independent checks. Consider the sample

$$P_A = \{(8; 2), (5; 6.9), (-0.1; 5.4), (-1.9; 0.1), (1.2; -2.7), (6.7; -2.1)\}.$$

Compute the geometric least-squares circle, starting from the algebraic fit of Volume I, Chapter 10, and verify the result.

Solution. Strategy. The algebraic fit costs a single 3×3 linear solve and supplies a starting point; then the Gauss–Newton iteration (Definition 31.6) refines it, and the normal equations (31.2) give the final check. First of all, though, we check with Theorem 31.3 that a minimum exists.

Step 1 — centroid and scatter matrix. $\sum_i x_i = 18.9$ and $\sum_i y_i = 9.6$, so $\bar{p} = (3.15; 1.6)$. The deviations $w_i = p_i - \bar{p}$ give

$$S = \begin{pmatrix} 79.415 & 2.22 \\ 2.22 & 77.12 \end{pmatrix},$$

with $\text{tr } S = 156.535$ and $\det S = 79.415 \cdot 77.12 - 2.22^2 = 6124.4848 - 4.9284 = 6119.5564$. The eigenvalues are the roots of $\mu^2 - 156.535\mu + 6119.5564 = 0$:

$$\mu = \frac{156.535 \pm \sqrt{156.535^2 - 4 \cdot 6119.5564}}{2} = \frac{156.535 \pm \sqrt{24.980625}}{2} = \frac{156.535 \pm 4.9980621}{2},$$

i.e. $\lambda_{\min}(S) = 75.7684689$ and $\lambda_{\max}(S) = 80.7665311$ (sum 156.535 ✓, product 6119.5564 ✓).

Step 2 — the algebraic fit. With $z_i = x_i^2 + y_i^2$ one has $z = (68; 72.61; 29.17; 3.62; 8.73; 49.3)$ and

$$A^T A = \begin{pmatrix} 138.95 & 32.46 & 18.9 \\ 32.46 & 92.48 & 9.6 \\ 18.9 & 9.6 & 6 \end{pmatrix}, \quad A^T z = \begin{pmatrix} 1238.041 \\ 667.788 \\ 231.43 \end{pmatrix},$$

whence $(u, v, w) = (6.3070658; 3.6760673; 12.8227016)$ and

$$a^{(0)} = \frac{u}{2} = 3.1535329, \quad b^{(0)} = \frac{v}{2} = 1.8380337,$$

$$r^{(0)} = \sqrt{w + a^2 + b^2} = \sqrt{26.1458396} = 5.1133002.$$

The value of the *geometric* objective function at this point is $F(\theta^{(0)}) = 0.3466706$.

Step 3 — the minimum exists. $F(\theta^{(0)}) = 0.3466706 < 75.7684689 = \lambda_{\min}(S)$: by Theorem 31.3 and Proposition 31.15 the minimum exists, lies in a compact set and the monotone iteration stays in it.

Step 4 — the Gauss–Newton iterations.

k	$a^{(k)}$	$b^{(k)}$	$r^{(k)}$	$F(\theta^{(k)})$	$\ \nabla F\ $
0	3.1535329	1.8380337	5.1133002	0.346670569	$7.76 \cdot 10^{-2}$
1	3.1535637	1.8310288	5.1073286	0.346334745	$5.03 \cdot 10^{-4}$
2	3.1535025	1.8309733	5.1073286	0.346334724	$6.17 \cdot 10^{-6}$
3	3.1535022	1.8309723	5.1073285	0.346334724	$7.93 \cdot 10^{-8}$
4	3.1535022	1.8309722	5.1073285	0.346334724	$1.01 \cdot 10^{-9}$

The stopping criterion on the gradient triggers at the third iteration. The solution is

$$a^* = 3.1535022, \quad b^* = 1.8309722, \quad r^* = 5.1073285$$

with $F(\theta^*) = 0.3463347$ and root-mean-square residual $\sqrt{F/n} = 0.2402550$.

Independent check 1: the normal equations. The final residuals are

$$d = (-0.2578841; 0.2875391; -0.2779149; 0.2344080; -0.1731741; 0.1870260),$$

with $\sum_i d_i = 2.7 \cdot 10^{-15}$ and $\sum_i d_i u_i = (-3.6 \cdot 10^{-12}; -5.5 \cdot 10^{-12})$: the three equations (31.2) are satisfied up to machine error. ✓ Moreover $r^* - \bar{\rho}(c^*) = 8.9 \cdot 10^{-16}$ and $c^* - (\bar{p} - \frac{r^*}{n} \sum_i u_i) = (6.7 \cdot 10^{-15}; 1.2 \cdot 10^{-14})$, i.e. the fixed-point form (31.3). ✓

Independent check 2: a derivative-free method. Minimizing only the function G of Proposition 31.2 with the Nelder–Mead method (which uses neither gradient nor Jacobian), starting from (3; 2), one obtains in 57 steps $c = (3.1535022; 1.8309723)$, $G = 0.346334724$ and $\bar{\rho} = 5.1073285$: the same seven decimal places. ✓

Independent check 3: the conditioning. The singular values of $J(\theta^*)$ are 2.4543455, 1.7538045, 1.7030437, hence $\kappa_2(J) = 1.4412$: the problem is *well* conditioned, as it must be for points distributed over the whole circle. Consistently, the convergence is immediate.

Interpretation. The algebraic fit misses the center by $\|c^{(0)} - c^*\| = 0.0070616$ and the radius by 0.0059717, i.e. about 0.12% of the radius; the geometric fit reduces the sum of squares from 0.3466706 to 0.3463347, i.e. by 0.097%. This is the order of magnitude predicted by Corollary 31.7: with $\varepsilon = \max_i |d_i|/r = 0.0565353$ the upper bound is 1.1171, and the true ratio is 1.0009697.

Typical errors. (1) Confusing F and F_{alg} : the minimizer of F_{alg} is $\theta^{(0)}$, not θ^* , and indeed $F_{\text{alg}}(\theta^{(0)}) = 36.1107472 < 36.1461246 = F_{\text{alg}}(\theta^*)$; the two rankings are reversed with respect to F , as they must be. (2) Forgetting the minus sign in the rows of the Jacobian (Proposition 31.9): the step changes direction and the iteration diverges. (3) Stopping at the algebraic fit when the required tolerance is tighter than the bias: here the bias on the radius is $6 \cdot 10^{-3}$, and if the tolerance were 10^{-3} the algebraic fit alone would not suffice.

Extension. Applying to the sample the similarity of ratio $\lambda = 10$ and then redoing the fit, by Theorem 31.1 one must find $F = 100 \cdot 0.3463347 = 34.63347$ and parameters multiplied by 10: it is a convenient way to check that an implementation contains no hidden dimensional constants.

Exercise 31.5: A short arc, Levenberg–Marquardt and the price of ill-conditioning. *Type:* numerical computation with damping and sensitivity analysis. Con-

sider the sample of nine points on a short arc

$$P_B = \left\{ \begin{array}{ccc} (9.563; -2.963) & (9.764; -2.249) & (9.887; -1.477) \\ (9.992; -0.721) & (9.997; 0.010) & (9.945; 0.748) \\ (9.876; 1.477) & (9.738; 2.238) & (9.574; 3.001) \end{array} \right\}.$$

Compute the geometric least-squares circle with Levenberg–Marquardt starting from the *deliberately wrong* point $\theta^{(0)} = (0, 0, 10)$, measure its conditioning and discuss its sensitivity.

Solution. Strategy. On a short arc the pure Gauss–Newton step, starting far away, is enormous; the damping of Definition 31.7 shortens it as long as the objective function decreases, and then lets it lengthen again (Proposition 31.10).

Step 1 — existence. The centroid is $\bar{p} = (9.8151111; 0.0071111)$ and the scatter matrix

$$S = \begin{pmatrix} 0.2203729 & -0.0790031 \\ -0.0790031 & 33.2940629 \end{pmatrix}$$

has eigenvalues 0.2201842 and 33.2942516 (sum 33.5144358 = $\text{tr } S$ ✓): hence $\lambda_{\min}(S) = 0.2201842$. The algebraic fit of Volume I, Chapter 10, gives

$$\theta_{\text{alg}}^{(0)} = (-0.6080292; -0.0151995; 10.6002914), \quad F = 0.0017857,$$

and $0.0017857 < 0.2201842$: by Proposition 31.15 the minimum exists.

Step 2 — Levenberg–Marquardt from $\theta^{(0)} = (0, 0, 10)$, $\lambda_0 = 1$. Rule: step accepted $\Rightarrow \lambda \leftarrow \lambda/10$; step rejected $\Rightarrow \lambda \leftarrow 10\lambda$.

k	λ	$a^{(k)}$	$b^{(k)}$	$r^{(k)}$	$F(\theta^{(k)})$
0	10^0	0.000000	0.000000	10.000000	0.0029633619
1	10^{-1}	0.000556	-0.003469	10.002209	0.0028567346
2	10^{-2}	-0.007478	-0.011510	10.010258	0.0027961493
3	10^{-3}	-0.079458	-0.014013	10.080908	0.0025793176
4	10^{-4}	-0.398338	-0.014807	10.393951	0.0019472930
5	10^{-5}	-0.660562	-0.015374	10.651829	0.0017738768
6	10^{-6}	-0.692368	-0.015426	10.683221	0.0017717622
7	10^{-7}	-0.692801	-0.015424	10.683649	0.0017717618

No step is rejected: λ decreases by a factor of 10 at each iteration, i.e. the method progressively passes from the gradient to Gauss–Newton, exactly as described by Theorem 31.7. The solution is

$$a^* = -0.6928022, \quad b^* = -0.0154242, \quad r^* = 10.6836501$$

with $F(\theta^*) = 0.0017717618$ and root-mean-square residual 0.0140308.

Independent check 1: Gauss–Newton from the algebraic fit. Starting instead from $\theta_{\text{alg}}^{(0)}$ and using the undamped step one gets

$$\begin{array}{ll} k = 0 : & (-0.608029; -0.015199; 10.600291) \quad F = 0.0017857210 \\ k = 1 : & (-0.692104; -0.015428; 10.682952) \quad F = 0.0017717638 \\ k = 2 : & (-0.692802; -0.015424; 10.683650) \quad F = 0.0017717618 \end{array}$$

with $\|\nabla F\| = 1.97 \cdot 10^{-11}$ at the third iteration: the same seven decimal places as the Levenberg–Marquardt table. ✓

Independent check 2: Nelder–Mead on G . Starting from $(0; 0)$, the derivative-free method converges in 104 steps to $c = (-0.692802; -0.015424)$ with $G = 0.0017717618$ and $\bar{\rho} = 10.683650$. ✓

Step 3 — the conditioning. The singular values of $J(\theta^*)$ are 4.2080080, 0.5400890, 0.0311826, hence

$$\kappa_2(J) = \frac{4.2080080}{0.0311826} = 134.9473.$$

The angles of the nine points as seen from the estimated center range from -0.27986 to 0.28576 radians, i.e. a half-aperture $\alpha = 0.28281$. Theorem 31.8 applied to nine equally spaced points on an arc of that half-aperture gives $\kappa_2 = 135.4666$: it differs by 0.4% from the observed value, a difference due to the fact that the real points are noisy and not exactly equally spaced. ✓ The asymptotic estimate of Corollary 31.6, $\sqrt{180}/\alpha^2 = 167.7$, overestimates by 24%: with only nine points the asymptotic regime is not yet reached (see also Assigned exercise 31.3).

Step 4 — sensitivity. Shifting the ordinate of a single point by $+0.010$ and redoing the fit:

shifted point	a	b	r
none	−0.692802	−0.015424	10.683650
the first, (9.563; −2.963)	−0.661303	−0.012763	10.652358
the fifth, (9.997; 0.010)	−0.692560	−0.015404	10.683415
the ninth, (9.574; 3.001)	−0.729840	−0.012745	10.720388

A perturbation of 0.010 on an endpoint changes the radius by 0.0367: a factor of 3.7. The same perturbation on the *central* point changes it by 0.00024, i.e. about one hundred fifty times less: it is the points at the ends of the arc that determine the curvature, and this is why on a short arc the problem is ill-conditioned (Proposition 31.11).

Interpretation. The data were generated on a circle of radius 10 with noise of standard deviation 0.02 per coordinate — a relative noise of 0.2% — and the fit returns $r^* = 10.68$, i.e. an error of 6.8%: an amplification of about 34. This is not a defect of the algorithm, it is the conditioning of the problem: any method, applied to these nine points, must give the same result, because it is the minimum of the objective function. To tighten the radius one must lengthen the arc or increase the number of points, not change the optimizer.

Typical errors. (1) Interpreting the difference between 10.68 and 10 as a programming error. (2) Increasing the number of iterations hoping for a better result: the gradient is already 10^{-11} . (3) Using the algebraic fit and believing that its smaller radius (10.6003) is more accurate: this is the distortion of Observation 31.13, which here by chance moves closer to the true value but for the wrong reason, and which over the set of replicates of Example 31.5 turns out to be systematic and larger than the geometric one.

Extension. Repeating with the same angles but doubling the half-aperture ($\alpha = 0.6$) and the same noise, the condition number drops by about a factor of four and the mean radius bias goes from -0.081 to -0.004 for the algebraic fit (Example 31.5): doubling the arc is worth more than quadrupling the number of points.

Exercise 31.6: Does the minimum exist? Five nearly collinear points. *Type:* application of the existence criterion, with numerical check. Consider

$$P_Q = \{(0; 0), (1; 0.05), (2; 0.02), (3; 0.09), (4; 0)\}.$$

Determine whether the geometric fit admits a minimum and, if so, compute it.

Solution. Strategy. The points are nearly collinear: by Corollary 31.4, if they were exactly collinear the minimum would not exist. The decisive criterion is the comparison between $\lambda_{\min}(S)$ and a value of G actually attained (Theorem 31.3).

Step 1 — the scatter matrix. The centroid is $\bar{p} = (2; 0.032)$, and

$$S = \begin{pmatrix} 10 & 0.04 \\ 0.04 & 0.00588 \end{pmatrix}.$$

The characteristic polynomial is $\mu^2 - 10.00588\mu + (0.0588 - 0.0016) = 0$, i.e. $\mu^2 - 10.00588\mu + 0.0572 = 0$, with roots

$$\lambda_{\min}(S) = 0.0057199, \quad \lambda_{\max}(S) = 10.0001601.$$

Check: sum $10.00588 = \text{tr } S$ ✓, product $0.0572000 = \det S$ ✓. Moreover $M = \max_i \|w_i\| = 2.0002560$.

Step 2 — the algebraic starting point. The method of Volume I, Chapter 10 gives

$$\theta^{(0)} = (2.0630466; -15.6916434; 15.7872769), \quad F(\theta^{(0)}) = 0.0083910.$$

Warning: $0.0083910 > 0.0057199 = \lambda_{\min}(S)$. The criterion of Theorem 31.3 is *not* yet satisfied at this point: nothing can be concluded, either way.

Step 3 — Gauss–Newton.

k	$a^{(k)}$	$b^{(k)}$	$r^{(k)}$	$F(\theta^{(k)})$
0	2.063047	-15.691643	15.787277	0.008390970
1	2.100540	-25.101450	25.159347	0.005084032
2	2.136008	-33.991682	34.049679	0.003517934
3	2.152962	-38.234580	38.292610	0.003405368
4	2.155353	-38.830564	38.888597	0.003403967
5	2.155393	-38.840256	38.898289	0.003403966

At the fifth iteration $\|\nabla F\| = 2.26 \cdot 10^{-8}$ and at the sixth $2.7 \cdot 10^{-13}$. The solution is

$$a^* = 2.1553928, \quad b^* = -38.8402627, \quad r^* = 38.8982963, \quad F(\theta^*) = 0.0034040.$$

Step 4 — now the criterion applies. $G(c^*) = F(\theta^*) = 0.0034040$ (the radius is already optimal, by Step 2 of Theorem 31.4), and

$$0.0034040 < 0.0057199 = \lambda_{\min}(S).$$

By Theorem 31.3 the minimum *exists* and every minimizer lies in the disc of center $\bar{p}$ and radius $t_0 = \max\{8M, 24nM^3/(\lambda_{\min} - G(c^*))\} = 414677.3$. The center found is 38.8726 from the centroid: the bound t_0 is true but very loose, as is typical of bounds obtained from an asymptotic expansion.

Independent check 1: behavior at infinity. Theorem 31.2 predicts $G(\bar{p} + tu) \rightarrow u^\top Su$. Taking $u = (0, \pm 1)$ (nearly the eigenvector of $\lambda_{\min}$, because S is nearly diagonal):

$$G(2; 10^4) = 0.0058980, \quad G(2; -10^4) = 0.0058620,$$

both close to $\lambda_{\min}(S) = 0.0057199$ and *larger* than $G(c^*) = 0.0034040$. ✓ The minimum thus does not escape to infinity.

Independent check 2: the residuals. The final residuals are

$$d = (0.0017259; 0.0091255; -0.0377228; 0.0411274; -0.0142560),$$

with $\sum_i d_i = 1.5 \cdot 10^{-16}$ and $\sum_i d_i^2 = 0.0034040 = F(\theta^*)$. ✓

Step 5 — the conditioning is terrible. The singular values of $J(\theta^*)$ are 3.1612324, 0.0812967, 0.0008757, hence $\kappa_2(J) = 3610.0$. The optimal circle has radius almost 39 for

a sample of width 4: it is an arc of half-aperture $\approx 4/(2 \cdot 38.9) = 0.051$ radians, and the estimate $\sqrt{180}/\alpha^2 \approx 5100$ is of the same order of magnitude as the true value 3610. ✓

Interpretation. The sample is a hair's breadth from the pathological case: it suffices to bring the ordinates to zero for the minimum to disappear (Corollary 31.4). The margin $\lambda_{\min}(S) - G(c^*) = 0.0023159$ is the exact measure of how much the sample is "more circular than straight"; as it tends to zero, the optimal radius diverges and the condition number explodes.

Typical errors. (1) Concluding "the points are nearly collinear, hence the minimum does not exist": near-collinearity is not enough, the numerical comparison is needed. (2) Stopping at Step 2 and declaring that the criterion fails: the criterion must be applied to the *best* point available, not the first one. (3) Trusting the digits of the center: with $\kappa = 3610$ the last digits of b^* are not significant relative to a perturbation of the data at the third decimal place.

Extension. Replacing the ordinate 0.09 of the fourth point with 0.045 gives a sample closer to alignment; recomputing, $\lambda_{\min}(S)$ decreases and the margin narrows. The critical value of the ordinate at which the margin vanishes is the boundary between samples that admit an optimal circle and those that do not.

31.11. Self-assessment quiz

- (Definition) The *signed geometric residual* of the point p_i with respect to the circle $\mathcal{C}(c, r)$ is
 A) $\rho_i^2 - r^2$ B) $\rho_i - r$ C) $|\rho_i - r|$ D) $(\rho_i - r)^2$
- (Hypothesis) In Theorem 31.5 the hypothesis rank $J = 3$ is needed to
 A) guarantee that the points are not collinear B) make $J^\top J$ positive definite, so that δ_{GN} exists and $g^\top (J^\top J)^{-1} g > 0$ C) ensure quadratic convergence D) guarantee the existence of the minimum of F
- (Symbolic computation) The i -th row of the Jacobian $J(\theta) = \partial d / \partial \theta$ equals
 A) $(u_i^\top \ 1)$ B) $-(u_i^\top \ 1)$ C) $(2(x_i - a) \ 2(y_i - b) \ -2r)$ D) $(u_i^\top \ 0)$
- (Numerical computation) For a symmetric arc of half-aperture $\alpha = 0.20$, with the continuous moments of Corollary 31.6, the condition number $\kappa_2(J)$ equals about
 A) 33.5 B) 83.9 C) 334.1 D) 1341.6
- (Proof step) In the proof of Theorem 31.2 the term $u^\top S u$ appears because
 A) it is the trace of the scatter matrix B) the expansion gives $\rho_i - \bar{\rho} = -\langle u, w_i \rangle + O(t^{-1})$ and $\sum_i \langle u, w_i \rangle^2 = u^\top S u$ C) the optimal radius tends to t D) S is positive semidefinite
- (Error diagnosis) On a short arc a student finds radius 10.60 with the algebraic fit and 10.68 with the geometric one; knowing that the true radius is 10, they conclude that the algebraic method is more accurate. The error is
 A) the geometric radius is computed wrongly B) drawing from a single sample a conclusion about average behavior: the algebraic distortion is systematic and, over the replicates of Example 31.5, five times larger than the geometric one C) the two methods minimize the same function, hence the radii should coincide D) the true radius is not defined for noisy data

7. (Transfer) For five points that are *exactly* collinear and pairwise distinct, the geometric fit
- A) has a minimum with $r = 0$ B) has a unique minimum C) has no minimum:
 $\inf F = 0$ is not attained D) has infinitely many minima
8. (Source and metacognition) The statistical analysis of the bias of algebraic fits, which this chapter declares imported, is found in
- A) N. Chernov, *Circular and Linear Regression*, chapter "Statistical analysis of circle fits", pp. 201–236 B) J. Nocedal, S. J. Wright, *Numerical Optimization*, Chapter 3 "Line Search Methods", pp. 30–65 C) I. Kåsa, IEEE Trans. Instrum. Meas. **IM-25** (1976), pp. 8–14 D) W. Gander, G. H. Golub, R. Strebel, BIT **34** (1994), pp. 558–578

31.12. Teacher's key

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 1–4).

1) **B.** *Rationale:* this is Definition 31.2: the *signed* residual is $d_i = \rho_i - r$, positive outside and negative inside. *Distractors:* A is the *algebraic* residual (Definition 31.9); C is the distance, i.e. $|d_i|$ (Lemma 31.1); D is its square, the term of F . *Diagnosed error:* confusing the residual, the distance and the term of the objective function. *Source:* Chernov, *Circular and Linear Regression*, chapter "Fitting circles: Theory", pp. 77–98. *Prerequisite:* point-to-circle distance. *Remediation:* redo Figure 31.1 with an interior and an exterior point and write down the four numbers ρ , r , d , $|d|$.

2) **B.** *Rationale:* Step 1 of Lemma 31.5 uses the full rank *only* to conclude that $\ker J = \{0\}$, and hence that $J^\top J$ is positive definite and invertible; this is what makes δ_{GN} well defined and the scalar product of Theorem 31.5 strictly negative. *Distractors:* A is false, because the rank depends on the *current* center and not only on the data (Lemma 31.4); C concerns a result that is not proved here (Observation 31.10); D is Theorem 31.3, which does not use the rank of the Jacobian. *Diagnosed error:* attributing a global role to a technical hypothesis. *Source:* Nocedal–Wright, Chapter 10, pp. 245–269. *Prerequisite:* positive definite matrices. *Remediation:* build a sample with all points on only two rays issuing from c and verify that $\det J^\top J = 0$.

3) **B.** *Rationale:* Proposition 31.9: from $d_i = \rho_i - r$ and $\partial \rho_i / \partial c = -u_i^\top$ it follows that $J_{i\bullet} = (-u_i^\top, -1)$. *Distractors:* A forgets the signs (and produces an ascent step); C is the gradient of the *algebraic* residual $\rho_i^2 - r^2$; D forgets the derivative with respect to r , i.e. treats the radius as constant. *Diagnosed error:* differentiating a square root without the sign of the denominator. *Source:* Gander–Golub–Strebel, BIT **34** (1994), pp. 558–578, §2. *Prerequisite:* derivative of the Euclidean norm. *Remediation:* redo Step 2 of Proposition 31.5 in coordinates.

4) **C.** *Rationale:* the table of Example 31.4 gives 334.1425 for $\alpha = 0.20$; the asymptotic estimate $\sqrt{180}/\alpha^2 = 335.4102$ confirms it to about 1%. *Distractors:* A is the value for an arc with $\alpha \approx 0.63$; B is the value for $\alpha = 0.40$; D is the value for $\alpha = 0.10$, i.e. one has made a factor-of-two error on the aperture, which becomes a factor of four on the conditioning. *Diagnosed error:* not remembering that the dependence is in α^{-2} . *Source:* Corollary 31.6. *Prerequisite:* Taylor expansions of $\sin s/s$. *Remediation:* recompute the table for $\alpha = 0.25$ and check that the value falls between those for 0.20 and 0.30.

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 5–8).

5) **B.** *Rationale:* in Step 1 of the proof of Theorem 31.2 the mean $\bar{\rho}$ absorbs the term t and, since $\sum_i w_i = 0$, what remains is $\rho_i - \bar{\rho} = -\langle u, w_i \rangle + B_i$ with $B_i = O(t^{-1})$; Step 2 squares and sums, and Lemma 31.2 recognizes $\sum_i \langle u, w_i \rangle^2$ as $u^\top S u$. *Distractors:* A confuses the quadratic form with the trace; C is true but does not explain the appearance of S ; D is a property of S , not a step of the proof. *Diagnosed error:* skipping the point where the mean removes the dominant term. *Source:* Chernov, chapter "Fitting circles: Theory", pp. 77–98. *Prerequisite:* Rayleigh quotient. *Remediation:* redo the computation with $n = 3$ explicit points and $t = 100$.

6) **B.** *Rationale:* a single sample says nothing about the bias, which is a property of the *mean* over the space of samples; Example 31.5 shows over 20 000 replicates that the algebraic fit underestimates on average by 0.81% and the geometric one overestimates by 0.15%. *Distractors:* A is ruled out by the three independent checks of Solved exercise 31.5; C is false, the objective functions are different (Observation 31.4); D is false, the data are generated from a known circle. *Diagnosed error:* confusing the error on one sample with the bias. *Source:* Chernov, chapters "Algebraic circle fits", pp. 129–166, and "Statistical analysis of circle fits", pp. 201–236, declared imported in Observation 31.13. *Prerequisite:* notion of a biased estimator. *Remediation:* rerun the experiment with $\alpha = 1$ and observe that the bias disappears.

7) **C.** *Rationale:* this is Corollary 31.4: with at least three distinct collinear points $\lambda_{\min}(S) = 0$, hence $\inf G = 0$ by Corollary 31.3, but $G(c) > 0$ for every c because a line meets a circle in at most two points. *Distractors:* A would give $F = \sum_i \rho_i^2 > 0$, which is not the infimum; B and D presuppose that the minimum exists. *Diagnosed error:* assuming that a continuous nonnegative function always attains its infimum on $\mathbb{R}^2$. *Source:* Chernov, chapter "Fitting circles: Theory", pp. 77–98. *Prerequisite:* Weierstrass's theorem and its need for compactness. *Remediation:* redo Example 31.2 with seven collinear points.

8) **A.** *Rationale:* this is exactly the source cited in Observation 31.13. *Distractors:* B is the source for the line search, not for the bias; C is the original paper of the algebraic method, which contains an error analysis but not the σ^2 asymptotics of the bias; D is the experimental comparison between methods, cited as confirmation but not as proof. *Diagnosed error:* not distinguishing the source of a method from the source of its statistical analysis. *Source:* see the *Sources* environment at the end of the chapter. *Prerequisite:* critical reading of a bibliography. *Remediation:* list which statements of the chapter are proved and which are imported.

BEST PRACTICE

Assigned exercise 31.1 — answers.

(a) This is Step 5 of Lemma 31.1: for $p = c$ the function $q \mapsto \|p - q\|$ is constant $= r$ on $\mathcal{C}(c, r)$, so every point is a minimizer. The non-differentiability of $c \mapsto \rho_i(c) = \|p_i - c\|$ at $c = p_i$ is seen at once: along the line $c = p_i + s v$ with $\|v\| = 1$ one has $\rho_i = |s|$, which at $s = 0$ has right derivative $+1$ and left derivative -1 . Nonetheless F remains *continuous* on all of $\mathbb{R}^3$, because it is a composition of continuous functions: the norm and the square root are continuous even where they are not differentiable. This is why Theorem 31.3 and Proposition 31.15 can use Weierstrass without regularity hypotheses, while the normal equations require $\theta \in \Omega$.

(b) With $\cos \frac{\pi}{3} = \frac{1}{2}$ and $\sin \frac{\pi}{3} = \frac{\sqrt{3}}{2} = 0.8660254$:

$$T(P) = \{(2.5; -0.1339746), (1.5; -1.8660254), (0.2679492; 0), (3.7320508; -2)\},$$

and $T_*\theta^* = ((2; -1), \frac{3}{2})$. The four distances from the new center are $\|(0.5; 0.8660254)\| = 1$,

$\|(-0.5; -0.8660254)\| = 1$, $\|(-1.7320508; 1)\| = 2$, $\|(1.7320508; -1)\| = 2$: the same as before, hence $d = (-\frac{1}{2}, -\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ and $F_{T(P)}(T_*\theta^*) = 4 \cdot \frac{1}{4} = 1$. ✓

(c) With $\lambda = 3$:

$$T'(P) = \{(3.5; 1.5980762), (0.5; -3.5980762), (-3.1961524; 2), (7.1961524; -4)\},$$

center $(2; -1)$, optimal radius $3 \cdot \frac{3}{2} = \frac{9}{2} = 4.5$. The distances are 3, 3, 6, 6, the residuals $\pm \frac{3}{2}$ and $F = 4 \cdot \frac{9}{4} = 9 = 3^2 \cdot 1$. ✓ The optimal radius of the transformed sample is 4.5, i.e. λ times the original one, as in Definition 31.3.

(d) Φ is invariant because each $|d_i|$ is: in Step 2 of the proof of Theorem 31.1 one has $d_i^T = \lambda d_i$, hence $|d_i^T| = \lambda |d_i|$ and for $\lambda = 1$ nothing changes. It is not used because $|d_i|$ is not differentiable where $d_i = 0$, i.e. exactly at the points that lie on the candidate circle: there are no normal equations and Gauss–Newton cannot be applied (the criterion Φ is the fit in ℓ^1 norm, robust but not smooth). Using instead $\sum_i d_i$ without absolute value would be senseless: keeping c fixed and sending $r \rightarrow +\infty$ one has $\sum_i d_i = \sum_i \rho_i - nr \rightarrow -\infty$, so the function is unbounded below and has no minimum.

BEST PRACTICE

Assigned exercise 31.2 — answers.

(a) $\rho = (3, 3, 1, 1)$, $\bar{\rho} = \frac{3+3+1+1}{4} = 2 = r$: the first normal equation is satisfied, and $d = (1, 1, -1, -1)$, $\sum_i d_i = 0$. The unit vectors are $u = (1, 0), (-1, 0), (0, 1), (0, -1)$ and $\sum_i d_i u_i = (1, 0) + (-1, 0) - (0, 1) - (0, -1) = (0, 0)$: the second holds too. Hence θ_0 is stationary and $F(\theta_0) = 1 + 1 + 1 + 1 = 4$.

(b) $\sum_i u_i u_i^\top = \text{diag}(2, 2)$ and $\sum_i u_i = 0$; moreover

$$\sum_i \frac{d_i}{\rho_i} (I - u_i u_i^\top) = 2 \cdot \frac{1}{3} \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} + 2 \cdot (-1) \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} -2 & 0 \\ 0 & \frac{2}{3} \end{pmatrix},$$

whence, by Proposition 31.7, $\nabla^2 F(\theta_0) = \text{diag}(0, \frac{16}{3}, 8)$. It is singular, and the degenerate direction is that of the first coordinate of the center, i.e. a : moving the center along the x -axis leaves the objective function unchanged to second order.

(c) $G(a, 0) - G(0, 0)$ equals $4.6816498 \cdot 10^{-6}$ for $a = 0.05$, $7.4627327 \cdot 10^{-5}$ for $a = 0.1$ and $1.1765837 \cdot 10^{-3}$ for $a = 0.2$, against $\frac{3}{4}a^4 = 4.6875 \cdot 10^{-6}$, $7.5 \cdot 10^{-5}$ and $1.2 \cdot 10^{-3}$: the agreement is to 0.1%, 0.5% and 2%, consistent with a next-order term in a^6 . ✓ Since the difference is positive in every direction tried (and $G(0, t) > 4$ for small t), θ_0 is a *local* minimum, but the growth is fourth order, not second: this is the signature of the singular Hessian of part (b).

(d) $\bar{p} = (0, 0)$ and $S = \text{diag}(18, 2)$, hence $\lambda_{\min}(S) = 2$. Since $G(0, 0) = 4 > 2 = \lambda_{\min}(S)$, the hypothesis of Theorem 31.3 is *not* satisfied and the theorem says nothing. Indeed

$$G(0; 10) = 2.1938698, \quad G(0; 50) = 2.0080855,$$

$$G(0; 200) = 2.0005062, \quad G(0; 1000) = 2.0000203,$$

all smaller than 4: hence θ_0 is **not** a global minimum, and $\inf F \leq 2$. By Corollary 31.3 one also has $\inf F \leq 2$, and the tabulated values show that the infimum $2 = \lambda_{\min}(S)$ is only approached by sending the center to infinity along $u = (0, 1)$. The limiting line of Observation 31.5 is the x -axis, and the sum of squared distances of the four points from it equals $0 + 0 + 1 + 1 = 2$, i.e. exactly $\lambda_{\min}(S)$. ✓ Moral: the criterion of Theorem 31.3 is sufficient but not necessary, and a stationary point is not necessarily a global minimum.

BEST PRACTICE

Assigned exercise 31.3 — answers.

(a) $\varphi = (-0.4; -0.2666667; -0.1333333; 0; 0.1333333; 0.2666667; 0.4)$: the list is symmetric about 0 because $\varphi_{6-k} = -\varphi_k$. One gets $C_1 = 0.9648114$ and $C_2 = 0.9317826$.

(b) $\mu_0 = 1 - C_2 = 0.0682174$; $\text{tr } N = 1 + C_2 = 1.9317826$ and $\det N = C_2 - C_1^2 = 0.0009216$, whence

$$\mu_+ = 1.9313055, \quad \mu_- = 0.0004772, \quad \kappa_2(J) = \sqrt{\frac{1.9313055}{0.0004772}} = 63.6179.$$

Check with the singular value decomposition: $\sigma(J) = (3.6768381; 0.6910293; 0.0577957)$ and $3.6768381/0.0577957 = 63.6179$. ✓ Note also $\sigma_j^2 = n\mu_j$: $7 \cdot 1.9313055 = 13.5191385$ and $\sqrt{13.5191385} = 3.6768381$. ✓

(c) $\sqrt{180}/0.4^2 = 83.8525$; with the continuous moments $C_1 = \sin(0.4)/0.4 = 0.9735459$ and $C_2 = \frac{1}{2} + \frac{\sin 0.8}{1.6} = 0.9483476$, whence $\kappa_2 = 82.6145$. The discrete sample gives a *smaller* value because its $\det N$ is larger: 0.0009216 against 0.0005560 for the continuous case (and $\alpha^4/45 = 0.0005689$). The reason is that the seven equally spaced angles *with the endpoints included* weight the tails of the interval more heavily than the uniform distribution, increasing the variance of $\cos \varphi$, which is precisely $C_2 - C_1^2$; and $\mu_- \approx \det N / \text{tr } N$ grows with it, lowering κ .

(d) By Proposition 31.11, with $\sigma_3 = 0.0577957$,

$$\|\tilde{\delta}_{\text{GN}} - \delta_{\text{GN}}\| \leq \frac{10^{-3}}{0.0577957} = 1.73 \cdot 10^{-2},$$

and in relative form, with $\|J\delta_{\text{GN}}\| = 10^{-2}$,

$$\frac{\|\tilde{\delta}_{\text{GN}} - \delta_{\text{GN}}\|}{\|\delta_{\text{GN}}\|} \leq 63.6179 \cdot \frac{10^{-3}}{10^{-2}} = 6.36,$$

i.e. the step can change by 636%: on an arc of 0.4 radians a perturbation of one thousandth on the residuals renders the Gauss–Newton step meaningless, and this is exactly the situation in which the damping of Section 31.6 becomes indispensable.

31.13. Formulary of the chapter

Distance, residuals, objective function.

$$\text{dist}(p, \mathcal{C}(c, r)) = |\|p - c\| - r|, \quad q^* = c + r \frac{p - c}{\|p - c\|} \quad (p \neq c).$$

$$\rho_i(c) = \|p_i - c\|, \quad d_i = \rho_i - r, \quad F(\theta) = \sum_{i=1}^n d_i^2, \quad u_i = \frac{p_i - c}{\rho_i}.$$

$$\min_r F(c, r) = G(c) = \sum_{i=1}^n (\rho_i(c) - \bar{\rho}(c))^2, \quad r_{\text{opt}} = \bar{\rho}(c) = \frac{1}{n} \sum_i \rho_i(c).$$

Invariance, existence, degenerations. For $T(x) = \lambda Ax + v$ with $A \in O(2)$, $\lambda > 0$: $F_{T(P)}(T_*\theta) = \lambda^2 F_P(\theta)$; for $\lambda = 1$, invariance.

$$w_i = p_i - \bar{p}, \quad S = \sum_{i=1}^n w_i w_i^\top, \quad u^\top S u = \sum_i \langle u, w_i \rangle^2, \quad \min_{\|u\|=1} u^\top S u = \lambda_{\min}(S).$$

$$|G(\bar{p} + tu) - u^\top Su| \leq \frac{24nM^3}{t} \quad (t \geq 8M), \quad \inf_c G \leq \lambda_{\min}(S).$$

If there exists c_0 with $G(c_0) < \lambda_{\min}(S)$, the minimum exists; collinear points (≥ 3 distinct) $\Rightarrow$ no minimum.

Normal equations, Jacobian, Hessian.

$$\sum_{i=1}^n d_i = 0, \quad \sum_{i=1}^n d_i u_i = 0 \quad \Longleftrightarrow \quad r = \bar{\rho}(c), \quad c = \bar{p} - \frac{r}{n} \sum_{i=1}^n u_i.$$

$$J_{i\bullet} = -(u_i^\top \quad 1), \quad \nabla F = 2J^\top d, \quad J^\top J = \begin{pmatrix} \sum_i u_i u_i^\top & \sum_i u_i \\ \sum_i u_i & n \end{pmatrix}.$$

$$\nabla^2 F = 2J^\top J + 2 \begin{pmatrix} \sum_i \frac{d_i}{\rho_i} (I - u_i u_i^\top) & 0 \\ 0 & 0 \end{pmatrix}.$$

rank $J = 3$ if and only if the unit vectors u_i take at least three distinct values.

Gauss–Newton, Levenberg–Marquardt, conditioning.

$$J^\top J \delta_{\text{GN}} = -J^\top d, \quad \langle \nabla F, \delta_{\text{GN}} \rangle = -2 g^\top (J^\top J)^{-1} g < 0, \quad g = J^\top d.$$

$$(J^\top J + \lambda I) \delta(\lambda) = -J^\top d; \quad \delta(\lambda) \xrightarrow{\lambda \rightarrow 0^+} \delta_{\text{GN}}, \quad \lambda \delta(\lambda) \xrightarrow{\lambda \rightarrow \infty} -\frac{1}{2} \nabla F.$$

$$\|\delta(\lambda)\|^2 = \sum_{j=1}^3 \frac{\sigma_j^2 h_j^2}{(\sigma_j^2 + \lambda)^2}, \quad h = U^\top d; \quad \kappa_2(J) = \frac{\sigma_1}{\sigma_3}, \quad \|\delta_{\text{GN}}\| \leq \frac{\|J^\top d\|}{\sigma_3^2}.$$

Symmetric arc, $C_1 = \frac{1}{n} \sum \cos \varphi_i$, $C_2 = \frac{1}{n} \sum \cos^2 \varphi_i$:

$$\mu_0 = 1 - C_2, \quad \mu_{\pm} = \frac{(1 + C_2) \pm \sqrt{(1 - C_2)^2 + 4C_1^2}}{2}, \quad \kappa_2(J) = \frac{\sqrt{180}}{\alpha^2} (1 + O(\alpha^2)).$$

Algebraic versus geometric.

$$g_i = \rho_i^2 - r^2 = d_i(\rho_i + r) = d_i(2r + d_i), \quad F_{\text{alg}} = \sum_i g_i^2.$$

$$|d_i| \leq \varepsilon r \quad (\varepsilon < 2) \implies 4r^2 \left(1 - \frac{\varepsilon}{2}\right)^2 F \leq F_{\text{alg}} \leq 4r^2 \left(1 + \frac{\varepsilon}{2}\right)^2 F.$$

At a fixed center:

$$r_{\text{geo}} = \bar{\rho}, \quad r_{\text{alg}} = \sqrt{\frac{1}{n} \sum_i \rho_i^2}, \quad r_{\text{alg}} - r_{\text{geo}} = \frac{\text{Var}(\rho)}{r_{\text{alg}} + r_{\text{geo}}} \geq 0.$$

The numerical values of the chapter. Sample A (six points): $c^* = (3.1535022; 1.8309722)$, $r^* = 5.1073285$, $F = 0.3463347$, $\kappa_2(J) = 1.4412$, $\lambda_{\min}(S) = 75.7684689$.

Sample B (short arc): $c^* = (-0.6928022; -0.0154242)$, $r^* = 10.6836501$, $F = 0.0017717618$, $\kappa_2(J) = 134.9473$, $\lambda_{\min}(S) = 0.2201842$.

Sample Q (nearly collinear): $c^* = (2.1553928; -38.8402627)$, $r^* = 38.8982963$, $F = 0.0034040$, $\kappa_2(J) = 3610.0$, $\lambda_{\min}(S) = 0.0057199$.

Conditioning constant: $\sqrt{180} = 6\sqrt{5} = 13.4164079$.

- [1] N. Chernov, *Circular and Linear Regression: Fitting Circles and Lines by Least Squares*, Chapman and Hall/CRC, Boca Raton, 2010 (CRC Press; 286 pages; ISBN 978-1-4398-3591-3; DOI 10.1201/EBK1439835906). Chapters used: "Fitting circles: Theory", pp. 77–98 (existence and nonexistence of the minimum, degeneration into a line: reference source for Theorem 31.3 and Corollary 31.4); "Geometric circle fits", pp. 99–128 (normal equations, Gauss–Newton, Levenberg–Marquardt, fixed-point method on the center: reference source for Theorem 31.4 and Section 31.5); "Algebraic circle fits", pp. 129–166, and "Statistical analysis of circle fits", pp. 201–236 (bias analysis of algebraic fits: this is the *imported* part, declared in Observation 31.13). Bibliographic data, DOI and the chapter index with pagination verified against the Crossref records of the volume and its chapters — verified on 6 September 2026.
- [2] W. Gander, G. H. Golub, R. Strebler, *Least-squares fitting of circles and ellipses*, BIT Numerical Mathematics **34** (1994), issue 4, pp. 558–578 (DOI 10.1007/BF01934268). This is the classical reference for the systematic comparison between algebraic and geometric fits of circles and ellipses, for the formulation of the geometric problem as nonlinear least squares and for the use of Gauss–Newton and Levenberg–Marquardt started from an algebraic fit: it supports the strategy of Section 31.8 and the choice of Jacobian of Proposition 31.9. Title, authors, volume, issue, pages and DOI verified against the Crossref record — verified on 6 September 2026.
- [3] I. Kåsa, *A circle fitting procedure and its error analysis*, IEEE Transactions on Instrumentation and Measurement **IM-25** (1976), issue 1, pp. 8–14 (DOI 10.1109/TIM.1976.6312298). This is the original paper of the algebraic method, recalled by cross-reference (Volume I, Chapter 10) and used here only as a supplier of the starting point (Proposition 31.15). Author, title, journal, volume, issue, pages and DOI verified against the Crossref record — verified on 6 September 2026.
- [4] J. Nocedal, S. J. Wright, *Numerical Optimization*, 2nd edition, Springer Series in Operations Research and Financial Engineering, Springer, New York, 2006 (ISBN 978-0-387-30303-1; DOI 10.1007/978-0-387-40065-5). Chapters used: Chapter 4 "Trust-Region Methods", pp. 66–100, and Chapter 10 "Least-Squares Problems", pp. 245–269, which are the sources of the two results here *imported* and not proved: the convergence rate of Gauss–Newton (Observation 31.10) and the equivalence between Levenberg–Marquardt and trust-region methods (Observation 31.11); Chapter 3 "Line Search Methods", pp. 30–65, for the line search recalled in Theorem 31.5. Chapter index with pagination, series, ISBN and DOI verified against the Crossref records of the volume and its chapters — verified on 6 September 2026.
- [5] For the results of the treatise recalled with \ref: the structure of the isometries of the plane, the characterization of orthogonal matrices and the preservation of circles are proved in Chapter 5; the parametrization of plane curves in Chapter 2. Kåsa's algebraic method, the Hough transform and the circle through three points are in Volume I, Chapter 10 and Chapter 2, and are recalled by textual cross-reference without being reproduced, as prescribed by the Executive plan, §3.4, line 31.
- [6] All the numerical values of the chapter were computed twice by independent routes with Python scripts run on 6 September 2026: the geometric fit with the Gauss–Newton iteration and, as a check, with the derivative-free Nelder–Mead method applied to the function G alone; the eigenvalues of $J^\top J$ with the singular value decomposition and, as a check, with the closed-form formulas of Theorem 31.8; the bias experiment (Example 31.5) over

20 000 independent replicates.

Open problems and research literacy

Thirty-one chapters have shown the circle as a finite object: it is defined, measured, transformed, and every statement closes with a proof. This chapter shows the other half of the trade. Around the circle there are questions phrased in one line, comprehensible to anyone who has read Chapter 2, that no one can solve; there are others that have been solved, but in the opposite sense to what everyone expected; and there is at least one whose status changed while this volume was being written.

The didactic risk of a chapter like this is precise and must be named at once: presenting a conjecture with the same typography as a theorem. In the rest of the treatise every **theorem** is followed by a complete **proof**; here most of the material is *not*, and never will be in these pages. So a rigid typographic rule holds, declared in Section 32.1 and respected line by line: *in this chapter no open or unproved statement appears in a **teorema** environment*. The environments **teorema**, **proposizione**, **lemma** and **corollario** are reserved for the results that are proved in full in this chapter — and there are some, because every great open problem has an elementary core that is solved completely: centrally symmetric convex bodies inscribe squares (Theorem 32.1) and indeed rectangles of every shape (Theorem 32.2); the kissing number of the plane equals 6 (Theorem 32.4); there exists on the circle a dense set of points with all mutual distances rational (Theorem 32.5); the curvatures of an integral Apollonian packing remain integral forever (Theorem 32.3 and Corollary 32.2). Everything else — Toeplitz, Greene and Lobb, the *local-global* conjecture, kissing numbers in high dimension, Erdős and Ulam — sits in **osservazione** or **infobox**, as panorama, with the date.

The last section (Section 32.8) teaches the craft needed not to get hurt by this material: reading a preprint, distinguishing a proved result from an announced one, understanding what "under review" means, citing so that the reader can check. It is not a rhetorical appendix. While this chapter was being written, the identifier **arXiv:2604.17116**, indicated at the planning stage as "the result of Greene and Lobb on aspect ratios", was verified: it exists, it is by Greene and Lobb, but it is *not* the article published in the *Annals* in 2021 — it is a preprint of 18 April 2026, with a different and weaker statement, not yet submitted to any journal at the time of verification. Confusing the two would have produced a chapter that attributes to a published article a theorem that article does not contain. Section 32.8 explains how this error is avoided, and Section 32.3 keeps the two works rigorously distinct.

INFO

Level and prerequisites. Level **B–C**: the chapter's proofs use nothing beyond single-variable analysis and elementary plane geometry; the level rises only in reading the sources, which are research articles.

Internal prerequisites. Plane curves and Jordan curves (Chapter 2); global theorems on closed curves (Chapter 4); tangencies between circles, Ford circles and optimality of packings (Chapter 14); hyperspheres in any dimension and the volume of the n -dimensional ball (Chapter 11); rational parametrization of the circle (Chapter 6).

Prerequisites in other volumes, recalled only in text. Descartes' circle theorem and the construction of the Apollonian packing are in Volume I, Chapter 5; points with rational

coordinates on the circle and Pythagorean triples are in Volume I, Chapter 9. Here they are used as acquired results and not reproof: Observation 32.8 states exactly what is imported. *External prerequisites, assumed and not reproof:*

- the intermediate value theorem and Weierstrass's theorem for continuous functions on a compact set;
- elementary notions on plane convex sets: convexity, interior, boundary;
- arithmetic of the rationals and the notion of a dense subset of $\mathbb{R}$;
- the volume of the n -dimensional ball and the notion of a lattice, for Observation 32.11 alone (the data on the lattices E_8 and Leech are *imported* and attributed to their source).

Everything stated in a **teorema**, **proposizione**, **lemma** or **corollario** environment is proved here in full.

What is learned. Recognizing the difference between an open problem, a refuted conjecture and a theorem; isolating the special case of an open problem that *can* be solved, and proving it; reading the header of a preprint and deriving its editorial status; building a verifiable citation; distinguishing "announced", "submitted", "accepted", "published"; dating a statement about the state of research.

Warning. Conventions of the chapter.

- Every statement about the *status* of a problem is accompanied by the date of verification. All the checks in this chapter were made on **7 September 2026**; Table 32.2 collects the status of every statement cited as of that date. A status can change: it is the one thing that distinguishes this chapter from the others.
- A **Jordan curve** is, as in Chapter 2, the image of a continuous injective map $\gamma: S^1 \rightarrow \mathbb{R}^2$; "smooth" means of class C^∞ and with derivative never zero; "rectifiable" means of finite length.
- The four points of an *inscribed* square or rectangle must be distinct; degenerate configurations (four points coinciding pairwise, or collinear) do not count.
- The curvatures of a circle are the reciprocals of the radii, with a negative sign for the circle that contains the others: the convention is that of Volume I, Chapter 5.
- Decimals are written with a point, 0.5, and thousands with a comma in braces, 196,560.

32.1. What "open" means

Definition 32.1: Conjecture, open problem, theorem. Let P be a precise mathematical statement, that is, a statement for which the setting, the hypotheses and the conclusion are fixed without ambiguity.

- P is a **theorem** if there exists a proof of P accepted by the mathematical community, that is, written, published and checked.
- P is **refuted** if the negation of P is a theorem: someone has exhibited a counterexample, or proved that P is false.
- P is an **open problem** if it falls under neither case (i) nor case (ii). A **conjecture** is an open problem for which someone has publicly declared they expect an affirmative answer, usually on the basis of proved special cases or computer verifications.

Remark 32.1: Why typography matters. In earlier chapters the sequence "teorema $\rightarrow$ dimostrazione" is a contract: the reader knows that every line of the statement has been paid for. If, in this chapter, an open problem appeared in a **teorema** environment, that

contract would be broken, and the reader would no longer be able to tell, while skimming, what is established from what is merely hoped for.

Hence: the environments `teorema`, `proposizione`, `lemma` and `corollario` are used in this chapter only for the eleven results that are proved in full here (*Lemma 32.1*, *Theorem 32.1*, *Proposition 32.1*, *Theorem 32.2*, *Corollary 32.1*, *Proposition 32.2*, *Theorem 32.3*, *Corollary 32.2*, *Theorem 32.4*, *Lemma 32.2*, *Theorem 32.5*). Every other statement — whether open, or proved elsewhere by means out of reach here — sits in `osservazione` or `infobox`, and is declared as such on its first line.

32.2. Toeplitz's inscribed square problem

Definition 32.2: Square inscribed in a curve. Let $\gamma \subset \mathbb{R}^2$ be a Jordan curve. We say that γ **inscribes a square** if there exist four distinct points $A, B, C, D \in \gamma$ that, in this order, are the vertices of a non-degenerate square, that is

$$|AB| = |BC| = |CD| = |DA| > 0, \quad |AC| = |BD|.$$

It is not required that the four points follow one another in the order in which the curve traces them out, nor that the square lie inside the region enclosed by γ .

INFO

Panorama — the inscribed square problem (Toeplitz, 1911). Open as of 7 September 2026.

Problem. Is it true that every Jordan curve $\gamma \subset \mathbb{R}^2$ inscribes a square?

Otto Toeplitz posed the question in a communication to the Swiss Society of Natural Sciences in 1911; the exact reference is in the list of sources at the end of the chapter. The statement carries no regularity hypothesis: the curve is merely continuous, simple and closed. A hundred and fifteen years later the answer is **not known**. No counterexample has been exhibited, and no general proof has been accepted: the problem is open in the sense of Definition 32.1(iii).

What is known is a long list of *classes* of curves for which the answer is yes: Table 32.1 summarizes it, with authors and years. All these classes share some form of regularity — convexity, analyticity, differentiability, finite total curvature, local monotonicity — and the open problem is exactly what remains when every regularity is removed.

The elementary core of the problem, instead, is solved completely, and it is proved here. The simplest class for which the answer is yes is that of *centrally symmetric* convex bodies: for these no topology is needed, the intermediate value theorem applied to the radial function is enough. The preparatory work is all in the next lemma.

Definition 32.3: Convex body and radial function. A **convex body** of the plane is a set $K \subset \mathbb{R}^2$ that is compact, convex and has non-empty interior. If 0 is an interior point of K , the **radial function** of K is

$$\rho: S^1 \rightarrow (0, +\infty), \quad \rho(u) = \max\{t \geq 0 : tu \in K\},$$

where $S^1 = \{u \in \mathbb{R}^2 : |u| = 1\}$. One also writes $\rho(\varphi)$ for $\rho(u_\varphi)$, with $u_\varphi = (\cos \varphi, \sin \varphi)$; in this notation ρ is a 2π -periodic function of $\varphi \in \mathbb{R}$. The body K is **centrally symmetric about 0** if $K = -K$.

Table 32.1: Classes of Jordan curves for which the inscribed square problem has an affirmative answer. List drawn from the historical survey of B. Matschke and from the bibliographies of the two Greene and Lobb papers, all listed among the sources at the end of the chapter and verified on 7 September 2026. The last row is the open problem.

Class of curves	Author	Year
Piecewise analytic curves, with finitely many singularities	A. Emch	1913–1916
Convex curves	Emch; Zindler; Christensen	1913 onward
Smooth curves (Jordan, of class C^∞)	L. Šnirel'man	1929
Analytic curves	R. P. Jerrard	1961
Locally monotone curves	W. Stromquist	1989
Polygonal curves (discrete case)	I. Pak	2008
C^1 curves and curves of finite total curvature without cusps	Cantarella, Denne, McCleary	2022
Curves that are the union of two Lipschitz graphs of slope < 1	T. Tao	2017
Arbitrary Jordan curves (merely continuous)	—	open

Lemma 32.1: *The radial function is well defined and Lipschitz. Let $K \subset \mathbb{R}^2$ be a convex body with 0 interior, and let $0 < r \leq R$ be such that*

$$rB \subseteq K \subseteq RB, \quad B = \{x \in \mathbb{R}^2 : |x| \leq 1\}.$$

Then:

- (i) $\rho(u)$ exists and is finite for every $u \in S^1$, and $r \leq \rho(u) \leq R$;
- (ii) for every $x \in K$ and every $s \in (0, 1)$, the closed disc of centre $(1-s)x$ and radius sr is contained in K ;
- (iii) $|\rho(u) - \rho(v)| \leq \frac{R^2}{r} |u - v|$ for every $u, v \in S^1$; in particular ρ is continuous;
- (iv) $\partial K = \{\rho(u)u : u \in S^1\}$;
- (v) if $K = -K$, then $\rho(-u) = \rho(u)$ for every u , that is, $\rho(\varphi + \pi) = \rho(\varphi)$: the function ρ is π -periodic.

Proof. (i). Fix $u \in S^1$, and let $T_u = \{t \geq 0 : tu \in K\}$. The set T_u is non-empty because $0 \in K$; it is bounded because $K \subseteq RB$ implies $|tu| = t \leq R$ for every $t \in T_u$; it is closed because K is closed and $t \mapsto tu$ is continuous. A non-empty, closed and bounded subset of $\mathbb{R}$ has a maximum: hence $\rho(u) = \max T_u$ exists and is $\leq R$. Moreover $ru \in rB \subseteq K$, that is $r \in T_u$, so $\rho(u) \geq r > 0$.

(ii). Let $x \in K$, $s \in (0, 1)$, and let y be a point of the closed disc of centre $(1-s)x$ and radius sr . Then $y - (1-s)x$ has norm $\leq sr$, that is, one can write $y = (1-s)x + sb$ with $b = \frac{1}{s}(y - (1-s)x)$ and $|b| \leq r$. Hence $b \in rB \subseteq K$. Since $x \in K$, $b \in K$, K is convex and $(1-s)x + sb = y$ with $0 < s < 1$, we get $y \in K$.

(iii). Let $u, v \in S^1$ and set

$$\delta = |u - v|, \quad s = \frac{R\delta}{r + R\delta} \in [0, 1).$$

If $\delta = 0$ there is nothing to prove; so let $\delta > 0$, so that $s \in (0, 1)$. Note that

$$1 - s = \frac{r}{r + R\delta}, \quad \text{hence} \quad (1-s)R\delta = \frac{rR\delta}{r + R\delta} = sr. \quad (32.1)$$

Let $x = \rho(u)u$; by definition of ρ , $x \in K$. The point $y = (1-s)\rho(u)v$ is at distance from

$(1-s)x = (1-s)\rho(u)u$ exactly

$$|(1-s)\rho(u)v - (1-s)\rho(u)u| = (1-s)\rho(u)|v-u| \leq (1-s)R\delta \stackrel{(32.1)}{=} sr,$$

where $\rho(u) \leq R$ from point (i) was used. Hence y belongs to the closed disc of centre $(1-s)x$ and radius sr , which by point (ii) is contained in K . Thus $(1-s)\rho(u) \in T_v$, that is

$$\rho(v) \geq (1-s)\rho(u).$$

It follows that

$$\rho(u) - \rho(v) \leq s\rho(u) \leq sR = \frac{R^2\delta}{r+R\delta} \leq \frac{R^2}{r}\delta,$$

having used $\rho(u) \leq R$ and $r+R\delta \geq r$. Exchanging the roles of u and v gives the same bound for $\rho(v) - \rho(u)$, hence $|\rho(u) - \rho(v)| \leq \frac{R^2}{r}\delta$. A Lipschitz function is continuous.

(iv). Let $u \in S^1$ and $x = \rho(u)u$. For every $t > \rho(u)$ we have $tu \notin K$ (otherwise $t \in T_u$ would contradict the maximality of $\rho(u)$); since $t \mapsto tu$ is continuous and $x \in K$, every neighbourhood of x contains points of K (the point x itself) and points not in K (the points tu with $t > \rho(u)$ close enough to $\rho(u)$). Hence $x \in \partial K$.

Conversely let $y \in \partial K$. Since 0 is interior to K and y is a boundary point, $y \neq 0$; write $y = |y|u$ with $u = y/|y| \in S^1$. From $y \in K$ it follows that $|y| \in T_u$, that is $|y| \leq \rho(u)$. If $|y| < \rho(u)$ held, set $s = 1 - \frac{|y|}{\rho(u)} \in (0, 1)$ and $x = \rho(u)u \in K$: then $(1-s)x = |y|u = y$, and by point (ii) the closed disc of centre y and radius $sr > 0$ is contained in K , that is, y would be interior to K , against $y \in \partial K$. Hence $|y| = \rho(u)$ and $y = \rho(u)u$.

(v). If $K = -K$, then $tu \in K \iff -tu \in K$, that is $T_u = T_{-u}$, hence $\rho(u) = \rho(-u)$. In terms of φ : $u_{\varphi+\pi} = -u_\varphi$, hence $\rho(\varphi+\pi) = \rho(\varphi)$. $\square$

Theorem 32.1: Centrally symmetric convex bodies inscribe a square. Let $K \subset \mathbb{R}^2$ be a convex body, centrally symmetric about one of its interior points, which may be assumed to be the origin, and let $\gamma = \partial K$. Then γ inscribes a square, and the centre of that square is the origin.

Proof. Apply Lemma 32.1: the radial function $\rho: \mathbb{R} \rightarrow [r, R]$, $\varphi \mapsto \rho(u_\varphi)$, is continuous (point (iii)) and π -periodic (point (v)), and $\rho(\varphi)u_\varphi \in \gamma$ for every φ (point (iv)).

Step 1 — a function that must vanish. Set

$$h(\varphi) = \rho(\varphi) - \rho(\varphi + \frac{\pi}{2}), \quad \varphi \in \mathbb{R}.$$

The function h is continuous, being the difference of two continuous functions. Moreover, using the π -periodicity of ρ ,

$$h(\varphi + \frac{\pi}{2}) = \rho(\varphi + \frac{\pi}{2}) - \rho(\varphi + \pi) = \rho(\varphi + \frac{\pi}{2}) - \rho(\varphi) = -h(\varphi). \quad (32.2)$$

In particular $h(0)$ and $h(\pi/2) = -h(0)$ have opposite signs (or are both zero).

Step 2 — the intermediate value theorem. If $h(0) = 0$, take $\varphi_0 = 0$. Otherwise $h(0)$ and $h(\pi/2)$ are non-zero and of opposite sign by (32.2); since h is continuous on the interval $[0, \pi/2]$, the intermediate value theorem gives $\varphi_0 \in (0, \pi/2)$ with $h(\varphi_0) = 0$, that is

$$\rho(\varphi_0) = \rho(\varphi_0 + \frac{\pi}{2}) =: \varrho > 0.$$

Step 3 — the four points. Set

$$A = \varrho u_{\varphi_0}, \quad B = \varrho u_{\varphi_0+\pi/2}, \quad C = -A, \quad D = -B.$$

All four lie on γ : for A and B this is point (iv) of Lemma 32.1 with $\rho(\varphi_0) = \rho(\varphi_0 + \pi/2) = \varrho$; for $C = \varrho u_{\varphi_0 + \pi}$ and $D = \varrho u_{\varphi_0 + 3\pi/2}$ the same point (iv) is used together with the π -periodicity (point (v)), which gives $\rho(\varphi_0 + \pi) = \rho(\varphi_0) = \varrho$ and $\rho(\varphi_0 + 3\pi/2) = \rho(\varphi_0 + \pi/2) = \varrho$.

The four points are distinct: $A \neq C$ and $B \neq D$ because $\varrho > 0$; $A \neq \pm B$ because u_{φ_0} and $u_{\varphi_0 + \pi/2}$ are orthogonal and non-zero.

Step 4 — $ABCD$ is a square. Since $C = -A$ and $D = -B$, the segments AC and BD both have the origin as midpoint, hence $ABCD$ is a parallelogram. The sides:

$$\vec{AB} = B - A, \quad \vec{BC} = C - B = -A - B.$$

Their dot product equals

$$\langle B - A, -A - B \rangle = -\langle B, A \rangle - \langle B, B \rangle + \langle A, A \rangle + \langle A, B \rangle = |A|^2 - |B|^2 = \varrho^2 - \varrho^2 = 0,$$

so consecutive sides are orthogonal: $ABCD$ is a rectangle. The lengths: since $\langle A, B \rangle = \varrho^2 \langle u_{\varphi_0}, u_{\varphi_0 + \pi/2} \rangle = 0$,

$$|AB|^2 = |B - A|^2 = |A|^2 - 2\langle A, B \rangle + |B|^2 = 2\varrho^2,$$

$$|BC|^2 = |A + B|^2 = |A|^2 + 2\langle A, B \rangle + |B|^2 = 2\varrho^2.$$

Hence $|AB| = |BC| = \varrho\sqrt{2} > 0$, and by the parallelogram property also $|CD| = |AB|$ and $|DA| = |BC|$: the four sides are equal and the angles are right angles. Finally $|AC| = |2A| = 2\varrho = |2B| = |BD|$. The quadrilateral $ABCD$ is therefore a non-degenerate square inscribed in γ , centred at the origin. $\square$

Example 32.1: The square inscribed in the ellipse $x^2/4 + y^2 = 1$. The ellipse $E = \{(x, y) : x^2/4 + y^2 = 1\}$ is the boundary of a convex body centrally symmetric about the origin, so Theorem 32.1 applies. Here the square can be found in closed form.

The radial function is obtained by imposing $\rho^2 \cos^2 \varphi/4 + \rho^2 \sin^2 \varphi = 1$:

$$\rho(\varphi) = \left(\frac{\cos^2 \varphi}{4} + \sin^2 \varphi \right)^{-1/2}.$$

The condition $\rho(\varphi) = \rho(\varphi + \pi/2)$ of Step 2 becomes

$$\frac{\cos^2 \varphi}{4} + \sin^2 \varphi = \frac{\sin^2 \varphi}{4} + \cos^2 \varphi \iff \left(\frac{1}{4} - 1 \right) (\cos^2 \varphi - \sin^2 \varphi) = 0 \iff \cos 2\varphi = 0,$$

that is $\varphi_0 = \pi/4$. Then

$$\varrho = \rho(\pi/4) = \left(\frac{1}{8} + \frac{1}{2} \right)^{-1/2} = \left(\frac{5}{8} \right)^{-1/2} = \sqrt{\frac{8}{5}} = \frac{2\sqrt{2}}{\sqrt{5}},$$

and the four vertices are

$$\left(\pm \frac{2}{\sqrt{5}}, \pm \frac{2}{\sqrt{5}} \right) = (\pm 0.8944272, \pm 0.8944272).$$

Independent check (direct substitution into the equation of the ellipse): with $x = y = 2/\sqrt{5}$ one has $x^2 = y^2 = 4/5$ and

$$\frac{x^2}{4} + y^2 = \frac{4/5}{4} + \frac{4}{5} = \frac{1}{5} + \frac{4}{5} = 1. \quad \checkmark$$

The side of the square equals $2 \cdot 2/\sqrt{5} = 4/\sqrt{5} = 1.7888544$, and the diagonal $2\varrho = 2\sqrt{8/5} = 2.5298221$; the check side $\cdot \sqrt{2} = 1.7888544 \cdot 1.4142136 = 2.5298221$ works out. $\checkmark$

Figure 32.1: The square inscribed in the ellipse $x^2/4 + y^2 = 1$ constructed in Example 32.1: the vertices are $(\pm 2/\sqrt{5}, \pm 2/\sqrt{5}) = (\pm 0.8944272, \pm 0.8944272)$, the centre is the origin, the side equals $4/\sqrt{5} = 1.7888544$. The coordinates are computed by hand and verified by substitution into the equation of the ellipse.

Remark 32.2: What we import: the history of the Toeplitz problem. Of the picture summarized in Table 32.1, only one row is proved in full in this chapter — and not even one of those: Theorem 32.1 concerns centrally symmetric convex bodies, which are a proper subset of the convex bodies of the second row. Every other row is **imported**: the statements are reported with author and year, the proofs are not here.

What exactly is missing:

- Convex curves in general. The classical proof does not use central symmetry but a continuity argument on the family of circumscribed squares, or an approximation argument; it cannot be reconstructed here in a few lines with the certainty the treatise requires.
- Smooth curves. Šnirel'man's argument is topological: one counts modulo 2 the number of inscribed squares of a regular curve, shows the count is invariant under deformation and equals 1 for the circle. It requires intersection theory and transversality.
- C^1 curves and curves of finite total curvature. The argument of Cantarella, Denne and McCleary uses multijet transversality in configuration spaces.
- Lipschitz curves. Tao's argument replaces the topological count with an integral identity.

None of these tools is developed in the treatise, and none of them solves the general problem: the bold row of Table 32.1 remains empty. Status verified: 7 September 2026.

32.3. Inscribed rectangles: Greene and Lobb

If the square is replaced by a rectangle of assigned shape, the problem changes nature: from a question about a single shape it becomes a question about a one-parameter family. It is convenient to parametrize the family by the angle between the diagonals, not by the ratio of the sides: the angle varies in a bounded interval, the ratio does not, and it is the angle that appears in the statements found in the literature.

Definition 32.4: θ -rectangle and aspect ratio. Let $\theta \in (0, \pi)$. A **θ -rectangle** is a non-degenerate rectangle of the plane whose diagonals meet at angle θ (the unoriented angle between two rays from the point of intersection, measured in $(0, \pi)$). The **aspect ratio** of a rectangle with sides $p \leq q$ is the number $p/q \in (0, 1]$.

A Jordan curve γ **inscribes** a θ -rectangle if there exist four distinct points of γ that are its vertices.

Proposition 32.1: *The angle of the diagonals determines the aspect ratio.* Let $\theta \in (0, \pi)$ and let $\mathcal{R}$ be a θ -rectangle of diagonal $d > 0$. Then the sides of $\mathcal{R}$ measure

$$d \sin\left(\frac{\theta}{2}\right) \quad \text{and} \quad d \cos\left(\frac{\theta}{2}\right),$$

and the aspect ratio of $\mathcal{R}$ equals

$$\min \left\{ \tan\left(\frac{\theta}{2}\right), \cot\left(\frac{\theta}{2}\right) \right\}.$$

In particular:

- (i) $\mathcal{R}$ is a square if and only if $\theta = \pi/2$;
- (ii) the function $\theta \mapsto \tan(\theta/2)$ is a strictly increasing bijection from $(0, \pi/2]$ onto $(0, 1]$; consequently, for every aspect ratio $\lambda \in (0, 1]$ there is exactly one $\theta \in (0, \pi/2]$ such that θ -rectangles have aspect ratio λ , and it is $\theta = 2 \arctan \lambda$;
- (iii) a θ -rectangle and a $(\pi - \theta)$ -rectangle have the same aspect ratio.

Proof. Step 1 — normal form. The diagonals of a rectangle are equal and bisect each other: letting O be their meeting point, the four vertices lie on the circle centred at O with radius $d/2$, and are pairwise opposite with respect to O . By an isometry of the plane (Chapter 5) one can move O to the origin and arrange the vertices symmetrically about the x -axis: let

$$A = \frac{d}{2} \left(\cos \frac{\theta}{2}, \sin \frac{\theta}{2} \right), \quad B = \frac{d}{2} \left(\cos \frac{\theta}{2}, -\sin \frac{\theta}{2} \right), \quad C = -A, \quad D = -B.$$

The angle between the rays OA and OB is θ by construction, and the diagonals are AC and BD : so this configuration, and only this one up to isometries, is a θ -rectangle of diagonal d . That $ABCD$ is indeed a rectangle is checked as in Step 4 of the proof of Theorem 32.1: $|A| = |B| = d/2$ implies $\langle B - A, -A - B \rangle = |A|^2 - |B|^2 = 0$.

Step 2 — the sides. A direct computation gives

$$A - B = \left(0, d \sin \frac{\theta}{2} \right) \implies |AB| = d \sin \frac{\theta}{2},$$

$$B - C = B + A = \left(d \cos \frac{\theta}{2}, 0 \right) \implies |BC| = d \cos \frac{\theta}{2}.$$

Both are positive because $\theta/2 \in (0, \pi/2)$. Since in a rectangle opposite sides are equal, these two measures exhaust the sides.

Step 3 — the ratio. The aspect ratio is the quotient of the smaller side by the larger one, that is

$$\frac{\min\{|AB|, |BC|\}}{\max\{|AB|, |BC|\}} = \min \left\{ \frac{\sin(\theta/2)}{\cos(\theta/2)}, \frac{\cos(\theta/2)}{\sin(\theta/2)} \right\} = \min \left\{ \tan \frac{\theta}{2}, \cot \frac{\theta}{2} \right\}.$$

(i). $\mathcal{R}$ is a square $\iff |AB| = |BC| \iff \sin(\theta/2) = \cos(\theta/2) \iff \tan(\theta/2) = 1$. Since $\theta/2 \in (0, \pi/2)$ and the tangent is strictly increasing and injective on $(0, \pi/2)$, this happens only for $\theta/2 = \pi/4$, that is $\theta = \pi/2$.

(ii). On $(0, \pi/2]$ one has $\theta/2 \in (0, \pi/4]$, where $\tan(\theta/2) \in (0, 1]$ and $\cot(\theta/2) \geq 1$: hence the minimum of Step 3 is $\tan(\theta/2)$. The map $\theta \mapsto \tan(\theta/2)$ is the composition of $\theta \mapsto \theta/2$, increasing, with the tangent, strictly increasing on $(0, \pi/4]$; it is thus strictly increasing, hence injective. It is surjective onto $(0, 1]$ because it is continuous, with $\tan(\theta/2) \rightarrow 0^+$ as $\theta \rightarrow 0^+$

and $\tan(\pi/4) = 1$: the intermediate value theorem covers the whole of $(0, 1]$. The inverse is $\lambda \mapsto 2 \arctan \lambda$.

(iii). Substituting θ with $\pi - \theta$ gives $\sin \frac{\pi-\theta}{2} = \cos \frac{\theta}{2}$ and $\cos \frac{\pi-\theta}{2} = \sin \frac{\theta}{2}$: the two side measures swap, and the minimum of Step 3 does not change. $\square$

Example 32.2: Three angles and three shapes. By Proposition 32.1, with $d = 2$:

θ	sides	aspect ratio	shape
$\pi/2 = 1.5707963$	1.4142136; 1.4142136	1	square
$\pi/3 = 1.0471976$	1; 1.7320508	0.5773503	$1 : \sqrt{3}$
$2 \arctan \frac{1}{2} = 0.9272952$	0.8944272; 1.7888544	0.5	$1 : 2$

Independent check (closed form against direct computation of the distances between the vertices, run with a Python script): for $\theta = 2 \arctan \frac{1}{2}$ one has $\theta/2 = \arctan \frac{1}{2}$, so $\tan(\theta/2) = 0.5$ exactly, and $\sin(\theta/2) = 1/\sqrt{5} = 0.4472136$, $\cos(\theta/2) = 2/\sqrt{5} = 0.8944272$; the sides equal $2 \cdot 0.4472136 = 0.8944272$ and $2 \cdot 0.8944272 = 1.7888544$, whose ratio is 0.5. The script, which builds the four vertices and measures the four sides and the angle between the diagonals, returns sides 0.8944272 and 1.7888544, ratio 2.0000000 (larger side over smaller) and angle between the diagonals 0.9272952: the three numbers agree with those from the formula. $\checkmark$

Note $2 \arctan \frac{1}{2} = 0.9272952 < \pi/2 = 1.5707963$: the $1 : 2$ rectangle corresponds to a diagonal angle *smaller* than that of the square. The more elongated the rectangle, the smaller the angle $\theta \in (0, \pi/2]$.

Figure 32.2: A θ -rectangle inscribed in the unit circle, with $\theta = 2 \arctan \frac{1}{2} = 0.9272952$ (that is 53.1301024°) and diagonal $d = 2$. The vertices are $(\pm 0.8944272, \pm 0.4472136)$, that is $(\pm 2/\sqrt{5}, \pm 1/\sqrt{5})$; the sides measure $2/\sqrt{5} = 0.8944272$ and $4/\sqrt{5} = 1.7888544$, in ratio $1 : 2$ (Proposition 32.1). Check: $(2/\sqrt{5})^2 + (1/\sqrt{5})^2 = \frac{4}{5} + \frac{1}{5} = 1$, the four vertices lie on the unit circle. $\checkmark$

Theorem 32.2: Centrally symmetric convex bodies inscribe every shape of rectangle. Let $K \subset \mathbb{R}^2$ be a convex body, centrally symmetric about one of its interior points, taken to be the origin, and let $\gamma = \partial K$. Then for every $\theta \in (0, \pi)$ the curve γ inscribes a θ -rectangle centred at the origin. Equivalently (Proposition 32.1(ii)), γ inscribes a rectangle of every aspect ratio $\lambda \in (0, 1]$.

Proof. Let ρ be the radial function of K : by Lemma 32.1 it is continuous, π -periodic and takes values in $[r, R]$ with $0 < r \leq R$, and $\rho(\varphi)u_\varphi \in \gamma$ for every φ .

Step 1 — a continuous function on the circle. Fix $\theta \in (0, \pi)$, and set

$$h_\theta(\varphi) = \rho(\varphi) - \rho(\varphi + \theta), \quad \varphi \in \mathbb{R}.$$

It is continuous and π -periodic (because ρ is).

Step 2 — h_θ changes sign (or vanishes). The function ρ is continuous on the compact set $[0, \pi]$, hence by Weierstrass's theorem it attains a maximum and a minimum: let $\varphi_M, \varphi_m \in [0, \pi]$ be such that

$$\rho(\varphi_M) = \max_{[0, \pi]} \rho, \quad \rho(\varphi_m) = \min_{[0, \pi]} \rho.$$

By π -periodicity these are the maximum and minimum of ρ over all of $\mathbb{R}$. Then

$$h_\theta(\varphi_M) = \rho(\varphi_M) - \rho(\varphi_M + \theta) \geq 0, \quad h_\theta(\varphi_m) = \rho(\varphi_m) - \rho(\varphi_m + \theta) \leq 0,$$

because $\rho(\varphi_M)$ is the maximum and $\rho(\varphi_m)$ the minimum of ρ on $\mathbb{R}$.

Step 3 — the intermediate value. The function h_θ is continuous on the closed interval with endpoints φ_m and φ_M (one of the two intervals $[\varphi_m, \varphi_M]$ or $[\varphi_M, \varphi_m]$, depending on the order), where it takes a value ≤ 0 and a value ≥ 0 . By the intermediate value theorem there exists φ_0 in that interval with $h_\theta(\varphi_0) = 0$, that is

$$\rho(\varphi_0) = \rho(\varphi_0 + \theta) =: \varrho \in [r, R], \quad \varrho > 0.$$

Step 4 — the four points and their membership in γ . Set

$$A = \varrho u_{\varphi_0}, \quad B = \varrho u_{\varphi_0 + \theta}, \quad C = -A = \varrho u_{\varphi_0 + \pi}, \quad D = -B = \varrho u_{\varphi_0 + \theta + \pi}.$$

By Lemma 32.1(iv) and π -periodicity (point (v)) all four belong to γ : indeed $\rho(\varphi_0 + \pi) = \rho(\varphi_0) = \varrho$ and $\rho(\varphi_0 + \theta + \pi) = \rho(\varphi_0 + \theta) = \varrho$.

The four points are distinct: $A \neq C$ and $B \neq D$ because $\varrho > 0$; $A \neq B$ and $A \neq D$ because u_{φ_0} , $u_{\varphi_0 + \theta}$ and $u_{\varphi_0 + \theta + \pi}$ are pairwise distinct unit vectors, since $\theta \in (0, \pi)$.

Step 5 — $ABCD$ is a θ -rectangle. The diagonals AC and BD both have the origin as midpoint, so $ABCD$ is a parallelogram; and

$$\langle B - A, -A - B \rangle = |A|^2 - |B|^2 = \varrho^2 - \varrho^2 = 0,$$

so consecutive sides are orthogonal and $ABCD$ is a rectangle. Its diagonals are the segments AC and BD , which lie on the lines through the origin with directions u_{φ_0} and $u_{\varphi_0 + \theta}$: the angle between the rays OA and OB is θ , hence $ABCD$ is a θ -rectangle. The diagonal measures $2\varrho > 0$, and the sides $2\varrho \sin(\theta/2) > 0$ and $2\varrho \cos(\theta/2) > 0$ by Proposition 32.1: the rectangle is non-degenerate.

Step 6 — every aspect ratio. Let $\lambda \in (0, 1]$. By Proposition 32.1(ii) there exists $\theta = 2 \arctan \lambda \in (0, \pi/2]$ whose θ -rectangles have aspect ratio λ ; Steps 1–5 provide a θ -rectangle inscribed in γ . $\square$

Corollary 32.1: *The square as the case $\theta = \pi/2$. Theorem 32.1 is the case $\theta = \pi/2$ of Theorem 32.2.*

Proof. Apply Theorem 32.2 with $\theta = \pi/2$: one obtains a $\pi/2$ -rectangle inscribed in γ and centred at the origin. By Proposition 32.1(i) a θ -rectangle is a square if and only if $\theta = \pi/2$; hence the rectangle obtained is a square, and this is exactly the conclusion of Theorem 32.1. $\square$

Remark 32.3: *Why central symmetry is a genuine hypothesis and not a convenience. In the proof, central symmetry is used twice, and in two different ways. In Step 4*

it guarantees that the points $-A$ and $-B$ still lie on γ : without it the four points would not all be on the curve. In Steps 1–3 it makes ρ π -periodic, which is what allows $\rho(\varphi)$ to be compared with $\rho(\varphi + \theta)$ on a compact domain and the argument to be concluded with the intermediate value theorem.

Remove the hypothesis, and the argument collapses entirely: nothing forces the four points to be pairwise opposite about a centre, and the proof provides no substitute. It is exactly here that the problem becomes hard: for curves without symmetry the inscribed rectangle has no privileged centre, and finding the four points becomes an intersection problem in a four-parameter configuration space. This is the leap that separates this page from the Greene and Lobb theorem of Observation 32.4.

Remark 32.4: Panorama — the Greene and Lobb theorem (2021). The result that follows **is not proved in this chapter**: it is reported as panorama, with the verified source, and for this reason it appears in a remark and not in a **teorema** environment.

Statement (J. E. Greene, A. Lobb, *The rectangular peg problem*, *Annals of Mathematics* **194** (2021), no. 2, pp. 509–517; verified on 7 September 2026). For every smooth Jordan curve γ and every rectangle R of the Euclidean plane, there exists a rectangle similar to R whose vertices lie on γ .

In the language of Definition 32.4: every smooth Jordan curve inscribes a θ -rectangle for every $\theta \in (0, \pi)$, that is, a rectangle of every aspect ratio. Theorem 32.2 is the same conclusion under the much stronger hypothesis that γ is the boundary of a centrally symmetric convex body — a hypothesis that allows the elementary proof given above.

What is left out. The hypothesis of smoothness cannot be removed with Greene and Lobb’s proof: for a merely continuous Jordan curve the statement is, as of 7 September 2026, **open** — just as the special case $\theta = \pi/2$ is open, namely the Toeplitz problem of Section 32.2.

Remark 32.5: What we import from the Greene and Lobb theorem. The theorem of Observation 32.4 is **imported**: its statement and exact location are reported, not its proof. What is missing, precisely: the translation of the problem into a question of symplectic geometry in $\mathbb{C}^2$; the construction, starting from a smooth curve with no inscribed θ -rectangles, of a smoothly immersed Lagrangian Klein bottle in $\mathbb{C}^2$; and the non-immersion theorem of V. Shevchishin (2009), cited by the authors, which asserts that no such immersion exists. None of these three ingredients is developed in the treatise, and they cannot be reconstructed here with the certainty required: for this reason the statement remains in a remark. The article’s bibliography, verified on 7 September 2026, is the source of this description.

Definition 32.5: The isodiametric constant $B(\gamma)$. Let $\gamma \subset \mathbb{R}^2$ be a Jordan curve, let $A(\gamma)$ be the area of the bounded region it encloses, and let

$$R(\gamma) = \frac{1}{2} \text{diam}(\gamma) = \frac{1}{2} \sup_{P, Q \in \gamma} |PQ|$$

be its **radius**, that is, half the diameter. One sets

$$B(\gamma) = \frac{A(\gamma)}{R(\gamma)^2}.$$

Remark 32.6: Panorama — a 2026 preprint, and how to read it. On 18 April 2026 Greene and Lobb deposited on arXiv the work *Jordan curves inscribe a positive measure*

of rectangles ([arXiv:2604.17116](#)). As of 7 September 2026 the deposit record shows a single version (*v1*, 18 April 2026), no journal reference and no editorial DOI: it is a **preprint** in the sense of Definition 32.9, not a published article. The two statements it contains are reported here as *panorama*.

Statement A. If $\gamma \subset \mathbb{C}$ is a Jordan curve, there exists a subset $\mathcal{S}(\gamma) \subset (0, \pi)$ of measure at least $B(\gamma)$ such that γ inscribes a θ -rectangle for every $\theta \in \mathcal{S}(\gamma)$.

Statement B. If $\gamma \subset \mathbb{C}$ is a rectifiable Jordan curve, then γ inscribes a θ -rectangle for every $\theta \in (0, B(\gamma))$.

These are statements about all Jordan curves, with no smoothness hypothesis — and this is where their interest lies with respect to the 2021 theorem — but they do not solve the problem: they give a set of angles of positive measure, not all angles. The authors explicitly declare open both the inscribed square problem and the rectangle problem for continuous curves.

How this material should be used. Until a journal reference appears, a work of this kind is cited as a preprint, with identifier, version and date, and its correctness has not yet been certified by any peer review (see Section 32.8). It must not be confused with the 2021 article of Observation 32.4, which is published, has different hypotheses (smooth curves) and a stronger conclusion (all angles).

Example 32.3: What Statement B says for concrete curves. $B(\gamma)$ is computed for five curves, using Definition 32.5. For a polygon, $R(\gamma)$ is half the maximum distance between two vertices.

γ	$A(\gamma)$	$R(\gamma)$	$B(\gamma)$	$B(\gamma)/\pi$
circle of radius 1	π	1	$\pi = 3.1415927$	1
regular hexagon of side 1	$\frac{3\sqrt{3}}{2}$	1	$\frac{3\sqrt{3}}{2} = 2.5980762$	0.8269933
square of side 1	1	$\frac{\sqrt{2}}{2}$	2	0.6366198
equilateral triangle of side 1	$\frac{\sqrt{3}}{4}$	$\frac{1}{2}$	$\sqrt{3} = 1.7320508$	0.5513289
ellipse $a = 2$, $b = 1$	2π	2	$\frac{\pi}{2} = 1.5707963$	0.5

Independent check (closed form against numerical computation): the area of the three polygons was recomputed with the Gauss ("shoelace") formula $A = \frac{1}{2} |\sum_i (x_i y_{i+1} - x_{i+1} y_i)|$ on the vertices, and the diameter as the maximum of the pairwise distances between vertices, using a Python script. The values obtained are: square, area 1, diameter 1.4142136, $B = 1.9999999\dots$ (floating-point rounding of 2); triangle, area 0.4330127 = $\sqrt{3}/4$, diameter 1, $B = 1.7320508$; hexagon, area 2.5980762, diameter 2, $B = 2.5980762$. These agree with the $B(\gamma)$ column. ✓

Reading. All five curves are rectifiable, so Statement B applies: for the square it guarantees inscribed θ -rectangles for every $\theta \in (0, 2)$, that is for 63.66% of the possible angles; for the equilateral triangle for every $\theta \in (0; 1.7320508)$, that is 55.13%; for the circle for every $\theta \in (0, \pi)$, that is all of them — and this is consistent, because the circle is the boundary of a centrally symmetric convex body and Theorem 32.2 gives the same conclusion by elementary means. The square, hexagon and ellipse are also centrally symmetric, and for them Theorem 32.2 gives *more* than Statement B; the equilateral triangle, which is not, is the case where Statement B says something new.

Proposition 32.2: From a threshold of angles to every aspect ratio. Let γ be a Jordan curve and let $b \in (0, \pi]$ be a number such that γ inscribes a θ -rectangle for every $\theta \in (0, b)$. If $b > \pi/2$, then γ inscribes a rectangle of every aspect ratio $\lambda \in (0, 1]$, including the square. If $b = \pi/2$, then γ inscribes a rectangle of every aspect ratio $\lambda \in (0, 1)$, but this hypothesis alone implies nothing about the square.

Proof. Let $\lambda \in (0, 1]$. By Proposition 32.1(ii) the rectangles of aspect ratio λ are exactly the θ_λ -rectangles with

$$\theta_\lambda = 2 \arctan \lambda \in (0, \pi/2],$$

and $\lambda \mapsto \theta_\lambda$ is strictly increasing with $\theta_1 = 2 \arctan 1 = 2 \cdot \frac{\pi}{4} = \frac{\pi}{2}$.

If $b > \pi/2$, then for every $\lambda \in (0, 1]$ one has $\theta_\lambda \leq \pi/2 < b$, that is $\theta_\lambda \in (0, b)$: by hypothesis γ inscribes a θ_λ -rectangle, which has aspect ratio λ . In particular for $\lambda = 1$ one obtains a square. If $b = \pi/2$, then for $\lambda \in (0, 1)$ one has $\theta_\lambda = 2 \arctan \lambda < 2 \arctan 1 = \pi/2 = b$, hence $\theta_\lambda \in (0, b)$ and the conclusion holds as above; but for $\lambda = 1$, $\theta_1 = \pi/2 = b \notin (0, b)$, and the hypothesis says nothing. $\square$

Remark 32.7: The computation that really matters. Combining Proposition 32.2 with Statement B of Observation 32.6 gives a criterion that can be checked by hand: a rectifiable Jordan curve with

$$B(\gamma) = \frac{A(\gamma)}{R(\gamma)^2} > \frac{\pi}{2} = 1.5707963,$$

that is, enclosing more than half the area of the disc of the same diameter, inscribes rectangles of every aspect ratio, including the square. In the table of Example 32.3, the circle (π), the hexagon (2.5980762), the square (2) and the equilateral triangle (1.7320508) exceed the threshold; the ellipse with semi-axes 2 and 1 reaches it exactly ($\pi/2$) and stays in the second case of the proposition. Note that this criterion depends on an imported statement not yet subjected to review: it is a good example of a conditional conclusion, and must be cited as such.

32.4. Apollonian packings and the local–global conjecture

Descartes' circle theorem and the construction of the Apollonian packing are developed in Volume I, Chapter 5, and tangencies between circles are taken up again in this volume in Chapter 14. Here only Descartes' statement is used, and from it the arithmetic fact that opens the problem is derived in full: *if four starting curvatures are integers, all curvatures of the packing are integers.*

Remark 32.8: What we import: Descartes' circle theorem. The following result is **imported** from Volume I, Chapter 5, where it is proved: if four circles of the plane are pairwise tangent at four distinct points, and a, b, c, d are their signed curvatures (the reciprocal of the radius, negative for the circle that contains the other three), then

$$(a + b + c + d)^2 = 2(a^2 + b^2 + c^2 + d^2). \quad (32.3)$$

What is missing here: the geometric proof of (32.3) and the discussion of degenerate cases (lines as circles of zero curvature, external and internal tangencies). Nothing that follows reproves (32.3): it is used as the starting algebraic identity.

Definition 32.6: Descartes quadruple, integral Apollonian packing. A **Descartes quadruple** is an ordered quadruple (a, b, c, d) of real numbers satisfying (32.3). The **Apollonian packing** generated by four mutually tangent circles is the set of circles obtained by repeatedly filling every curvilinear gap between three mutually tangent circles with the circle tangent to all three. The packing is called **integral** if all the curvatures of its circles are integers.

Theorem 32.3: Vieta's reflection. Let a, b, c, d be real numbers satisfying (32.3), and set $s = a + b + c$. Then:

(i) d is a root of the quadratic equation

$$X^2 - 2sX + (2(a^2 + b^2 + c^2) - s^2) = 0;$$

(ii) the other root is

$$d' = 2(a + b + c) - d,$$

and (a, b, c, d') also satisfies (32.3);

(iii) if a, b, c, d are integers, so is d' .

Proof. (i). Set $q = a^2 + b^2 + c^2$. Identity (32.3) can be rewritten

$$(s + d)^2 = 2(q + d^2),$$

that is $s^2 + 2sd + d^2 = 2q + 2d^2$, that is

$$d^2 - 2sd + (2q - s^2) = 0.$$

This is exactly the equation $X^2 - 2sX + (2q - s^2) = 0$ evaluated at $X = d$: hence d is a root of it.

(ii). A monic quadratic polynomial $X^2 - \sigma X + \pi_0$ has the sum of its roots equal to σ (Vieta's formulas). Here $\sigma = 2s$: if d is a root, the other is

$$d' = 2s - d = 2(a + b + c) - d.$$

Since d' is a root of the same equation, $d'^2 - 2sd' + (2q - s^2) = 0$, and retracing the steps of point (i) with d' in place of d :

$$d'^2 - 2sd' + 2q - s^2 = 0 \iff s^2 + 2sd' + d'^2 = 2q + 2d'^2 \iff (s + d')^2 = 2(q + d'^2),$$

that is $(a + b + c + d')^2 = 2(a^2 + b^2 + c^2 + d'^2)$: the quadruple (a, b, c, d') satisfies (32.3).

(iii). $d' = 2(a + b + c) - d$ is obtained from a, b, c, d using only sums, products by 2 and a difference: if $a, b, c, d \in \mathbb{Z}$, then $d' \in \mathbb{Z}$, because $\mathbb{Z}$ is closed under these operations. $\square$

Corollary 32.2: Hereditary integrality of Apollonian packings. Let $\mathcal{A}$ be an Apollonian packing generated by four mutually tangent circles whose curvatures a, b, c, d are integers. Then all the curvatures of the circles of $\mathcal{A}$ are integers: $\mathcal{A}$ is integral.

Proof. Every circle of $\mathcal{A}$ is obtained from the initial quadruple by a finite sequence of steps, in each of which one of the four circles of a mutually tangent quadruple is replaced by the other circle tangent to the remaining three. Let n be the number of steps; the proof proceeds by induction on n .

Base $n = 0$: the quadruple is (a, b, c, d) , with integer curvatures by hypothesis.

Inductive step: suppose that after n steps a quadruple of mutually tangent circles with integer curvatures (a_n, b_n, c_n, d_n) has been obtained. The four curvatures satisfy (32.3) (Observation 32.8). At step $n + 1$ one of the four circles, say the fourth, is replaced by the other circle tangent to the first three: its curvature d_{n+1} is the other root of the equation in Theorem 32.3(i), that is

$$d_{n+1} = 2(a_n + b_n + c_n) - d_n,$$

which is an integer by Theorem 32.3(iii). The same holds if the circle replaced is the first, second or third, by symmetry of the roles in (32.3). Hence the quadruple after $n + 1$ steps also

has integer curvatures.

By induction, every circle reachable in finitely many steps has integer curvature; since $\mathcal{A}$ is by construction the set of circles reachable in this way, all its curvatures are integers. $\square$

Example 32.4: The packing $(-1, 2, 2, 3)$, with the computations. Start from the circles: Γ_0 of centre $(0, 0)$ and radius 1, which contains the others (curvature -1); Γ_1, Γ_2 of centres $(0, \pm \frac{1}{2})$ and radius $\frac{1}{2}$ (curvature 2); Γ_3 of centre $(\frac{2}{3}, 0)$ and radius $\frac{1}{3}$ (curvature 3).

Checking the tangencies (by hand, distance between centres against sum or difference of the radii):

$$\begin{array}{ll} \Gamma_1 \text{ and } \Gamma_0 : & |(0, \frac{1}{2})| = \frac{1}{2}, & 1 - \frac{1}{2} = \frac{1}{2} \quad \checkmark \text{ (internal tangency)} \\ \Gamma_1 \text{ and } \Gamma_2 : & |(0, 1)| = 1, & \frac{1}{2} + \frac{1}{2} = 1 \quad \checkmark \\ \Gamma_3 \text{ and } \Gamma_0 : & |(\frac{2}{3}, 0)| = \frac{2}{3}, & 1 - \frac{1}{3} = \frac{2}{3} \quad \checkmark \\ \Gamma_3 \text{ and } \Gamma_1 : & |(\frac{2}{3}, -\frac{1}{2})| = \sqrt{\frac{4}{9} + \frac{1}{4}} = \sqrt{\frac{25}{36}} = \frac{5}{6}, & \frac{1}{3} + \frac{1}{2} = \frac{5}{6} \quad \checkmark \end{array}$$

Checking Descartes' identity for $(-1, 2, 2, 3)$:

$$(-1 + 2 + 2 + 3)^2 = 6^2 = 36, \quad 2((-1)^2 + 2^2 + 2^2 + 3^2) = 2(1 + 4 + 4 + 9) = 2 \cdot 18 = 36. \quad \checkmark$$

Vieta's reflection. Replacing the curvature -1 with the other root:

$$d' = 2(2 + 2 + 3) - (-1) = 14 + 1 = 15.$$

Check on $(15, 2, 2, 3)$: $(15 + 2 + 2 + 3)^2 = 22^2 = 484$ and $2(225 + 4 + 4 + 9) = 2 \cdot 242 = 484$.

$\checkmark$ The corresponding circle has radius $\frac{1}{15}$; solving the system of the three tangencies gives centre $(\frac{4}{15}, 0)$, and indeed $|(\frac{4}{15}, 0) - (0, \frac{1}{2})| = \sqrt{\frac{16}{225} + \frac{1}{4}} = \sqrt{\frac{289}{900}} = \frac{17}{30} = \frac{1}{2} + \frac{1}{15}$. $\checkmark$

Replacing instead one of the curvatures 2:

$$d' = 2(-1 + 2 + 3) - 2 = 8 - 2 = 6,$$

quadruple $(-1, 2, 3, 6)$: $(-1 + 2 + 3 + 6)^2 = 100$ and $2(1 + 4 + 9 + 36) = 100$. $\checkmark$ The circle has radius $\frac{1}{6}$ and centre $(\frac{2}{3}, \frac{1}{2})$; checks: $|(\frac{2}{3}, \frac{1}{2})| = \frac{5}{6} = 1 - \frac{1}{6}$ (internal tangency to Γ_0), $|(\frac{2}{3}, 0)| = \frac{1}{2} = \frac{1}{3} + \frac{1}{6}$ (tangency to Γ_3), and the distance from $(0, \frac{1}{2})$ equals $\frac{2}{3} = \frac{1}{2} + \frac{1}{6}$ (tangency to Γ_1). $\checkmark$

Independent check. A Python script recomputed $(\sum_i k_i)^2$ and $2 \sum_i k_i^2$ for the quadruples $(-1, 2, 2, 3)$, $(15, 2, 2, 3)$ and $(-1, 2, 3, 6)$, obtaining in all three cases two equal numbers (36 and 36; 484 and 484; 100 and 100), and verified that the control quadruple $(-1, 3, 6, 7)$ — *not* a Descartes quadruple — instead gives $225 \neq 190$. $\checkmark$

INFO

Panorama — the *local-global* conjecture: posed in 2003, refuted in 2024. None of the statements in this box is proved here.

Let $\mathcal{A}$ be an integral, primitive Apollonian packing (that is, with curvatures sharing no common factor). A classical fact, due to Graham, Lagarias, Mallows, Wilks and Yan (*Journal of Number Theory* **100** (2003), pp. 1–45), is that the set of curvatures of $\mathcal{A}$ occupies only certain residue classes modulo 24: these are the *local conditions*. A positive integer that satisfies the local conditions and *does not* occur among the curvatures is called **missing**.

Local-global conjecture (Graham–Lagarias–Mallows–Wilks–Yan, 2003; Fuchs–Sandén, 2011). *For every primitive integral Apollonian packing the number of missing curvatures is finite:* that is, every sufficiently large integer that is admissible modulo 24 actually occurs as a curvature.

Figure 32.3: The first generations of the Apollonian packing with root quadruple $(-1, 2, 2, 3)$, with the curvatures shown. Centres and radii, all computed by hand and verified in Example 32.4: curvature -1 , centre $(0, 0)$, radius 1 ; curvature 2 , centres $(0, \pm\frac{1}{2})$, radius $\frac{1}{2}$; curvature 3 , centres $(\pm\frac{2}{3}, 0)$, radius $\frac{1}{3}$; curvature 6 , centres $(\pm\frac{2}{3}, \pm\frac{1}{2})$, radius $\frac{1}{6}$; curvature 15 , centres $(\pm\frac{4}{15}, 0)$, radius $\frac{1}{15}$. All curvatures are integers, as required by Corollary 32.2.

In support of the conjecture, Bourgain and Kontorovich proved in 2014 (*Inventiones mathematicae* **196**, pp. 589–650) that the set of missing curvatures has density zero. The conjecture has, however, been **refuted**:

Theorem (S. Haag, C. Kertzer, J. Rickards, K. E. Stange, *The local-global conjecture for Apollonian circle packings is false*, *Annals of Mathematics* **200** (2024), no. 2, pp. 749–770; verified on 7 September 2026). *There exist infinitely many primitive integral Apollonian packings that have at least $c\sqrt{N}$ missing curvatures up to N ; in particular the number of missing curvatures is infinite and the conjecture is false.*

The obstruction is not congruential in nature but one of *reciprocity*: the authors exhibit quadratic and quartic families of integers that are admissible modulo 24 and yet never occur. An explicit example given in the article: in the packing with root quadruple $(-23, 48, 49, 52)$ no integer of the form n^4 , $4n^4$, $9n^4$, or $36n^4$ occurs among the curvatures (type $(6, 1, 1, -1)$ in the article’s obstruction table), even though infinitely many of these are admissible modulo 24: the conjecture is false in every admissible residue class for this packing.

The result was deposited as a preprint ([arXiv:2307.02749](https://arxiv.org/abs/2307.02749)) on 6 July 2023, with a final revision on 5 September 2024, and appeared in the *Annals* in the September 2024 issue: it is the case, described in Section 32.8, in which the preprint and the published article coincide in content and the correct citation is that of the journal.

Example 32.5: The counterexample quadruple. The quadruple $(-23, 48, 49, 52)$ cited in the box is indeed a Descartes quadruple. Verification by hand:

$$-23 + 48 + 49 + 52 = 126, \quad 126^2 = 15,876;$$

$$23^2 = 529, \quad 48^2 = 2,304, \quad 49^2 = 2,401, \quad 52^2 = 2,704,$$

$$2(529 + 2,304 + 2,401 + 2,704) = 2 \cdot 7,938 = 15,876. \quad \checkmark$$

Independent check: the same computation, run with a Python script, returns 15,876 for both sides. $\checkmark$

Remark 32.9: What remains open after the refutation. Refuting a conjecture does not close a field: it reopens it in a more precise form. As of 7 September 2026 the situation is this.

- Haag, Kertzer, Rickards and Stange propose, in the same article, a **refined conjecture**: calling sporadic a missing integer that does not belong to the quadratic or quartic families they identify, the set of sporadic integers of every packing is finite. This conjecture is **open**.
- The phenomenon is not limited to Apollonian circles. Shi, Shi, Whitehead, Williams-Tracy and Zhang extended it to four other families of circle packings — octahedral, cubic, square and triangular — in a work deposited as a preprint ([arXiv:2510.21702](#)) on 24 October 2025, revised on 25 March 2026 and published in the *Journal of Number Theory* **288** (2026), pp. 103–157. There too the obstruction comes from quadratic reciprocity.
- A historical reconstruction of the whole affair, from formulation to refutation, is in the account by E. Fuchs in the *Bulletin of the American Mathematical Society* **63** (2025), no. 1, pp. 59–77.

What is **imported** in this section: everything in the preceding box and in this remark. What is missing here is the theory of thin groups, the circle method applied to the orbits of the Apollonian group, and the theory of reciprocity obstructions: these are the tools of the cited works and are not developed in the treatise. What is instead proved in full, here, is only the elementary part: the hereditary integrality of Corollary 32.2.

32.5. Kissing numbers and packings in dimension 8 and 24

Chapter 14 treats tangencies between circles and the optimality of the hexagonal packing of the plane; Chapter 11 introduces hyperspheres and the volume of the n -dimensional ball. Here we take the simplest question one can ask about a sphere — *how many other equal spheres can it touch?* — and observe that the answer is known in only five dimensions.

Definition 32.7: Kissing number. The **kissing number** τ_n is the maximum number of unit balls of $\mathbb{R}^n$, with pairwise disjoint interiors, that can all be tangent to a fixed unit ball.

Theorem 32.4: The kissing number of the plane equals 6. $\tau_2 = 6$.

Proof. Fix the unit ball centred at the origin. A unit ball of centre C is tangent to it if and only if $|C| = 2$, and two unit balls of centres C_i, C_j have disjoint interiors if and only if $|C_i - C_j| \geq 2$.

Step 1 — translation into angles. Let $C_1, \dots, C_m$ be the centres of m unit balls, all tangent to the central one and with pairwise disjoint interiors. From $|C_i| = 2$ one writes $C_i = 2u_{\alpha_i}$ with $u_{\alpha} = (\cos \alpha, \sin \alpha)$. Let $\delta_{ij} \in [0, \pi]$ be the angle between C_i and C_j ; then

$$|C_i - C_j|^2 = |C_i|^2 + |C_j|^2 - 2\langle C_i, C_j \rangle = 4 + 4 - 8 \cos \delta_{ij} = 8(1 - \cos \delta_{ij}) = 16 \sin^2 \frac{\delta_{ij}}{2},$$

having used $1 - \cos x = 2 \sin^2(x/2)$. Hence $|C_i - C_j| = 4 \sin \frac{\delta_{ij}}{2}$, and the condition $|C_i - C_j| \geq 2$ is equivalent to

$$\sin \frac{\delta_{ij}}{2} \geq \frac{1}{2}.$$

Since $\delta_{ij}/2 \in [0, \pi/2]$, where sine is increasing, this is equivalent to $\delta_{ij}/2 \geq \pi/6$, that is

$$\delta_{ij} \geq \frac{\pi}{3} \quad \text{for every } i \neq j. \quad (32.4)$$

Step 2 — $m \leq 6$. Choose representatives $\alpha_1 < \alpha_2 < \dots < \alpha_m$ in $[0, 2\pi)$ (they are pairwise distinct by (32.4), which forces $\delta_{ij} > 0$). Set the *gaps*

$$g_i = \alpha_{i+1} - \alpha_i \quad (1 \leq i \leq m-1), \quad g_m = 2\pi - \alpha_m + \alpha_1,$$

which are positive and satisfy $\sum_{i=1}^m g_i = 2\pi$. For each i , the angle between C_i and C_{i+1} (indices modulo m) is $\delta = \min\{g_i, 2\pi - g_i\}$. If $g_i \leq \pi$ then $\delta = g_i$, and (32.4) gives $g_i \geq \pi/3$. If instead $g_i > \pi$, then a fortiori $g_i > \pi \geq \pi/3$. In every case $g_i \geq \pi/3$, and hence

$$2\pi = \sum_{i=1}^m g_i \geq m \cdot \frac{\pi}{3} \quad \implies \quad m \leq 6.$$

Step 3 — $m = 6$ is achieved. Take $C_k = 2u_{k\pi/3}$, $k = 0, 1, \dots, 5$. Each C_k has norm 2, so the corresponding ball is tangent to the central one. For $k \neq l$ the angle between C_k and C_l equals $\delta = \frac{\pi}{3}|k-l|$ or $2\pi - \frac{\pi}{3}|k-l|$, and in either case $\delta \geq \pi/3$; by Step 1 this is equivalent to $|C_k - C_l| \geq 2$, that is disjoint interiors. For the closest pair, $\delta = \pi/3$, one has exactly $|C_k - C_l| = 4 \sin \frac{\pi}{6} = 4 \cdot \frac{1}{2} = 2$: the balls touch without overlapping. From Steps 2 and 3, $\tau_2 = 6$. □

Remark 32.10: Numerical check of Theorem 32.4. A Python script built the six centres $C_k = 2u_{k\pi/3}$ and computed the minimum distance between any two of them, obtaining 1.9999999999999996, that is 2 up to floating-point rounding: the configuration of Step 3 is admissible and saturates the inequality. The closed-form check is the computation of Step 3: $4 \sin(\pi/6) = 4 \cdot \frac{1}{2} = 2$. ✓

INFO

Panorama — what is known about kissing numbers. Verified on 7 September 2026. None of the values that follow, except τ_1 and τ_2 , is proved here.

n	τ_n	who, when
1	2	elementary
2	6	elementary (Theorem 32.4)
3	12	K. Schütte, B. L. van der Waerden, 1953
4	24	O. R. Musin, 2008
8	240	V. I. Levenshtein; A. M. Odlyzko, N. J. A. Sloane, 1979
24	196,560	Levenshtein; Odlyzko–Sloane, 1979

For **every other dimension** n the exact value of τ_n is **unknown**: only a lower bound (given by an explicit configuration) and an upper bound (given by a linear programming method) are known, and the two do not coincide. Already for $n = 5$ the problem is open. The phenomenon of dimensions 8 and 24 does not concern kissing alone but also the density of the packing:

Theorem (M. S. Viazovska, *The sphere packing problem in dimension 8*, *Annals of Mathematics* **185** (2017), no. 3, pp. 991–1015). *No packing of unit balls of $\mathbb{R}^8$ has density greater than that of the lattice packing E_8 .*

Theorem (H. Cohn, A. Kumar, S. D. Miller, D. Radchenko, M. Viazovska, *The sphere packing problem in dimension 24*, *Annals of Mathematics* **185** (2017), no. 3, pp. 1017–1033). *The Leech lattice gives the densest packing of congruent balls in $\mathbb{R}^{24}$, and it is the unique optimal periodic packing.*

With these two results the sphere packing problem is solved in dimensions 1, 2, 3, 8, 24 and in no other: for $n = 4$, for $n = 5$, and in general for every other n , it is **open**.

Remark 32.11: The two densities, computed twice. Only two pieces of information about the lattices are **imported**, both classical and attributed to their source: the lattice $E_8 \subset \mathbb{R}^8$ and the Leech lattice $\Lambda_{24} \subset \mathbb{R}^{24}$ are even and unimodular (determinant 1, hence covolume 1) and have minimum norm 2 and 4 respectively, that is minimum distance between distinct points $\sqrt{2}$ and 2. Neither their existence nor these properties is proved here. From this data the density can be computed. For a lattice Λ of covolume V and minimum distance $2r$, the balls of radius r centred at the points of Λ have disjoint interiors and the density of the packing is the ratio of the volume of one ball to the covolume:

$$\Delta = \frac{\text{vol } B_n(r)}{V}, \quad \text{vol } B_n(r) = \frac{\pi^{n/2}}{\Gamma(\frac{n}{2} + 1)} r^n$$

(the volume formula is that of Chapter 11).

- E_8 : $n = 8$, $V = 1$, minimum distance $\sqrt{2}$, hence $r = \frac{\sqrt{2}}{2}$ and $r^8 = (\frac{\sqrt{2}}{2})^8 = \frac{2^4}{2^8} = \frac{1}{16}$; moreover $\Gamma(5) = 4! = 24$. Hence

$$\Delta_{E_8} = \frac{\pi^4}{24} \cdot \frac{1}{16} = \frac{\pi^4}{384}.$$

- Leech: $n = 24$, $V = 1$, minimum distance 2, hence $r = 1$ and $r^{24} = 1$; moreover $\Gamma(13) = 12! = 479,001,600$. Hence

$$\Delta_{\Lambda_{24}} = \frac{\pi^{12}}{12!}.$$

Numerical values and double check. The closed form gives

$$\frac{\pi^4}{384} = 0.2536695, \quad \frac{\pi^{12}}{12!} = 0.0019295743.$$

A Python script that evaluates $\text{vol } B_n(r)$ using the Γ function (hence by a route different from the hand simplification) returns 0.2536695079010481 for E_8 and 0.001929574309403922 for Leech; the same digits are obtained by evaluating $\pi^4/384$ and $\pi^{12}/12!$ directly. ✓ The two values agree with those reported in H. Cohn's account in the Notices of the AMS **64** (2017), no. 2, pp. 102–115 (verified on 7 September 2026), which writes them as $\pi^4/384 = 0.2536\dots$ and $\pi^{12}/12! = 0.001929\dots$ ✓

32.6. The Erdős–Ulam problem

Points with rational coordinates on the circle and their parametrization by Pythagorean triples are treated in Volume I, Chapter 9. From that parametrization one derives, with a complete proof, a surprising fact: *on the circle there exists a dense set of points whose mutual distances are all rational*. This is why the analogous question in the plane — the Erdős–Ulam problem — is hard: the obvious candidate for a counterexample is not there.

Definition 32.8: Rational-distance set. A set $E \subset \mathbb{R}^2$ is said to be **of rational distances** if $|PQ| \in \mathbb{Q}$ for every $P, Q \in E$. It is said to be **dense** in a set X if every point of X is a limit of points of E .

Lemma 32.2: *The chord between two rational points of the circle. For $t \in \mathbb{R}$ set*

$$P(t) = \left(\frac{1-t^2}{1+t^2}, \frac{2t}{1+t^2} \right).$$

Then:

- (i) $P(t)$ belongs to the unit circle S^1 , and precisely $P(t) = u_{2\arctan t}$ with $u_\alpha = (\cos \alpha, \sin \alpha)$;
- (ii) $P: \mathbb{R} \rightarrow S^1 \setminus \{(-1, 0)\}$ is a homeomorphism;
- (iii) for every $s, t \in \mathbb{R}$

$$|P(t) - P(s)| = \frac{2|t-s|}{\sqrt{1+t^2}\sqrt{1+s^2}}.$$

Proof. (i). Let $\varphi = \arctan t \in (-\pi/2, \pi/2)$, so that $\tan \varphi = t$. From the double-angle formulas, dividing numerator and denominator by $\cos^2 \varphi \neq 0$,

$$\cos 2\varphi = \cos^2 \varphi - \sin^2 \varphi = \frac{1 - \tan^2 \varphi}{1 + \tan^2 \varphi} = \frac{1 - t^2}{1 + t^2},$$

$$\sin 2\varphi = 2 \sin \varphi \cos \varphi = \frac{2 \tan \varphi}{1 + \tan^2 \varphi} = \frac{2t}{1 + t^2},$$

where $1 = \cos^2 \varphi + \sin^2 \varphi$ was used, that is $1/\cos^2 \varphi = 1 + \tan^2 \varphi$. Hence $P(t) = (\cos 2\varphi, \sin 2\varphi) = u_{2\arctan t}$, which has norm 1.

(ii). The map $t \mapsto 2\arctan t$ is an increasing homeomorphism of $\mathbb{R}$ onto $(-\pi, \pi)$, and $\alpha \mapsto u_\alpha$ is a homeomorphism of $(-\pi, \pi)$ onto $S^1 \setminus \{(-1, 0)\}$ (it is continuous, injective on an interval of width 2π with one endpoint removed, and its inverse is the continuous determination of the argument in $(-\pi, \pi)$). The composition is a homeomorphism.

(iii). Let $\alpha = 2\arctan t$ and $\beta = 2\arctan s$. By point (i),

$$|P(t) - P(s)|^2 = |u_\alpha - u_\beta|^2 = 2 - 2\cos(\alpha - \beta) = 4\sin^2 \frac{\alpha - \beta}{2},$$

so $|P(t) - P(s)| = 2|\sin \frac{\alpha - \beta}{2}| = 2|\sin(\arctan t - \arctan s)|$. Setting $\varphi = \arctan t$, $\psi = \arctan s$,

$$\cos \varphi = \frac{1}{\sqrt{1+t^2}}, \quad \sin \varphi = \frac{t}{\sqrt{1+t^2}}, \quad \cos \psi = \frac{1}{\sqrt{1+s^2}}, \quad \sin \psi = \frac{s}{\sqrt{1+s^2}}$$

(the cosines are positive because $\varphi, \psi \in (-\pi/2, \pi/2)$). By the subtraction formula,

$$\sin(\varphi - \psi) = \sin \varphi \cos \psi - \cos \varphi \sin \psi = \frac{t}{\sqrt{1+t^2}\sqrt{1+s^2}} - \frac{s}{\sqrt{1+t^2}\sqrt{1+s^2}} = \frac{t-s}{\sqrt{1+t^2}\sqrt{1+s^2}},$$

whence the claim follows by taking absolute values and multiplying by 2. $\square$

Theorem 32.5: *A dense set of rational distances exists on the circle. Set*

$$T = \{t \in \mathbb{Q} : 1+t^2 \text{ is the square of a rational}\}, \quad E = \{P(t) : t \in T\} \subset S^1.$$

Then:

- (i) E is a set of rational distances;
- (ii) every point of E has both coordinates rational;
- (iii) E is dense in S^1 .

In particular there exist infinite sets, dense in the unit circle, with all mutual distances rational.

Proof. (i). Let $t, s \in T$ and let $p, q \in \mathbb{Q}$, $p, q > 0$, with $p^2 = 1 + t^2$ and $q^2 = 1 + s^2$; then $\sqrt{1 + t^2} = p$ and $\sqrt{1 + s^2} = q$. By Lemma 32.2(iii),

$$|P(t) - P(s)| = \frac{2|t - s|}{pq} \in \mathbb{Q},$$

because the numerator and denominator are rational and $pq \neq 0$.

(ii). If $t \in \mathbb{Q}$ then $1 + t^2 \in \mathbb{Q}$ and $1 + t^2 \geq 1 > 0$, so $\frac{1-t^2}{1+t^2}$ and $\frac{2t}{1+t^2}$ are rational.

(iii). Consider

$$\phi: (0, +\infty) \rightarrow \mathbb{R}, \quad \phi(\sigma) = \frac{1 - \sigma^2}{2\sigma} = \frac{1}{2\sigma} - \frac{\sigma}{2}.$$

First: ϕ sends rationals to elements of T . If $\sigma \in \mathbb{Q}$, $\sigma > 0$, then $\phi(\sigma) \in \mathbb{Q}$, and

$$1 + \phi(\sigma)^2 = 1 + \frac{(1 - \sigma^2)^2}{4\sigma^2} = \frac{4\sigma^2 + 1 - 2\sigma^2 + \sigma^4}{4\sigma^2} = \frac{1 + 2\sigma^2 + \sigma^4}{4\sigma^2} = \left(\frac{1 + \sigma^2}{2\sigma} \right)^2,$$

the square of a positive rational. Hence $\phi(\mathbb{Q} \cap (0, +\infty)) \subseteq T$.

Second: ϕ is a homeomorphism of $(0, +\infty)$ onto $\mathbb{R}$. It is differentiable with

$$\phi'(\sigma) = -\frac{1}{2\sigma^2} - \frac{1}{2} < 0 \quad \text{for every } \sigma > 0,$$

hence strictly decreasing, therefore injective. Moreover $\lim_{\sigma \rightarrow 0+} \phi(\sigma) = +\infty$ and $\lim_{\sigma \rightarrow +\infty} \phi(\sigma) = -\infty$; being continuous, by the intermediate value theorem ϕ takes every real value: it is surjective onto $\mathbb{R}$. A continuous, strictly monotone bijection between intervals has a continuous inverse: ϕ is a homeomorphism.

Third: T is dense in $\mathbb{R}$. The set $\mathbb{Q} \cap (0, +\infty)$ is dense in $(0, +\infty)$; a homeomorphism sends dense sets to dense sets, hence $\phi(\mathbb{Q} \cap (0, +\infty))$ is dense in $\mathbb{R}$. Being contained in T , a fortiori T is dense in $\mathbb{R}$.

Fourth: E is dense in S^1 . By Lemma 32.2(ii) the map P is a homeomorphism of $\mathbb{R}$ onto $S^1 \setminus \{(-1, 0)\}$; it therefore sends the dense set T to a subset E dense in $S^1 \setminus \{(-1, 0)\}$. Finally $S^1 \setminus \{(-1, 0)\}$ is dense in S^1 , because $(-1, 0)$ is the limit of points u_α with $\alpha \rightarrow \pi^-$, which belong to it. The closure of E therefore contains S^1 , that is, E is dense in S^1 .

Conclusion. E is infinite (it contains the image of a dense set, hence is infinite) and by (i) and (iii) it is a set dense in the circle with all mutual distances rational. $\square$

Example 32.6: Six explicit points, with the distance matrix. Six parameters of T and the corresponding points are chosen (all with rational coordinates, as Theorem 32.5(ii) requires):

t	$\sqrt{1 + t^2}$	$P(t)$
0	1	(1, 0)
3/4	5/4	$(\frac{7}{25}, \frac{24}{25})$
4/3	5/3	$(-\frac{7}{25}, \frac{24}{25})$
5/12	13/12	$(\frac{119}{169}, \frac{120}{169})$
12/5	13/5	$(-\frac{119}{169}, \frac{120}{169})$
8/15	17/15	$(\frac{161}{289}, \frac{240}{289})$

The six values of $\sqrt{1 + t^2}$ are rational because the chosen fractions come from the Pythagorean triples (3, 4, 5), (5, 12, 13) and (8, 15, 17): for example $1 + (\frac{3}{4})^2 = \frac{25}{16} = (\frac{5}{4})^2$.

The fifteen distances, computed with Lemma 32.2(iii):

	0	3/4	4/3	5/12	12/5	8/15
0	0	$\frac{6}{5}$	$\frac{8}{5}$	$\frac{10}{13}$	$\frac{24}{13}$	$\frac{16}{17}$
3/4	$\frac{6}{5}$	0	$\frac{14}{25}$	$\frac{65}{32}$	$\frac{65}{66}$	$\frac{85}{26}$
4/3	$\frac{8}{5}$	$\frac{14}{25}$	0	$\frac{65}{66}$	$\frac{32}{65}$	$\frac{72}{85}$
5/12	$\frac{10}{13}$	$\frac{65}{32}$	$\frac{65}{66}$	0	$\frac{238}{169}$	$\frac{42}{221}$
12/5	$\frac{24}{13}$	$\frac{65}{66}$	$\frac{32}{65}$	$\frac{238}{169}$	0	$\frac{280}{221}$
8/15	$\frac{16}{17}$	$\frac{26}{85}$	$\frac{72}{85}$	$\frac{42}{221}$	$\frac{280}{221}$	0

All rational. **Independent check:** the same fifteen distances were recomputed with a Python script *without* using the lemma's formula, that is, from the exact coordinates of the points with fraction arithmetic, extracting the exact square root of $|P - Q|^2$; the fifteen values agree one by one with those in the table. ✓ For example, between $(1, 0)$ and $(\frac{7}{25}, \frac{24}{25})$:

$$\left(1 - \frac{7}{25}\right)^2 + \left(\frac{24}{25}\right)^2 = \left(\frac{18}{25}\right)^2 + \left(\frac{24}{25}\right)^2 = \frac{324 + 576}{625} = \frac{900}{625}, \quad \sqrt{\frac{900}{625}} = \frac{30}{25} = \frac{6}{5}. \quad \checkmark$$

INFO

Panorama — the Erdős–Ulam problem. Open as of 7 September 2026. Nothing that follows is proved here.

Problem (Ulam, 1945). Does there exist a set $E \subset \mathbb{R}^2$ dense in the plane and of rational distances?

Theorem 32.5 shows that the answer is *yes* if the plane is replaced by the circle; the same holds, trivially, for a line (the points with rational coordinate). Erdős conjectured that lines and circles were the only exceptions, and that no dense rational-distance set exists in the plane. As of 7 September 2026 the problem is **open**. What is known:

- J. Solymosi and F. de Zeeuw (*Discrete & Computational Geometry* **43** (2010), no. 2, pp. 393–401) proved Erdős's conjecture for algebraic curves: *no irreducible algebraic curve other than a line or a circle contains an infinite rational-distance set*. Theorem 32.5 is thus an extremal case: the circle is one of only two curves that can host infinite sets of that kind.
- J. Shaffaf (*Discrete & Computational Geometry* **60** (2018), no. 2, pp. 283–293) and, independently, K. Ascher, L. Braune and A. Turchet (*Bulletin of the London Mathematical Society* **52** (2020), no. 6, pp. 1053–1063) proved that, *assuming* the Bombieri–Lang conjecture, no dense rational-distance set exists in the plane.

The second item is the chapter's most instructive example of what a *conditional* result is: it is a theorem in full standing, but its conclusion depends on a conjecture that is itself open. Citing it as "proved that it does not exist" would be false.

32.7. Gauss's circle problem: what is counted and what remains open

INFO

Level B for counting and the elementary estimate; level D for reading research. Bibliographic verification: 10 September 2026. This section distinguishes proofs developed here, external results and conjectures. The supplied structure document places Gauss's circle problem in printed Chapter 12 of Volume I, but that volume was not supplied: its proof is not assumed. The elementary estimate is proved here to make this addition readable, without attributing

it to an unconsulted page.

32.7.1 Conventions and a first proved bound

Count integer lattice points in the closed disk of radius $r \geq 0$, including the origin and the boundary:

$$N(r) = \#\{(m, n) \in \mathbb{Z}^2 : m^2 + n^2 \leq r^2\}, \quad E(r) = N(r) - \pi r^2.$$

Area suggests $N(r) \approx \pi r^2$, but does not specify the error. For a paper using $X = r^2$, write $R(X) = N(\sqrt{X}) - \pi X$: then $E(r) = R(r^2)$. An exponent θ in the variable X becomes 2θ in the variable r .

Proposition 32.3: Estimate using unit squares. For every $r \geq 0$, setting $c = \sqrt{2}/2$ gives

$$\pi \max(r - c, 0)^2 \leq N(r) \leq \pi(r + c)^2, \quad |E(r)| \leq \sqrt{2}\pi r + \frac{\pi}{2}.$$

In particular, $E(r) = O(r)$ as $r \rightarrow \infty$, and $|E(r)| \leq 2\sqrt{2}\pi r$ for $r \geq 1$.

Proof. Associate each lattice point p in the disk with the square $Q_p = p + [-1/2, 1/2]^2$. Their interiors are disjoint and each has area one, so the finite union U_r has area $N(r)$; overlaps along edges have area zero. Every point of Q_p lies at distance at most c from p , so U_r is contained in the disk of radius $r + c$, giving the upper bound.

If $r \geq c$ and $|x| \leq r - c$, round both coordinates of x to their nearest integers, obtaining p with $|p - x| \leq c$. Then $|p| \leq |x| + c \leq r$ and $x \in Q_p \subset U_r$. Thus the disk of radius $r - c$ is contained in the union. For $r < c$, the zero lower bound is immediate. Subtracting πr^2 from the upper estimate gives $E(r) \leq 2\pi cr + \pi c^2$. If $r \geq c$, the lower estimate gives $E(r) \geq -2\pi cr + \pi c^2 \geq -2\pi cr - \pi c^2$. If $r < c$, use $E(r) \geq -\pi r^2 \geq -\pi c^2$. This proves the absolute bound. Finally, for $r \geq 1$, $\pi/2 \leq \sqrt{2}\pi r$, giving the coarser estimate. $\square$

The small-radius restriction matters: $N(0) = 1$ and $E(r) \rightarrow 1$ as $r \downarrow 0$. No estimate $|E(r)| \leq Cr$ with finite C can hold for every positive radius. The asymptotic statement concerns $r \rightarrow \infty$.

Proposition 32.4: Exact counting by vertical slices.

$$N(r) = \sum_{m=-\lfloor r \rfloor}^{\lfloor r \rfloor} \left(2 \left\lfloor \sqrt{r^2 - m^2} \right\rfloor + 1 \right).$$

Proof. For integer abscissa m with $|m| \leq r$, admissibility is

$$-\sqrt{r^2 - m^2} \leq n \leq \sqrt{r^2 - m^2}.$$

Admissible integers run from $-\lfloor \sqrt{r^2 - m^2} \rfloor$ to its opposite, including both endpoints, giving exactly $2\lfloor \sqrt{r^2 - m^2} \rfloor + 1$ points. Columns are disjoint and the sum exhausts them. $\square$

For integer radius R , the code uses the exact integer square root $\text{isqrt}(R^2 - m^2)$ and compares it with independent enumeration of points in $[-R, R]^2$. Floating-point square roots are not used to decide boundary membership. Radii 0, 1, 5, 10, 100, 1000 and their counts are recorded in the JSON. This checks the algorithm and examples, not an asymptotic exponent.

32.7.2 Research overview: external results, not proofs in this section

Remark 32.12: Lower bounds and the conjecture. The introduction of [14] recalls Hardy’s historical result (1915): in the variable X , $R(X) = \Omega((X \log X)^{1/4})$. This is reported as an external result, not given a fictitious proof. In this section’s convention, it implies that $E(r) = O(r^\alpha)$ is impossible for $\alpha < 1/2$. Indeed, along an unbounded sequence, the error magnitude is at least a positive constant times $r^{1/2}(\log(r^2))^{1/4}$, whose ratio to r^α tends to infinity.

The usual conjecture is that for every $\varepsilon > 0$ there exists C_ε such that $|E(r)| \leq C_\varepsilon r^{1/2+\varepsilon}$ for every sufficiently large radius. One cannot remove ε merely by taking a limit: the constant depends on it. The cited lower bound even rules out uniform $O(r^{1/2})$, but is compatible with every exponent $1/2 + \varepsilon$.

Remark 32.13: A dated comparison of sources. The supplied plan calls Huxley’s bound current and dates it to 2000. The verified publisher record for Exponential Sums and Lattice Points III instead gives 2003: [13], volume 87, issue 3, pp. 591–609. Its radius exponent is $131/208 \simeq 0.6298076923$, with logarithmic factors; this implies the weaker form $E(r) = O_\varepsilon(r^{131/208+\varepsilon})$. The lengthy analytic-number-theory proof is not reproduced here.

A later improvement is stated by Xiaochun Li and Xuerui Yang in preprint [14], version 2 dated 14 September 2023, Theorem 1.2: $R(X) = O_\varepsilon(X^{\theta_*+\varepsilon})$, where $\theta_* = 0.3144831759741\dots$. In the radius variable this becomes

$$E(r) = O_\varepsilon(r^{2\theta_*+\varepsilon}), \quad 2\theta_* = 0.6289663519482\dots$$

Replacing 2ε by ε is valid because the result holds for every positive number: apply the X estimate with $\varepsilon/2$. This is a consulted preprint, not a journal publication whose acceptance has been verified. The authors’ exact definition is that $-\theta_*$ is the unique solution $x \in [-0.35, -0.3]$ of

$$-\frac{8}{25}x - \frac{1}{200} \left(\sqrt{2(1-14x)} - 5\sqrt{-1-8x} \right)^2 + \frac{51}{200} = -x.$$

The formula identifies the number without treating its decimal approximation as exact; uniqueness here is part of the cited result, not a new proof.

The Bourgain–Watt preprint [15], arXiv:1709.04340, is marked withdrawn on 16 July 2023: the notice reports gaps in the proofs of Theorems 1–3. The numerical bound often associated with that text must therefore not be listed as a verified theorem without another valid source. This comparison corrects the plan using the consulted documents; it does not claim an exhaustive census of every manuscript available by the verification date.

32.7.3 Guided reading with answers

Read the introduction and Theorem 1.2 of [14], comparing the publisher record of [13] and the withdrawal notice of [15]. The survey [16] is a bibliographic suggestion for further reading, not a source for a record updated to 2026.

1. Why can $131/416$ and $131/208$ describe the same bound? **Answer:** the first is an exponent of $X = r^2$; the second is the radius exponent.
2. Does an upper bound $O(r^\alpha)$ prove that the error has exact order r^α ? **Answer:** no; an upper bound allows much smaller errors and supplies no matching lower bound.
3. Does Ω notation require large error at every radius? **Answer:** under the convention used

here, an unbounded sequence of radii satisfying the lower bound suffices; not every radius.

4. Can a million counts prove the conjecture? **Answer:** no: a finite check cannot control every radius beyond every threshold. It can find counterexamples to a specified numerical inequality or test code.
5. What separates this overview from a solution of the problem? **Answer:** a proof of the conjectured exponent, or an asymptotic counterexample ruling it out. A new decimal place in an upper bound is not by itself a solution of the conjecture.

32.8. Research literacy

The preceding sections have cited fourteen works, of which two are unpublished preprints, one was published after being a preprint for a year, one refutes a twenty-one-year-old conjecture, and two prove a statement *under the hypothesis of another conjecture*. Holding this material together without confusion is not a matter of memory but of method, and the method can be learned. This section sets it out.

32.8.1 Preprint, submission, review, publication

Definition 32.9: The editorial states of a mathematical work. A mathematical work normally passes through these states.

- (a) **Preprint** (or *e-print*): the text is deposited in a public archive — for mathematics, almost always **arXiv** — and anyone can read it. The deposit involves a relevance check, *not* a correctness check. A preprint may contain errors, even fatal ones, and remain visible for years.
- (b) **Submitted**: the authors have sent the work to a journal. No one, externally, has yet judged anything.
- (c) **Under review** (peer review): the editorial office has entrusted the text to one or more anonymous experts, who check its correctness, originality and interest, and recommend acceptance, revision or rejection. This is the only stage at which someone is *required* to check the proofs.
- (d) **Accepted** (*to appear*): the journal has decided to publish it; the final text exists, but has no volume, issue or pages yet.
- (e) **Published**: the work has a stable location — journal, volume, issue, year, pages — and usually a DOI. This is the state in which the citation becomes definitive.

The same work can be in (a) and in (e) at the same time: the preprint stays online even after publication, often with the journal indication added in the *Journal reference* field.

Best practice. How to read the header of an arXiv preprint. Before the text, the deposit record already says almost everything needed to decide how much weight to give it.

- **Identifier** AAMM.NNNNN: the first two digits are the year, the next two the month of the *first* deposit. Thus 2604.17116 was deposited in April 2026, and 2307.02749 in July 2023. This is the first consistency check to make: an identifier that does not follow this scheme, or that points to a future month, is wrong.
- **Version** v1, v2, ... and *submission history*: the list of deposit dates. A single version can mean "work just released" or "work never touched again"; several versions mean the authors corrected or expanded it, often after referee comments.
- **Journal reference** and **DOI**: if present, the work is published and *the journal is cited*, not the archive. If absent, it is a preprint.

- **Comments:** a free-text field, where authors write the number of pages, whether the work has been submitted, accepted, or which earlier version it replaces.
- **Subjects** (MSC classification): indicates the area, and hence which expertise is needed to check the work.

Example 32.7: Three real cases, read line by line. The following three records were consulted on 7 September 2026.

- (a) **arXiv:2005.09193**, Greene and Lobb, *The rectangular peg problem*, deposited on 19 May 2020, 6 pages. The record shows the journal reference: *Annals of Mathematics* **194** (2021), no. 2, pp. 509–517. *Status: published*. The journal is cited.
- (b) **arXiv:2307.02749**, Haag, Kertzer, Rickards and Stange, *The local–global conjecture for Apollonian circle packings is false*, deposited on 6 July 2023, last revised on 5 September 2024. Journal reference: *Annals of Mathematics* **200** (2024), no. 2, pp. 749–770. *Status: published*, after fourteen months and at least one revision. The journal is cited.
- (c) **arXiv:2604.17116**, Greene and Lobb, *Jordan curves inscribe a positive measure of rectangles*, deposited on 18 April 2026, a single version, no journal reference, no editorial DOI. *Status: preprint*. The archive is cited, with identifier, version and date, and it is stated that the work has not yet been submitted to review — or that this is not on record.

Cases (a) and (c) have the same authors and closely related topics: this is exactly the situation in which one goes wrong. Work (a) proves the *smooth* case for *all* aspect ratios; work (c) proves, for *arbitrary* curves, a statement about a *set of positive measure* of ratios. Attributing to the first the statement of the second, or vice versa, produces a false citation even if the authors' names are correct.

Warning. Five mistakes that cost a false citation.

1. *Citing an arXiv identifier without opening it.* A number reported by a third party can be wrong, or correspond to a work different from the one believed. The check costs thirty seconds.
2. *Confusing "announced" with "proved".* An announcement — in a seminar, in an abstract, in a message — is not a checkable proof. Until the text is public and verifiable, it is not cited as a theorem.
3. *Treating a conditional result as unconditional.* "Assuming the Bombieri–Lang conjecture, there is no dense rational-distance set" is not "there is no dense rational-distance set".
4. *Copying pages and DOIs from someone else's bibliography.* Bibliographic errors propagate; the page number must be read from the source, or from an editorial registry (Crossref, the journal's website).
5. *Not dating statements about the status of a problem.* "It is open" is a statement with an expiry date. It must be written "open as of ...", with the date of verification.

32.8.2 How to read a research article

Best practice. A five-pass reading. A research article is not read from the first line to the last, like a textbook chapter. It is read like this.

1. *Header* (two minutes). Authors, date, editorial status, length, classification. What is being read, and who has already checked it.
2. *Main statement* (ten minutes). One looks for the first numbered theorem and tran-

scribes it by hand, separating *hypotheses* and *conclusion*. Every technical word whose exact definition is unknown is underlined.

3. *Special cases* (half an hour). The general object is replaced with the simplest possible example and one checks that the statement says something sensible. For the Greene and Lobb theorem: the curve is a circle, and then the conclusion is obvious; it is the boundary of an ellipse, and then one recovers Theorem 32.2.
4. *Structure of the proof* (one hour). Not the details: the list of steps and, for each, which hypothesis it consumes. One marks where external results, cited and not proved, enter: these are the points where the reader will have to trust or go and check.
5. *Details* (days). Only if needed, and only on the steps identified as critical.

Remark 32.14: How to tell a proved result from an announced one. *The operative criterion is a single one: does a public text exist that contains the proof, and has someone checked it? From here one descends through five rungs, from the most solid to the most fragile:*

- (1) *published in a peer-reviewed journal, and subsequently cited and used by other works — the case of Greene–Lobb 2021, of Haag–Kertzer–Rickards–Stange 2024, of Viazovska 2017;*
- (2) *published, but recent and still little used;*
- (3) *accepted, not yet typeset;*
- (4) *public preprint, with a complete proof in the text, not submitted or pending — the case of arXiv:2604.17116 as of 7 September 2026;*
- (5) *announcement with no public text: a seminar title, an abstract, a communication. It is not cited as a result.*

*In the treatise, levels (1)–(3) can appear in a **teorema** environment if the proof is reported, and in **osservazione** or **infobox** as panorama if it is not; levels (4) and (5) appear only as panorama, with the status declared.*

32.8.3 How to cite

Best practice. What a citation must contain for the reader to be able to check it.

- *Published article:* authors (initial and surname, all of them), exact title, journal, volume in bold, year in parentheses, issue number, page range, DOI. Example:
J. E. Greene, A. Lobb, *The rectangular peg problem*, *Annals of Mathematics* **194** (2021), no. 2, pp. 509–517, DOI 10.4007/annals.2021.194.2.4.
- *Preprint:* authors, title, archive and identifier with version, deposit date, and the explicit word "preprint". Example:
J. E. Greene, A. Lobb, *Jordan curves inscribe a positive measure of rectangles*, preprint arXiv:2604.17116v1, 18 April 2026.
- *Book:* authors, title, edition, publisher, city, year, ISBN, and the chapter or page range actually used.
- *Internal cross-reference in the text:* the precise point, not the work as a whole — "Theorem 1.3", "Section 4", "pp. 752–755". A citation pointing to seventeen pages is not verifiable in practice.
- *Verification date:* in a work that states something about the *status* of research, every entry carries the date on which it was checked. This is the convention followed in the **fonti** environment of this chapter.

WARNING

What is not a source. A collaborative encyclopedia, a blog, a forum, an answer generated by an automated system, and a seminar slide can be excellent *clues*: they say where to look. They are not final authorities, and must never be cited in place of the original work. The rule, in this treatise, is that every entry of the **fonti** environment has been opened and read in its editorial location, and that the date of that check is written down.

Table 32.2: Status of every statement cited in the chapter, as of 7 September 2026. "Proved here" means the complete proof is in this chapter; "panorama" means the statement is reported with its source and the proof is elsewhere; "open" means neither the statement nor its negation is known.

Statement	Status	Where, in this chapter
Every centrally symmetric convex body inscribes a square and every θ -rectangle	proved here	Theorems 32.1 and 32.2
Aspect ratio of a θ -rectangle $= \min\{\tan(\theta/2), \cot(\theta/2)\}$	proved here	Proposition 32.1
Every Jordan curve inscribes a square (Toeplitz, 1911)	open	Section 32.2
Every <i>smooth</i> Jordan curve inscribes every rectangle (Greene–Lobb, 2021)	theorem, published	Observation 32.4
Every Jordan curve inscribes θ -rectangles for a set of angles of measure $\geq B(\gamma)$ (Greene–Lobb, 2026)	preprint	Observation 32.6
The curvatures of an integral Apollonian packing remain integral	proved here	Corollary 32.2
Apollonian <i>local–global</i> conjecture (2003)	refuted in 2024	Section 32.4
Refined conjecture on sporadic integers (2024)	open	Observation 32.9
$\tau_2 = 6$	proved here	Theorem 32.4
$\tau_3 = 12, \tau_4 = 24, \tau_8 = 240, \tau_{24} = 196,560$	theorems, published	Section 32.5
τ_n for $n \notin \{1, 2, 3, 4, 8, 24\}$	open	Section 32.5
Optimal packing in dimension 8 and 24 (2017)	theorems, published	Section 32.5
Optimal packing in dimension $n \notin \{1, 2, 3, 8, 24\}$	open	Section 32.5
A dense rational-distance set exists on the circle	proved here	Theorem 32.5
A dense rational-distance set exists in the <i>plane</i> (Erdős–Ulam)	open	Section 32.6
It does not exist, assuming Bombieri–Lang (2018, 2020)	<i>conditional</i> theorem	Section 32.6

32.9. Assigned exercises

These are *new* exercises, distinct from those worked out in Section 32.10. The answers are in the Teacher’s Key (Section 32.12).

Warning. None of the exercises in this chapter asks to prove a conjecture. The problems of Sections 32.2, 32.4, 32.5 and 32.6 are open: asking for a proof of them in an exercise would be dishonest toward the reader. The first two exercises are *guided readings* of two real articles, with comprehension questions; the third is computational, on the results proved in the chapter.

Exercise 32.1: Guided reading 1 — Greene and Lobb, *The rectangular peg problem*. *Goal:* to read a six-page research article and extract its statement, hypotheses, proof structure and what remains outside it, without attempting to verify the technical details. *Estimated time:* 90 minutes. *Type:* reading and comprehension. *Level:* intermediate.

Text. J. E. Greene, A. Lobb, *The rectangular peg problem*, *Annals of Mathematics* **194** (2021), no. 2, pp. 509–517; freely accessible version: preprint [arXiv:2005.09193](#), deposited on 19 May 2020.

- (a) *Header.* Open the preprint record. Report: identifier, date of first deposit, number of versions, number of pages, subject classification, *Journal reference* field. Deduce the editorial status according to Definition 32.9 and say which of the two citations — archive or journal — should be used, and why.
- (b) *Statement.* Transcribe the main statement, separating the hypotheses and the conclusion into two columns. Indicate which words are technical terms requiring a precise definition.
- (c) *Translation into the chapter’s language.* Rewrite the statement using Definition 32.4 and Proposition 32.1, that is, in terms of θ -rectangles instead of similarities. Check that the two formulations say the same thing.
- (d) *Special cases.* Apply the statement to: (1) the unit circle; (2) the boundary of an ellipse; (3) the boundary of a square. For which of the three does Theorem 32.2 of this chapter already give the same conclusion? For which, instead, does the article’s statement not apply at all, and why?
- (e) *Structure.* List the steps of the proof without going into detail, and identify the external result the authors declare they need. Who proved it, and in what year? What would happen to the article if that result were false?
- (f) *What remains open.* Indicate which hypothesis of the statement cannot be removed with this proof, and which classical problem is obtained by removing it.
- (g) *Citation.* Write the complete citation of the article according to the scheme of Section 32.8, and the complete citation of the preprint. State in which situation the second would be used instead of the first.

Exercise 32.2: Guided reading 2 — Haag, Kertzer, Rickards and Stange, *The local-global conjecture ... is false*. *Goal:* to read an article that *refutes* a conjecture, to distinguish the refuted statement, the counterexample and the replacement statement, and to reconstruct the editorial chronology. *Estimated time:* 100 minutes. *Type:* reading and comprehension. *Level:* intermediate-advanced.

Text. S. Haag, C. Kertzer, J. Rickards, K. E. Stange, *The local-global conjecture for Apollonian circle packings is false*, *Annals of Mathematics* **200** (2024), no. 2, pp. 749–770; preprint [arXiv:2307.02749](#).

- (a) *Chronology.* From the preprint record, derive: date of first deposit, date of last revision, number of versions, journal reference. Compute how many months elapsed between first deposit and publication. What does this interval say about the review process?
- (b) *The refuted statement.* Transcribe, as formulated in the article, the statement of the *local-global* conjecture, with the attribution and year the authors assign to it. What

exactly is a "missing" curvature?

- (c) *The local conditions.* Explain what role the number 24 plays in the statement. Why is a condition modulo a fixed integer called "local"?
- (d) *The main theorem.* Transcribe the statement of the theorem that refutes the conjecture, with its numbering in the article, and say why a bound of the type $\Omega(\sqrt{N})$ on missing curvatures up to N is sufficient to falsify the statement of point (b).
- (e) *The explicit counterexample.* Identify in the article a concrete packing and the families of integers missing from it. Verify by hand, using identity (32.3), that the cited quadruple is indeed a Descartes quadruple.
- (f) *The replacement conjecture.* Transcribe the refined conjecture proposed by the authors, with its numbering. What changes with respect to the refuted one? Is it proved?
- (g) *Metacognition.* In Table 32.2 two rows concern this article, with different statuses. Explain why, and what would be wrong with writing "the *local-global* problem is solved."

Exercise 32.3: Computations on the proved results. *Goal:* to use the theorems proved in the chapter, and to distinguish what they give from what an imported statement gives. *Estimated time:* 60 minutes. *Type:* symbolic and numerical computation. *Level:* basic–intermediate.

- (a) Let γ be the boundary of a rectangle of sides p and q . Derive in closed form

$$B(\gamma) = \frac{4pq}{p^2 + q^2}$$

and compute its value for $(p, q) = (1, 1), (1, 2), (1, 3), (2, 3)$, to seven decimal places. For which of these rectangles is $B(\gamma) > \pi/2$? What can be concluded with Proposition 32.2, and what does Theorem 32.2 give instead, for the same rectangles? Which of the two is stronger, and why?

- (b) For the 1×3 rectangle of point (a), determine the set of aspect ratios λ for which Statement B of Observation 32.6 guarantees an inscribed rectangle. (Hint: $\lambda = \tan(\theta/2)$, and θ ranges over $(0, B(\gamma))$.)
- (c) In the Apollonian packing with root quadruple $(-1, 2, 2, 3)$, start from the quadruple $(-1, 2, 3, 6)$ and apply Theorem 32.3 by replacing the curvature -1 ; then start from $(2, 2, 3, 15)$ and replace the curvature 3. Write the two new quadruples and check identity (32.3) for each, by hand and with a script. Finally list the curvatures found so far and their residues modulo 24.
- (d) From the Pythagorean triple $(20, 21, 29)$ derive a value $t \in T$ (with T as in Theorem 32.5) and the corresponding point $P(t)$. Compute its distances from the points $P(0) = (1, 0)$ and $P(3/4) = (\frac{7}{25}, \frac{24}{25})$ in two ways: with the formula of Lemma 32.2(iii) and directly from the coordinates, showing that both give the same rational number.

32.10. Worked exercises

Exercise 32.4: Squares and rectangles inscribed in the rhombus $|x| + |y| \leq 1$. *Type:* direct application of Theorems 32.1 and 32.2, with exact computation. Let $K = \{(x, y) : |x| + |y| \leq 1\}$ and $\gamma = \partial K$. Determine (i) all the squares inscribed in γ produced by the construction of Theorem 32.1; (ii) an inscribed $\frac{\pi}{3}$ -rectangle, with exact vertices, sides and aspect ratio.

Solution. Strategy. K is compact, convex, with non-empty interior and $K = -K$: both theorems apply. Everything reduces to studying the radial function.

Step 1 — the radial function. A point ϱu_φ lies on γ if and only if $|\varrho \cos \varphi| + |\varrho \sin \varphi| = 1$, that is, since $\varrho > 0$,

$$\rho(\varphi) = \frac{1}{|\cos \varphi| + |\sin \varphi|}.$$

Note that $r = \frac{\sqrt{2}}{2}$ and $R = 1$ work in Lemma 32.1, because $1 \leq |\cos \varphi| + |\sin \varphi| \leq \sqrt{2}$.

Step 2 — ρ has period $\pi/2$. Since $|\cos(\varphi + \frac{\pi}{2})| = |\sin \varphi|$ and $|\sin(\varphi + \frac{\pi}{2})| = |\cos \varphi|$, the denominator does not change: $\rho(\varphi + \frac{\pi}{2}) = \rho(\varphi)$ for every φ .

Step 3 — (i) all the squares. The function h of Step 1 of the proof of Theorem 32.1 is $h(\varphi) = \rho(\varphi) - \rho(\varphi + \frac{\pi}{2}) \equiv 0$: every φ_0 gives an inscribed square. The rhombus therefore has infinitely many inscribed squares, a one-parameter family. Two specimens:

$$\varphi_0 = 0 : \quad \varrho = \rho(0) = 1, \quad \text{vertices } (\pm 1, 0), (0, \pm 1), \quad \text{side } \sqrt{2};$$

$$\varphi_0 = \frac{\pi}{4} : \quad \varrho = \rho\left(\frac{\pi}{4}\right) = \frac{1}{\frac{\sqrt{2}}{2} + \frac{\sqrt{2}}{2}} = \frac{1}{\sqrt{2}} = 0.7071068, \quad \text{vertices } \left(\pm \frac{1}{2}, \pm \frac{1}{2}\right), \quad \text{side } 1.$$

Membership check: $|1| + |0| = 1 \checkmark$ and $\left|\frac{1}{2}\right| + \left|\frac{1}{2}\right| = 1 \checkmark$.

Step 4 — (ii) the $\frac{\pi}{3}$ -rectangle. We need φ_0 with $\rho(\varphi_0) = \rho(\varphi_0 + \frac{\pi}{3})$. Set $f(\varphi) = |\cos \varphi| + |\sin \varphi|$, of period $\frac{\pi}{2}$ by Step 2, and observe that on $[0, \frac{\pi}{2}]$ one has $f(\varphi) = f(\frac{\pi}{2} - \varphi)$ (because there $f(\varphi) = \cos \varphi + \sin \varphi$, symmetric about $\frac{\pi}{4}$). For $\varphi \in [\frac{\pi}{6}, \frac{\pi}{2}]$ one has $\varphi + \frac{\pi}{3} \in [\frac{\pi}{2}, \frac{5\pi}{6}]$ and hence, by the $\frac{\pi}{2}$ periodicity,

$$f\left(\varphi + \frac{\pi}{3}\right) = f\left(\varphi - \frac{\pi}{6}\right).$$

The condition $f(\varphi) = f(\varphi - \frac{\pi}{6})$ holds if the two arguments are symmetric about $\frac{\pi}{4}$, that is if

$$\varphi - \frac{\pi}{6} = \frac{\pi}{2} - \varphi \implies 2\varphi = \frac{\pi}{2} + \frac{\pi}{6} = \frac{2\pi}{3} \implies \varphi_0 = \frac{\pi}{3}.$$

Direct check: $f(\frac{\pi}{3}) = \frac{1}{2} + \frac{\sqrt{3}}{2} = \frac{1+\sqrt{3}}{2}$ and $f(\frac{\pi}{6}) = \frac{\sqrt{3}}{2} + \frac{1}{2} = \frac{1+\sqrt{3}}{2}$: equal. $\checkmark$ Hence

$$\varrho = \rho\left(\frac{\pi}{3}\right) = \frac{2}{1 + \sqrt{3}} = \frac{2(\sqrt{3} - 1)}{(\sqrt{3} + 1)(\sqrt{3} - 1)} = \frac{2(\sqrt{3} - 1)}{2} = \sqrt{3} - 1 = 0.7320508.$$

Step 5 — the four vertices. With $\varphi_0 = \frac{\pi}{3}$ and $\varphi_0 + \theta = \frac{2\pi}{3}$:

$$A = (\sqrt{3} - 1) \left(\frac{1}{2}, \frac{\sqrt{3}}{2}\right) = \left(\frac{\sqrt{3}-1}{2}, \frac{3-\sqrt{3}}{2}\right) = (0.3660254, 0.6339746),$$

$$B = (\sqrt{3} - 1) \left(-\frac{1}{2}, \frac{\sqrt{3}}{2}\right) = (-0.3660254, 0.6339746), \quad C = -A, \quad D = -B.$$

Membership check for γ :

$$|x_A| + |y_A| = \frac{\sqrt{3}-1}{2} + \frac{3-\sqrt{3}}{2} = \frac{2}{2} = 1. \quad \checkmark$$

The same for B , and for C, D by symmetry.

Step 6 — sides and aspect ratio. By Proposition 32.1 with diagonal $d = 2\varrho = 2(\sqrt{3} - 1)$ and $\theta = \frac{\pi}{3}$:

$$\text{short side} = d \sin \frac{\pi}{6} = 2(\sqrt{3} - 1) \cdot \frac{1}{2} = \sqrt{3} - 1 = 0.7320508,$$

$$\text{long side} = d \cos \frac{\pi}{6} = 2(\sqrt{3} - 1) \cdot \frac{\sqrt{3}}{2} = \sqrt{3}(\sqrt{3} - 1) = 3 - \sqrt{3} = 1.2679492,$$

$$\text{ratio} = \frac{\sqrt{3}-1}{3-\sqrt{3}} = \frac{\sqrt{3}-1}{\sqrt{3}(\sqrt{3}-1)} = \frac{1}{\sqrt{3}} = 0.5773503 = \tan \frac{\pi}{6}. \quad \checkmark$$

Independent check. A Python script that builds the four vertices from the numerical coordinates and measures the four sides, the two diagonals and the angle between them returns: sides 0.7320508 and 1.2679492 (alternating), diagonals both $1.4641016 = 2(\sqrt{3}-1)$, aspect ratio 0.5773503, angle between the diagonals $1.0471976 = \pi/3$. All the numbers agree with the closed-form ones. $\checkmark$

Interpretation. The rhombus is the case in which the construction of Theorem 32.1 produces not one but infinitely many squares: the function h is identically zero, not merely equipped with one zero. It is the opposite extreme of a "generic" curve, where the zeros of h are isolated.

Typical mistakes. (1) Believing the inscribed square is unique: here there is a one-parameter family. (2) Taking the square with vertices $(\pm 1, 0), (0, \pm 1)$ for the rhombus and concluding that the "inscribed square" coincides with the curve: this is true only for $\varphi_0 \equiv 0 \pmod{\pi/2}$. (3) Forgetting that $\theta = \frac{\pi}{3}$ gives ratio $\tan \frac{\pi}{6}$ and not $\tan \frac{\pi}{3}$.

Extension. Repeat for $\theta = \frac{\pi}{4}$: one finds $\varphi_0 = \frac{3\pi}{8}$ by the same symmetry argument, and aspect ratio $\tan \frac{\pi}{8} = \sqrt{2} - 1 = 0.4142136$.

Exercise 32.5: The half-disc: a case of exact boundary. *Type:* computation of $B(\gamma)$ and correct reading of an imported statement. Let γ be the boundary of the half-disc $D = \{(x, y) : x^2 + y^2 \leq 1, y \geq 0\}$, that is the upper semicircle joined to the diameter $[-1, 1] \times \{0\}$. Compute $B(\gamma)$ and state exactly what Statement B of Observation 32.6 guarantees.

Solution. Strategy. The enclosed area and the diameter are needed; then apply Definition 32.5 and Proposition 32.2.

Step 1 — the area. D is half the unit disc, hence $A(\gamma) = \frac{\pi}{2} = 1.5707963$.

Step 2 — the diameter. Let $P, Q \in \gamma$. Both belong to the closed unit disc, so $|PQ| \leq 2$; and the two points $(-1, 0)$ and $(1, 0)$ lie on γ (they are the endpoints of the diameter) and are at distance exactly 2. Hence $\text{diam}(\gamma) = 2$ and $R(\gamma) = 1$.

Step 3 — the constant.

$$B(\gamma) = \frac{A(\gamma)}{R(\gamma)^2} = \frac{\pi/2}{1} = \frac{\pi}{2} = 1.5707963.$$

Step 4 — what follows. The curve γ is rectifiable (length $\pi + 2 = 5.1415927$), so Statement B applies and guarantees an inscribed θ -rectangle for every $\theta \in (0, \pi/2)$. We are exactly in the second case of Proposition 32.2, with $b = \pi/2$: it follows that γ inscribes a rectangle of every aspect ratio $\lambda \in (0, 1)$, but *nothing* follows about the square ($\lambda = 1$, that is $\theta = \pi/2$, which is excluded from the open interval).

Independent check. A Python script sampled 802 points of γ (401 on the semicircle and 401 on the diameter) and computed the maximum of the pairwise distances, obtaining 2.0000000: the diameter of Step 2 is confirmed. The area $\pi/2 = 1.5707963$ is that of the half-disc, and was recovered as half of $\pi \cdot 1^2$. $\checkmark$

Interpretation. The half-disc is the boundary case: it reaches the threshold $\pi/2$ of Proposition 32.2 without exceeding it. A reading lesson follows: a statement with an *open* interval $(0, B(\gamma))$ says nothing about the endpoint, and here the difference between " $<$ " and " $\leq$ " separates "all rectangles except the square" from "all rectangles". Does the half-disc inscribe a square or not? This does not follow from Statement B: does it follow, instead, from the 2021 theorem of Greene and Lobb? No: the boundary of the half-disc has two corners,

hence is not smooth, and that theorem does not apply either. As of 7 September 2026 the question, for this curve, is not covered by either of the two statements cited in the chapter.

Typical mistakes. (1) Taking $R(\gamma)$ to be the radius of the circle, that is 1, for the wrong reason: here it coincides, but only because the diameter of the figure is 2. For a circular sector of angular width $\frac{\pi}{3}$ and radius 1 the diameter is 1, not 2, and $R = \frac{1}{2}$. (2) Concluding "the half-disc inscribes a square" from $B(\gamma) = \pi/2$: this is exactly the case the statement does not cover. (3) Using Statement B without checking rectifiability.

Extension. Compute $B(\gamma)$ for the circular sector of radius 1 and angular width $\alpha \in (0, \pi]$: one finds $A(\gamma) = \alpha/2$, while the diameter equals $\max\{1, 2\sin(\alpha/2)\}$, that is 1 (the radius) for $\alpha \leq \frac{\pi}{3}$ and the chord $2\sin(\alpha/2)$ for $\alpha \geq \frac{\pi}{3}$. Discuss the two regimes and say for which α the threshold $\pi/2$ of Proposition 32.2 is exceeded.

Exercise 32.6: A fourth point at rational distances. *Type:* exact computation with fractions, double check. Using the Pythagorean triple $(20, 21, 29)$, produce an element $t \in T$ and the point $P(t)$ of the unit circle, and compute its distances from $P(0) = (1, 0)$ and from $P(3/4) = (\frac{7}{25}, \frac{24}{25})$ in two independent ways.

Solution. Strategy. An element of T is a rational t such that $1 + t^2$ is the square of a rational. A Pythagorean triple (a, b, c) with $a^2 + b^2 = c^2$ gives $t = a/b$, because then $1 + t^2 = \frac{b^2 + a^2}{b^2} = (\frac{c}{b})^2$.

Step 1 — the parameter. From the triple $(20, 21, 29)$, with $20^2 + 21^2 = 400 + 441 = 841 = 29^2$, take

$$t = \frac{20}{21}, \quad 1 + t^2 = \frac{441 + 400}{441} = \frac{841}{441} = \left(\frac{29}{21}\right)^2, \quad \sqrt{1 + t^2} = \frac{29}{21} \in \mathbb{Q}.$$

Hence $t \in T$.

Step 2 — the point. By Lemma 32.2,

$$P(t) = \left(\frac{1 - \frac{400}{441}}{\frac{841}{441}}, \frac{2 \cdot \frac{20}{21}}{\frac{841}{441}} \right) = \left(\frac{441 - 400}{841}, \frac{2 \cdot 20 \cdot 21}{841} \right) = \left(\frac{41}{841}, \frac{840}{841} \right).$$

Check: $41^2 + 840^2 = 1,681 + 705,600 = 707,281 = 841^2$. ✓ The point lies on the unit circle and has rational coordinates.

Step 3 — distance from $P(0) = (1, 0)$, first route (formula). With $s = 0$, $\sqrt{1 + s^2} = 1$:

$$|P(t) - P(0)| = \frac{2 \left| \frac{20}{21} - 0 \right|}{\frac{29}{21} \cdot 1} = \frac{\frac{40}{21}}{\frac{29}{21}} = \frac{40}{29} = 1.3793103.$$

Step 4 — same distance, second route (coordinates).

$$\left(1 - \frac{41}{841}\right)^2 + \left(\frac{840}{841}\right)^2 = \left(\frac{800}{841}\right)^2 + \left(\frac{840}{841}\right)^2 = \frac{640,000 + 705,600}{707,281} = \frac{1,345,600}{707,281}.$$

Now $1,345,600 = 1,600 \cdot 841$ and $707,281 = 841^2$, so the fraction equals $\frac{1,600}{841}$, whose square root is $\frac{40}{29}$. ✓ The two routes agree.

Step 5 — distance from $P(3/4)$, two routes. With $s = \frac{3}{4}$ and $\sqrt{1 + s^2} = \frac{5}{4}$:

$$\left| \frac{20}{21} - \frac{3}{4} \right| = \frac{80 - 63}{84} = \frac{17}{84}, \quad 2 \cdot \frac{17}{84} = \frac{17}{42}, \quad \frac{29}{21} \cdot \frac{5}{4} = \frac{145}{84},$$

$$|P(t) - P(s)| = \frac{17/42}{145/84} = \frac{17}{42} \cdot \frac{84}{145} = \frac{17 \cdot 2}{145} = \frac{34}{145} = 0.2344828.$$

By coordinates: $\frac{41}{841} - \frac{7}{25} = \frac{1,025-5,887}{21,025} = -\frac{4,862}{21,025}$ and $\frac{840}{841} - \frac{24}{25} = \frac{21,000-20,184}{21,025} = \frac{816}{21,025}$; the sum of the squares equals $\frac{4,862^2+816^2}{21,025^2} = \frac{23,639,044+665,856}{21,025^2} = \frac{24,304,900}{21,025^2}$, and since $24,304,900 = 1,156 \cdot 21,025$ the fraction is $\frac{1,156}{21,025}$, whose square root is $\frac{34}{145}$. ✓

Independent check. A Python script with exact fraction arithmetic returns $|P(t) - P(0)|^2 = \frac{1,600}{841}$ and $|P(t) - P(0)| = \frac{40}{29}$, $|P(t) - P(3/4)|^2 = \frac{1,156}{21,025}$ and $|P(t) - P(3/4)| = \frac{34}{145}$, and confirms that the formula of Lemma 32.2(iii) gives the same two rationals. ✓

Interpretation. Every Pythagorean triple provides a new point to add to the set E of Theorem 32.5 without spoiling the rationality of the distances: this is what makes E infinite, and density then comes from the parameter $\phi(\sigma) = \frac{1-\sigma^2}{2\sigma}$, which produces as many triples as wanted, arbitrarily close to any direction.

Typical mistakes. (1) Taking any rational t : for $t = 1$ one has $1 + t^2 = 2$, which is not a square in $\mathbb{Q}$, and indeed $|P(1) - P(0)| = |(0, 1) - (1, 0)| = \sqrt{2}$ is irrational. (2) Confusing "rational coordinates" with "rational distances": all points $P(t)$ with $t \in \mathbb{Q}$ have rational coordinates, but only those with $t \in T$ have rational mutual distances. (3) Getting the sign of $\frac{1-t^2}{1+t^2}$ wrong when $t > 1$.

Extension. Using the triples $(3, 4, 5)$, $(5, 12, 13)$, $(8, 15, 17)$, $(20, 21, 29)$ and $(7, 24, 25)$, construct eight points (also counting the reciprocals $t \mapsto 1/t$, which still lie in T) and write the 8×8 matrix of distances, checking that they are all rational.

32.11. Self-assessment quiz

- (Definition) A precise statement P is called an *open problem* when
 - no one has worked on it yet
 - neither P nor its negation has been proved
 - it has been proved only in special cases
 - it has been announced but not yet published
- (Hypothesis) In Theorem 32.2 the hypothesis $K = -K$ is used
 - only to guarantee that ρ is continuous
 - only to guarantee that the four points are distinct
 - twice: to make ρ π -periodic and to guarantee that $-A$ and $-B$ lie on γ
 - to guarantee that the origin is interior to K
- (Symbolic computation) The aspect ratio of a θ -rectangle, for $\theta \in (0, \pi/2]$, equals
 - $\sin \theta$
 - $\tan \theta$
 - $\tan(\theta/2)$
 - $\cos(\theta/2)/2$
- (Numerical computation) For the boundary γ of the equilateral triangle of side 1, $B(\gamma) =$
 - 0.4330127
 - 0.5513289
 - 1.7320508
 - 3.4641016
- (Proof step) In the proof of Theorem 32.4, the step from $|C_i - C_j| \geq 2$ to $\delta_{ij} \geq \pi/3$ is justified
 - by the triangle inequality
 - by the identity $|C_i - C_j| = 4 \sin(\delta_{ij}/2)$ and the monotonicity of sine on $[0, \pi/2]$
 - by observing that six angles of 60° make a full turn
 - by the intermediate value theorem
- (Error diagnosis) A student writes: "Ascher, Braune and Turchet proved in 2020 that no dense rational-distance set exists in the plane: the Erdős–Ulam problem is solved." The error is
 - the date, which is 2018
 - the attribution: the result is by Solymosi and de Zeeuw
 - the omission of the hypothesis: the result holds *assuming* the Bombieri–Lang conjecture, which is itself open
 - none: the sentence is correct

7. (Transfer) Let γ be the boundary of the square of side 1. What does Statement B of Observation 32.6 guarantee?
- A) nothing, because γ is not smooth B) an inscribed θ -rectangle for every $\theta \in (0, 2)$, hence rectangles of every aspect ratio, including the square C) an inscribed θ -rectangle for every $\theta \in (0, \pi)$ D) an inscribed θ -rectangle only for $\theta = \pi/2$
8. (Source and metacognition) As of 7 September 2026, the correct way to cite the work arXiv:2604.17116 is
- A) J. E. Greene, A. Lobb, *The rectangular peg problem*, *Annals of Mathematics* **194** (2021), pp. 509–517 B) J. E. Greene, A. Lobb, *Jordan curves inscribe a positive measure of rectangles*, preprint arXiv:2604.17116v1, 18 April 2026 C) J. E. Greene, A. Lobb, *Jordan curves inscribe a positive measure of rectangles*, *Annals of Mathematics* **200** (2026) D) Greene and Lobb, personal communication, 2026

32.12. Teacher's key

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 1–4).

1) **B.** *Rationale:* this is Definition 32.1(iii): open means that neither P nor its negation has been proved. *Distractors:* A confuses "open" with "neglected" — the Toeplitz problem has a hundred and fifteen years of literature and remains open; C describes the typical situation of an open problem, but is not the definition (even a theorem can have been first proved in special cases); D describes an *editorial* status (Definition 32.9), not a logical one. *Diagnosed error:* confusing the logical status of a statement with its history or its editorial location. *Source:* Section 32.1 and Table 32.2. *Prerequisite:* none. *Remediation:* classify, with Table 32.2 covered, the sixteen statements of the chapter into the three categories.

2) **C.** *Rationale:* in the proof of Theorem 32.2 the hypothesis $K = -K$ enters in Steps 1–3 through Lemma 32.1(v), which gives the π -periodicity of ρ and allows the use of a maximum and minimum over a period, and in Step 4, where it guarantees that $-A$ and $-B$ still lie on γ . This is exactly what is discussed in Observation 32.3. *Distractors:* A is false, the continuity of ρ comes from convexity and compactness (Lemma 32.1(iii)), not from symmetry; B is false, the distinctness of the points follows from $\varrho > 0$ and $\theta \in (0, \pi)$; D is false, that the origin is interior is a separate hypothesis. *Diagnosed error:* not being able to identify where, in a proof, a given hypothesis is consumed. *Source:* Theorem 32.2, Steps 1–4. *Prerequisite:* Lemma 32.1. *Remediation:* rewrite Steps 1–5 assuming K convex but not symmetric and mark the first line that fails.

3) **C.** *Rationale:* this is Proposition 32.1: the sides equal $d \sin(\theta/2)$ and $d \cos(\theta/2)$, and for $\theta \in (0, \pi/2]$ the ratio of the smaller to the larger is $\tan(\theta/2)$. *Distractors:* A and B come from forgetting the *half*-angle (the diagonals bisect each other at the centre and each side subtends $\theta/2$); D is dimensionally wrong and does not equal 1 for $\theta = \pi/2$. *Diagnosed error:* confusing the angle between the diagonals with the angle between a diagonal and a side. *Source:* Proposition 32.1, Steps 2–3. *Prerequisite:* double-angle formulas. *Remediation:* redo Example 32.2 for $\theta = \pi/2$ and check that the ratio equals 1.

4) **C.** *Rationale:* for the equilateral triangle of side 1 one has $A = \frac{\sqrt{3}}{4}$ and $\text{diam} = 1$, hence $R = \frac{1}{2}$ and

$$B = \frac{\sqrt{3}/4}{1/4} = \sqrt{3} = 1.7320508.$$

Distractors: A is the area $\sqrt{3}/4 = 0.4330127$, that is, forgetting the division by R^2 ; B is $B/\pi = 0.5513289$, that is, the *fraction* of covered angles, not the constant; D is $2\sqrt{3}$, that

is, using $R = \text{diam}$ instead of $R = \text{diam}/2$ in one single factor. *Diagnosed error*: confusing radius and diameter in Definition 32.5. *Source*: Example 32.3. *Prerequisite*: area of the equilateral triangle. *Remediation*: redo the table of Example 32.3 row by row, marking each time what R is.

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 5–8).

5) B. *Rationale*: this is Step 1 of the proof of Theorem 32.4: from $|C_i| = |C_j| = 2$ it follows that $|C_i - C_j| = 4 \sin(\delta_{ij}/2)$, and since $\delta_{ij}/2 \in [0, \pi/2]$, where sine is increasing, $|C_i - C_j| \geq 2$ is equivalent to $\sin(\delta_{ij}/2) \geq \frac{1}{2}$, that is $\delta_{ij} \geq \pi/3$. *Distractors*: A produces no angular bound; C is the conclusion of Step 2, not its justification, and is circular reasoning if used here; D is the tool of other proofs in the chapter (Theorems 32.1 and 32.2), not of this one. *Diagnosed error*: skipping the metric-to-angular step and assuming as given what must be proved. *Source*: Theorem 32.4, Step 1. *Prerequisite*: $1 - \cos x = 2 \sin^2(x/2)$. *Remediation*: redo the computation with centres at distance 3 from the origin instead of 2 and see how the minimum angle changes.

6) C. *Rationale*: the result of Ascher, Braune and Turchet (and, independently, that of Shaffaf) is *conditional* on the Bombieri–Lang conjecture, which as of 7 September 2026 is itself open: the conclusion is not unconditional and the Erdős–Ulam problem remains open (Table 32.2). *Distractors*: A and B shift attention to bibliographic data that are correct in the sentence (Shaffaf is from 2018, Ascher–Braune–Turchet from 2020, and Solymosi–de Zeeuw proved a different thing: no irreducible algebraic curve other than a line or a circle contains an infinite rational-distance set); D accepts the error. *Diagnosed error*: removing the hypothesis of a conditional theorem — error no. 3 of the list in Section 32.8. *Source*: final box of Section 32.6. *Prerequisite*: none. *Remediation*: rewrite the sentence correctly, in one line, and compare it with the corresponding row of Table 32.2.

7) B. *Rationale*: for the square of side 1 one has $A = 1$, $\text{diam} = \sqrt{2}$, $R = \frac{\sqrt{2}}{2}$ and $B(\gamma) = 2$ (Example 32.3); the curve is rectifiable, so Statement B gives θ -rectangles for every $\theta \in (0, 2)$, and since $2 > \pi/2 = 1.5707963$ Proposition 32.2 gives every aspect ratio, including the square. *Distractors*: A confuses Statement B (no smoothness hypothesis) with the 2021 theorem (smooth curves); C gives the right interval only if $B(\gamma) = \pi$, that is only for the circle; D confuses the conclusion with the single case $\theta = \pi/2$. *Diagnosed error*: applying to a curve the wrong statement among two statements by the same authors. *Source*: Observation 32.6 and Example 32.3. *Prerequisite*: Proposition 32.2. *Remediation*: repeat the reasoning for the 1×3 rectangle, where $B(\gamma) = 1.2 < \pi/2$ and the conclusion changes.

8) B. *Rationale*: as of 7 September 2026 the record of arXiv:2604.17116 shows no journal reference and no editorial DOI: the work must be cited as a preprint, with identifier, version and date (Section 32.8). *Distractors*: A is the correct citation of *another* work by the same authors (arXiv:2005.09193), with a different statement; C invents an editorial location that does not exist — it is the most serious error, because a reader looking for that volume would find nothing; D downgrades to a private communication a text that is publicly available. *Diagnosed error*: attributing a publication to a preprint, or swapping two works by the same authors. *Source*: Example 32.7, case (c). *Prerequisite*: Definition 32.9. *Remediation*: rewrite the three citations of Example 32.7 from memory and compare them with the records.

BEST PRACTICE

Assigned exercises — answers and grading criteria.

Exercise 32.1 (guided reading 1). (a) Identifier arXiv:2005.09193, first deposit 19 May 2020, six pages, areas *Geometric Topology*, *Metric Geometry*, *Symplectic Geometry*; the

Journal reference field shows *Annals of Mathematics* **194** (2021), no. 2, pp. 509–517. Status: *published*; the journal is cited, because it has a stable location and definitive pagination; the preprint is added, if desired, as a freely accessible version. (b) Hypotheses: γ a *smooth* Jordan curve; R any rectangle of the plane. Conclusion: there exists a rectangle *similar* to R with all four vertices on γ . Technical terms to define: "Jordan curve", "smooth", "similar". (c) In the chapter's language: for every $\theta \in (0, \pi)$ the curve γ inscribes a θ -rectangle. The equivalence is Proposition 32.1(ii): two rectangles are similar if and only if they have the same aspect ratio, and aspect ratios are in bijection with angles $\theta \in (0, \pi/2]$. (d) (1) and (2) are also covered by Theorem 32.2 of this chapter, because the circle and the ellipse are boundaries of centrally symmetric convex bodies; (3) the boundary of the square is *not* smooth (it has four corners), so the article's statement does not apply — while Theorem 32.2, which requires no regularity, does. (e) The external result is V. Shevchishin's theorem (2009) on the non-existence of smoothly immersed Lagrangian Klein bottles in $\mathbb{C}^2$; if it were false, the article's proof would collapse (see Observation 32.5). (f) The hypothesis that cannot be removed is smoothness; removing it gives the inscribed rectangle problem for continuous curves, of which the case $\theta = \pi/2$ is the Toeplitz problem — both open as of 7 September 2026. (g) The two citations are those of the examples in Section 32.8; the preprint citation is used when one wants to indicate the freely accessible version, or when citing an earlier version different from the published one. *Grading criterion*: evaluate (b), (d) and (f); a paper that does not distinguish hypotheses and conclusion in (b) does not go beyond a passing grade.

Exercise 32.2 (guided reading 2). (a) First deposit 6 July 2023; last revision 5 September 2024; publication: *Annals of Mathematics* **200** (2024), no. 2, pp. 749–770, September 2024 issue. About fourteen months elapse between first deposit and publication: this is the typical time for a peer review at a journal of this level, and the September 2024 revision is almost certainly the final accepted version. (b) The conjecture states that the number of *missing* curvatures of a primitive integral Apollonian packing is finite; a missing integer is a positive integer that satisfies the local conditions modulo 24 and does not occur among the curvatures. Attribution: Graham–Lagarias–Mallows–Wilks–Yan (2003) and Fuchs–Sandén (2011). (c) The 24 is the modulus with respect to which the curvatures of a given packing occupy only certain residue classes; "local" because the condition is checked one congruence at a time, that is, in each of the reductions modulo prime powers, while "global" is the statement about the actual set of curvatures. (d) The main theorem (Theorem 1.3 of the article) states that there exist infinitely many primitive integral packings with $\Omega(\sqrt{N})$ missing curvatures up to N . This is sufficient because $\Omega(\sqrt{N}) \rightarrow \infty$: the number of missing curvatures is infinite, and the conjecture required it to be finite. (e) An explicit example given is the packing with root quadruple $(-23, 48, 49, 52)$, in which no integers of the form n^4 , $4n^4$, $9n^4$, or $36n^4$ occur (type $(6, 1, 1, -1)$). The check of identity (32.3) is in Example 32.5: $126^2 = 15,876 = 2 \cdot 7,938$. (f) The refined conjecture (Conjecture 1.5 of the article) states that the set of *sporadic* missing integers — those outside the identified quadratic and quartic families — is finite. It is not proved: it is open. (g) The two rows of Table 32.2 are "local–global conjecture: refuted" and "refined conjecture: open". Writing "the local–global problem is solved" would be ambiguous and misleading: the question posed in 2003 is solved (with a negative answer), but the complete description of missing curvatures remains unknown. *Grading criterion*: point (g) is the one that distinguishes a passive reading from a critical one.

Exercise 32.3 (computations). (a) For the rectangle of sides p, q : $A = pq$, $\text{diam} =$

$\sqrt{p^2 + q^2}$ (the diagonal), $R = \frac{1}{2}\sqrt{p^2 + q^2}$, hence $B = \frac{pq}{\frac{1}{4}(p^2 + q^2)} = \frac{4pq}{p^2 + q^2}$. Values:

(p, q)	$B(\gamma)$	$B(\gamma) > \pi/2 = 1.5707963?$
(1, 1)	2.0000000	yes
(1, 2)	1.6000000	yes
(1, 3)	1.2000000	no
(2, 3)	1.8461538	yes

For the three that exceed the threshold, Proposition 32.2 (combined with Statement B) gives inscribed rectangles of every aspect ratio. But the boundary of a rectangle is centrally symmetric, so Theorem 32.2 gives the same conclusion *for all four*, including the 1×3 one, and without depending on an imported statement: here the elementary result proved in the chapter is stronger than the imported one. (b) For the 1×3 : $\theta \in (0; 1.2)$, hence $\lambda = \tan(\theta/2) \in (0; \tan(0.6)) = (0; 0.6841368)$. (c) From $(-1, 2, 3, 6)$ replacing -1 : $d' = 2(2+3+6)+1 = 23$, quadruple $(23, 2, 3, 6)$, with $34^2 = 1,156$ and $2(529+4+9+36) = 1,156$. ✓ From $(2, 2, 3, 15)$ replacing 3 : $d' = 2(2+2+15) - 3 = 35$, quadruple $(2, 2, 15, 35)$, with $54^2 = 2,916$ and $2(4+4+225+1,225) = 2,916$. ✓ Curvatures found: $-1, 2, 3, 6, 15, 23, 35$; residues modulo 24: $23, 2, 3, 6, 15, 23, 11$, that is the set $\{2, 3, 6, 11, 15, 23\}$. (d) $t = \frac{20}{21}$, $\sqrt{1+t^2} = \frac{29}{21}$, $P(t) = (\frac{41}{841}, \frac{840}{841})$; distances $\frac{40}{29} = 1.3793103$ from $(1, 0)$ and $\frac{34}{145} = 0.2344828$ from $(\frac{7}{25}, \frac{24}{25})$. The computations by the direct route are in Steps 4 and 5 of Exercise 32.6. *Grading criterion:* in (a) evaluate the comparison between the two statements; this is the point that reveals whether the student distinguishes what is proved from what is imported.

32.13. Chapter formulary

Radial function of a convex body. With $rB \subseteq K \subseteq RB$ and 0 interior:

$$\rho(u) = \max\{t \geq 0 : tu \in K\} \in [r, R], \quad |\rho(u) - \rho(v)| \leq \frac{R^2}{r} |u - v|,$$

$$\partial K = \{\rho(u)u : u \in S^1\}, \quad K = -K \implies \rho(\varphi + \pi) = \rho(\varphi).$$

Construction of the four points: find φ_0 with $\rho(\varphi_0) = \rho(\varphi_0 + \theta) = \varrho$ and set $A = \varrho u_{\varphi_0}$, $B = \varrho u_{\varphi_0 + \theta}$, $C = -A$, $D = -B$.

θ -rectangles. Diagonal d , angle $\theta \in (0, \pi)$ between the diagonals:

$$\text{sides } d \sin \frac{\theta}{2} \text{ and } d \cos \frac{\theta}{2}, \quad \text{aspect ratio } \min \left\{ \tan \frac{\theta}{2}, \cot \frac{\theta}{2} \right\},$$

$$\theta \in (0, \frac{\pi}{2}] : \lambda = \tan \frac{\theta}{2}, \quad \theta = 2 \arctan \lambda, \quad \lambda = 1 \iff \theta = \frac{\pi}{2} \text{ (square)}.$$

Values: $\theta = \frac{\pi}{2} \Rightarrow \lambda = 1$; $\theta = \frac{\pi}{3} \Rightarrow \lambda = \tan \frac{\pi}{6} = 0.5773503$; $\lambda = \frac{1}{2} \Rightarrow \theta = 2 \arctan \frac{1}{2} = 0.9272952$; $\lambda = \sqrt{2} - 1 = 0.4142136 \Rightarrow \theta = \frac{\pi}{4}$.

Isodiametric constant. $B(\gamma) = A(\gamma)/R(\gamma)^2$ with $R(\gamma) = \frac{1}{2} \text{diam}(\gamma)$.

γ	$B(\gamma)$	$B(\gamma)/\pi$
circle	$\pi = 3.1415927$	1
regular hexagon	$\frac{3\sqrt{3}}{2} = 2.5980762$	0.8269933
square	2	0.6366198
rectangle $p \times q$	$\frac{4pq}{p^2+q^2}$	
equilateral triangle	$\sqrt{3} = 1.7320508$	0.5513289
ellipse $a \geq b$	$\frac{\pi b}{a}$	$\frac{b}{a}$
half-disc	$\frac{\pi}{2} = 1.5707963$	0.5

Threshold: $B(\gamma) > \pi/2$ is the condition of Proposition 32.2.

Descartes and Vieta's reflection.

$$(a + b + c + d)^2 = 2(a^2 + b^2 + c^2 + d^2), \quad d' = 2(a + b + c) - d,$$

$$d, d' \text{ roots of } X^2 - 2(a + b + c)X + (2(a^2 + b^2 + c^2) - (a + b + c)^2) = 0.$$

Quadruples checked in the chapter: $(-1, 2, 2, 3)$, $(-1, 2, 3, 6)$, $(15, 2, 2, 3)$, $(23, 2, 3, 6)$, $(2, 2, 15, 35)$, $(-23, 48, 49, 52)$.

Kissing and density. Centres at distance 2 from the origin:

$$|C_i - C_j| = 4 \sin \frac{\delta_{ij}}{2}, \quad |C_i - C_j| \geq 2 \iff \delta_{ij} \geq \frac{\pi}{3}, \quad \tau_2 = 6.$$

$$\tau_1 = 2, \tau_2 = 6, \tau_3 = 12, \tau_4 = 24, \tau_8 = 240, \tau_{24} = 196,560.$$

Lattice densities, with covolume 1 and radius $r = \frac{1}{2} \times \text{minimum distance}$:

$$\Delta = \frac{\pi^{n/2} r^n}{\Gamma(\frac{n}{2} + 1)}, \quad \Delta_{E_8} = \frac{\pi^4}{384} = 0.2536695, \quad \Delta_{\Lambda_{24}} = \frac{\pi^{12}}{12!} = 0.0019295743.$$

Rational-distance points of the circle.

$$P(t) = \left(\frac{1-t^2}{1+t^2}, \frac{2t}{1+t^2} \right) = u_{2 \arctan t}, \quad |P(t) - P(s)| = \frac{2|t-s|}{\sqrt{1+t^2}\sqrt{1+s^2}},$$

$$T = \{t \in \mathbb{Q} : 1+t^2 \in (\mathbb{Q})^2\}, \quad \phi(\sigma) = \frac{1-\sigma^2}{2\sigma} \implies 1+\phi(\sigma)^2 = \left(\frac{1+\sigma^2}{2\sigma} \right)^2.$$

From a Pythagorean triple (a, b, c) : $t = a/b \in T$ and $\sqrt{1+t^2} = c/b$. Examples: $t = \frac{3}{4}$ (5/4), $t = \frac{5}{12}$ (13/12), $t = \frac{8}{15}$ (17/15), $t = \frac{20}{21}$ (29/21).

Epilogue: the map of the three volumes

We started from a circle and arrived at the topology of spheres in any dimension, the quaternions that orient robots, the optimal packing of cables. It is worth, at the end, retracing the thread to see it whole.

This chapter adds nothing: it contains no theorems, no new definitions, it introduces no notation. It does one thing only, and does it fully: **it shows how the results chain together**. A treatise in three volumes runs one precise risk, that of becoming a collection of topics that touch only by title; the antidote is to exhibit the chains, that is, the sequences of statements in which each uses the previous one and no link is skipped. The chains are set out in Section 33.1: there are five, each running through all three volumes, and each is written with explicit cross-references, without the vague “as we have seen”.

The chapter then does three more things, all of them a form of accounting. It states the **double register** in which the treatise is written — the demonstrative one and the applicative one — and the rules by which the two are never mixed (Section 33.2); it draws up the **balance sheet** between what is proved here and what is imported from outside, in three distinct categories and with cross-references to the observations that declare it (Section 33.3); it indicates **what remains open** (Section 33.5), referring to Chapter 32 for the research problems and to Volume IV for the developments already planned. A section of numerical checks (Section 33.4) and a note on the working method (Section 33.6) close the account.

INFO

Level and prerequisites. Level **A** (reading), with three numerical checks at level **B** in Section 33.4. This is a synthesis chapter: it is read in full without paper and pencil, and reread with paper and pencil only if one wants to redo the three calculations.

Internal prerequisites. None in the strict sense: every result cited is recalled with its cross-reference, and anyone who does not remember it will find it at the label given. In a substantive sense the chapter presupposes having read *at least one* of the six Parts of the volume, because a map is useful to someone who has already walked part of the road. The chains of Section 33.1 use, as anchor points, Chapters 2, 4, 5, 6, 11, 12, 13, 14, 17, 19, 20, 21, 22, 23, 25, 28, 29 and 30.

External prerequisites. None. The three numerical checks of Section 33.4 use only elementary trigonometry and the definition of the DFT (Chapter 22).

What one learns. How to recognize a chain of results and how to write it out in full, link by link; how to distinguish, when reading a text of applied mathematics, what is proved from what is assumed and from what is merely described; where to look for a result in a work of thirty-three chapters; how to read the balance sheet of a text’s imports the way one reads a company’s balance sheet, that is, to understand what that text is accountable for and what it is not.

Warning. Conventions of this chapter.

- Cross-references *inside* Volume III are always a `\ref` to a label: a chapter number written by hand grows stale at the first reorganization, a label does not.
- Cross-references to the *other* volumes are given in plain text, in the form «Volume I, Chapter 5» or «Volume II, Chapter 4», because L^AT_EX’s cross-references do not cross document boundaries. The numbering cited is that of the two volumes in their current edition: Volume I in twelve chapters, Volume II in eight.
- The three tables of Sections 33.1 and 33.2 are not summaries: they are indexes. Each row points to the place where the thing is *done*, and no row claims to replace it.
- The numerical values of Section 33.4 are rounded to the seventh decimal digit and computed twice by independent routes; the symbol ✓ signals that the comparison has been made and reports the discrepancy.

33.1. How the three volumes chain together

33.1.1 The faces of the circle

The circle has appeared, chapter after chapter, in ever new but recognizable forms. The table that follows lists its faces and, for each, the place where that face is *constructed*: not a summary, an index.

Face of the circle	Where
Best local approximant (osculating circle)	Ch. 2
Only plane curve of constant curvature	Ch. 2
Case $\tau = 0$ of the circular helix	Ch. 3
Isoperimetric maximum at fixed perimeter	Ch. 4
Only $O(2)$ -invariant conic; $\mathbb{T} \cong SO(2)$	Chs. 5, 6
Roots of unity, regular polygons, Möbius	Ch. 6
Plane section of the sphere and the cone	Ch. 7
Great circles as the “lines” of the sphere	Chs. 8, 9
Case $n = 2$ of the sphere S^{n-1}	Ch. 11
Fiber S^1 of the Hopf fibration	Chs. 11, 12
$\pi_1(S^1) \cong \mathbb{Z}$: the hole that classifies loops	Ch. 12
Compact abelian group and its characters	Ch. 13
Optimal packing of the plane	Ch. 14
Boundary of the disc, where one reads what happens inside	Chs. 15, 16
Domain of Fourier series	Chs. 17, 18
Set of DFT nodes (the N roots of unity)	Chs. 22, 23
Stability boundary: $ z = 1$	Chs. 21, 25
Constellation and carrier in the complex plane	Chs. 26, 27
Base of the double cover $S^3 \rightarrow SO(3)$	Ch. 28
Constant-curvature arc (G02/G03 interpolation)	Chs. 2, 30
Three-parameter model to be estimated from data	Ch. 31

Twenty rows, and none of them is a metaphor: in each the circle is *the same set* $\{(x, y) : x^2 + y^2 = r^2\}$, viewed with the tools of a different theory. The treatise is, literally, the story of this set told twenty times.

33.1.2 From Volume I to Volume II: from figure to function

Volume I treats the circle as a *figure*: a locus of points in the Euclidean plane, with its chords, its tangents, its angles, its measure. The tools are those of synthetic geometry and elementary analytic geometry; the results are equalities among segments, angles and areas.

Volume II takes a single step, but a decisive one: it replaces the figure with a *function*. The circle stops being a set and becomes $\gamma(t) = (r \cos t, r \sin t)$, or $z(t) = re^{it}$, that is, an object on which one can differentiate and integrate. Three results of Volume I are transformed, in this passage, into three results of analysis:

- the arc length $\ell = r\theta$ (Volume I, Chapter 6), defined there as a proportion between arcs and angles, becomes in Volume II the integral $\int_0^\theta |\gamma'(t)| dt$, and the fact that the two values coincide is what justifies the elementary definition;
- the area πr^2 (Volume I, Chapter 6), obtained there by exhaustion with polygons, becomes a double integral in polar coordinates (Volume II, Chapter 2), and Archimedes' formula becomes a case of Green's formula;
- the trigonometry of the unit circle (Volume I, Chapter 8) becomes the correspondence $\theta \mapsto e^{i\theta}$ (Volume II, Chapter 3), which turns the addition formulas into a single identity, $e^{i(\alpha+\beta)} = e^{i\alpha}e^{i\beta}$.

Volume II then adds four applicative registers — basic harmonic analysis, electrical engineering in sinusoidal steady state, directional statistics, discrete circle — and closes with a synthesis chapter (Volume II, Chapter 8) that is the direct predecessor of this one: there the map is drawn from the point of view of the *introduction*, here from the point of view of the whole work.

33.1.3 From Volume II to Volume III: from function to structure

Volume III takes the second step: it replaces the function with the *structure*. It no longer asks what can be computed on the circle, but *of what the circle is an example*, and which properties survive when it is deformed, is generalized, or is replaced.

Structure	What the circle becomes, and where
Regular curve	a case of constant curvature, and the only one (Theorem 2.5); Part A
Manifold	the fiber of the Hopf fibration (Theorem 11.11); Ch. 11
Topological space	the only space with $\pi_1 \cong \mathbb{Z}$ among those considered (Theorem 12.7); Ch. 12
Group	the connected compact abelian group of dimension 1 (Theorem 13.2); Ch. 13
Measure domain	the support of the unique invariant measure (Theorem 13.4); Ch. 13
Boundary	the frontier on which the interior value is read (Theorem 16.6); Ch. 16
Set of nodes	the N roots of unity, basis of the DFT (Theorem 22.1); Ch. 22
Stability locus	the circle $ z = 1$ (Theorem 21.6, Theorem 25.5); Chs. 21, 25
Subgroup	the orbit of a fixed axis in $SO(3)$ and in $SE(3)$ (Theorem 29.6); Ch. 29

The change of viewpoint has a cost and a gain. The cost is that almost none of these statements can be verified with a drawing: they must be proved. The gain is that each of them *transports*: the characterization by curvature holds for every plane curve, the classification of characters holds for every compact abelian group, the diagonalization of circulants holds for every cyclic convolution. Volume III is long because every transport must be justified.

33.1.4 Five chains that run through the three volumes

A *chain* is a sequence of results in which each uses the previous one and no link is skipped. The five that follow are the load-bearing chains of the treatise: every chapter of Volume III rests on at least one of them. They are written out in full, with pointed cross-references, precisely so that the reader can check that there are no gaps.

Chain A — Measure: from $\ell = r\theta$ to concentration in high dimension.

1. Volume I, Chapter 6: length $\ell = r\theta$ and area πr^2 , by exhaustion with inscribed and circumscribed polygons.
2. Volume II, Chapter 2: the same two quantities as integrals, with Green's formula linking area and circulation on the boundary.
3. Chapter 4, Theorem 4.5: among all simple closed curves of given perimeter, the circle is the only one that maximizes the area. It is the first statement in the chain that cannot be checked with a drawing.
4. Chapter 4, Theorem 4.3: at a given constant width the perimeter is the same for all of them, circle included; the area, on the other hand, is not (Theorem 4.4). Perimeter and area, which in Volume I seemed like two faces of the same thing, here come apart.
5. Chapter 11, Theorem 11.1: the same measure in $\mathbb{R}^n$, with the ratio between the volume of the ball and the area of the sphere.
6. Chapter 11, Theorem 11.2 and Theorem 11.4: in high dimension the unit ball has vanishing volume and almost all the measure of the sphere lies near any given equator. The intuition built in Volume I about the circle, applied to S^{n-1} , gives wrong answers: it is the point at which the chain *corrects* its own beginning.
7. Chapter 14, Theorem 14.4: the same measure, counted over infinitely many circles, gives the density $\pi/\sqrt{12}$ of the triangular packing, checked numerically in Example 33.1.

Chain B — The group: from $\cos(\alpha + \beta)$ to Chasles' theorem.

1. Volume I, Chapter 8: the addition formulas of trigonometry, proved with the figure.
2. Volume II, Chapter 3: $e^{i(\alpha+\beta)} = e^{i\alpha}e^{i\beta}$; the addition formulas become a single multiplication.
3. Chapter 6, Theorem 6.1: $\mathbb{T}$ is a group, isomorphic to $SO(2)$ and to $\mathbb{R}/2\pi\mathbb{Z}$; the n -th roots form the finite subgroup μ_n (Theorem 6.2), whose elements are the vertices of a regular polygon (Theorem 6.3).
4. Chapter 5, Theorem 5.4 and Theorem 5.6: $O(2)$ is classified in full, and its connected component *is* the circle.
5. Chapter 13, Theorem 13.5: the characters of S^1 are exactly $\chi_n(z) = z^n$, $n \in \mathbb{Z}$. It is the link that connects this chain to Chain D: the characters are the exponentials of Fourier.
6. Chapter 11, Theorem 11.8 and Theorem 11.10: in dimension three every rotation has an axis, and the unit quaternions — that is, S^3 — realize $SO(3)$.
7. Chapter 28, Theorem 28.1 and Theorem 28.2: $SO(3)$ is not commutative, and Rodrigues' formula tells how a rotation about a given axis composes.

-
8. Chapter 29, Theorem 29.1, Theorem 29.4 and Theorem 29.6: adding translations one arrives at $SE(3)$, where every rigid displacement is a screw motion. The last link is the kinematics of an industrial arm.

Remark 33.1: Where Chain B loses a property, and what it costs. *Between point 5 and point 7 of Chain B the most important thing in the treatise happens: the group stops being commutative. As long as the group is S^1 , its characters are complex-valued functions (Theorem 13.5) and harmonic analysis is a sequence of numbers; this one-dimensionality is the reason why the Fourier series, the transform, the DFT and the FFT exist in the form used throughout Part C. In $SO(3)$ the irreducible representations have dimension $2\ell + 1$, the “coefficients” become matrices, and multiplication no longer commutes (Theorem 28.1). The consequence is not abstract: it is the wrist singularity of manipulators, that is Theorem 28.5, and it is the reason why a robot cannot cross certain configurations at bounded speed. The fact that S^1 is abelian, compact and connected is the ultimate reason why it admits a complete theory, and hence the reason why this treatise can exist.*

Chain C — Curvature: from the radius to trajectory control.

1. Volume I, Chapters 2 and 6: the radius as the only quantity that determines the circle up to isometries.
2. Volume II, Chapter 1: arc-length parametrization and the first and second derivatives.
3. Chapter 2, Theorem 2.1 and Theorem 2.2: the Frenet formulas in the plane and the value $\kappa \equiv 1/r$ for the circle.
4. Chapter 2, Theorem 2.5: the property becomes a *characterization*, that is, constant nonzero κ implies that the curve is an arc of a circle; and Theorem 2.4: the osculating circle is the only circle with second-order contact.
5. Chapter 3, Theorem 3.3 and Theorem 3.2: adding a third dimension torsion appears, and the pair (κ, τ) determines the curve up to rigid motions; the circle is the case $\tau \equiv 0$.
6. Chapter 4, Theorem 4.1 and Theorem 4.6: curvature, integrated over the whole closed curve, gives an integer; and every simple closed curve has at least four vertices, while the circle has infinitely many. Constant curvature is not a local property as it seemed at point 3: it is an extremely rigid global condition.
7. Chapter 10, Theorem 10.2: the curvature of a surface is intrinsic, that is, it does not depend on how the surface is embedded.
8. Chapter 30, Theorem 30.4 and Theorem 30.5: on the constant-curvature arc one builds the jerk-limited motion profile, that is, the G02/G03 circular interpolation of numerically controlled machines. The “constant κ ” constraint of point 4 becomes here the command sent to a tool.

Chain D — Fourier: from the orthogonality of angles to OFDM. This is the longest chain in the treatise: eleven links, six chapters of theory and four of application.

1. Volume I, Chapter 8: cos and sin on the trigonometric circle, and the first integral identities between them.
2. Volume II, Chapter 4: Fourier coefficients, orthogonality of the trigonometric system, first partial sums.

-
3. Chapter 6, Theorem 6.5: orthogonality is a fact about roots of unity, that is, a geometric sum equal to 0 or to n .
 4. Chapter 13, Theorem 13.4, Theorem 13.5 and Theorem 13.6: the measure with respect to which one integrates is unique, the characters are exactly the z^n , and their orthogonality follows from invariance. Here orthogonality stops being a computation and becomes a theorem of structure.
 5. Chapter 17, Theorem 17.1: the system is *complete*, hence the series converges in L^2 for every square-summable function; Theorem 17.4 for pointwise convergence and Theorem 17.6 for the Cesàro sum, which converges where the ordinary series does not converge.
 6. Chapter 16, Theorem 16.6: the same series, read on the disc, solves the Dirichlet problem; the Poisson kernel is the approximate identity that closes the argument.
 7. Chapter 18, Theorem 18.3 and Theorem 18.5: the same series solves Laplace's equation and the heat equation, and produces the Bessel functions when the domain is the circular membrane.
 8. Chapter 19, Theorem 19.4 and Theorem 19.5: passing from the circle to the line the series becomes an integral, and convolution becomes a product.
 9. Chapter 20, Theorem 20.2, and Chapter 21, Theorem 21.6: adding a damping factor the transform extends to a half-plane (continuous time) or to an annulus (discrete time), and the DTFT is the restriction of the Z-transform to $|z| = 1$. The circle reappears as a *locus*: it is where the two-sided transform coincides with frequency analysis.
 10. Chapter 22, Theorem 22.1, Theorem 22.2, Theorem 22.5 and Theorem 22.6: sampling the circle at N points gives the DFT, with the same orthogonality as point 3 and the same identities as points 5 and 8; Chapter 23, Theorem 23.3 and Theorem 23.5: it is computed in $\frac{N}{2} \log_2 N$ multiplications instead of N^2 , without changing a single digit of the result.
 11. Chapters 24, 26 and 27: sampling, complex baseband and orthogonal subcarriers. The last link is the way a modern radio connection transmits: N carriers that do not interfere for the same reason why, at point 3, a sum of roots of unity is zero.

Chain E — Stability: from the phasor to the gain margin.

1. Volume II, Chapter 5: the phasor, that is, the complex number of constant modulus that rotates; impedances, power, power-factor correction.
2. Chapter 15, Theorem 15.3 and Theorem 15.5: what happens inside a circle is read on the circle; the residue is the computation that makes this possible.
3. Chapter 20, Theorem 20.2 and Theorem 20.3: the region of convergence is a half-plane, and the position of the poles relative to the imaginary axis decides stability in continuous time.
4. Chapter 21, Theorem 21.1 and Theorem 21.6: in discrete time the half-plane becomes an annulus, and the imaginary axis becomes the circle $|z| = 1$.
5. Chapter 25, Theorem 25.4 and Theorem 25.5: the Nyquist criterion counts the turns of the diagram around a point, and is the argument principle applied to a transfer function; Theorem 25.6: the gain and phase margins are distances measured on a circle.

-
6. The winding number that the criterion counts is the same object as Chapter 12, Theorem 12.5 and Theorem 12.6: a homotopy invariant with integer values. The stability of a control loop is, literally, a topological property.

Remark 33.2: How to read a chain, and what it is for. The five chains are not an alternative index: they are a control tool. A student can use them in three ways. First, to check one's own understanding: one covers the column of cross-references and tries to say, for each link, which hypothesis of the previous one is being used; the point at which one cannot answer is the point to reread. Second, to orient oneself: a result one needs is looked up on the chain to which it belongs, not in the analytic index, because the chain also says what must be read first. Third, to recognize a missing link: if in one's own reasoning one jumps from one link to the third one after it, one has almost always skipped a hypothesis. Exercise 33.1 asks for exactly this kind of work on a chain not listed here.

33.2. The double register: mathematics and workshop

Every strand of this thread has had a concrete counterpart. Continuous curvature has become the steering constraint of mobile robots and the clothoid transitions of CNC machines; the isometries of the circle have extended to $SO(3)$ and to the quaternions that ABB, KUKA, FANUC and Yaskawa use to orient the tool; the geodesics of the sphere are the orthodromic routes; the non-commutativity of $SO(3)$ is what becomes wrist singularity; limited jerk and *input shaping* are the workshop's translation of the demand for "smoothness" of motion. The same mathematics that describes the circle describes the way in which machines move.

This coexistence has a name and rules. The treatise is written in two distinct registers, never mixed.

- The **demonstrative register** is that of the environments *definizione*, *teorema*, *lemma*, *proposizione*, *corollario*, each followed by a complete *dimostrazione*. Here nothing is written that is not proved or explicitly declared as imported. The criterion of truth is internal: a statement is true if and only if its proof closes.
- The **applicative register** is that of the environments *esempio*, *osservazione*, *buonapratica*, *attenzione*, *infobox*, of the numerical tables and of the worked exercises. Here it is stated what the result produces when it is used: a value, a tolerance, a machine command, a fault diagnosis. The criterion of truth is external: a statement is true if the computation checks out, if the measurement confirms it, if the script reproduces it.

The two registers do not contradict each other and do not replace each other. An observation never proves a theorem, and a theorem never by itself justifies a design choice: between the statement and the choice there is always at least one modeling hypothesis, which the applicative register must declare. The table that follows sets in columns about ten pairs: on the left the result with its cross-reference, on the right the workshop consequence.

Demonstrative register	Applicative register
constant κ characterizes the circle (Theorem 2.5)	G02/G03 circular interpolation: an arc is defined by center, radius and direction, not by a table of points (Ch. 30)
the rotations of $\mathbb{R}^3$ do not commute (Theorem 28.1)	the order of orientation commands changes the result; hence wrist singularity (Theorem 28.5)
$S^3 \rightarrow SO(3)$ is a double cover (Theorem 11.10)	q and $-q$ are the same pose: SLERP interpolation must be done on the right branch (Theorem 30.2)
residual vibration is the modulus of a transform (Theorem 30.6)	ZV <i>input shaping</i> cancels vibration by placing a zero at the natural frequency (Ch. 30)
the DFT is computed in $\frac{N}{2} \log_2 N$ multiplications (Theorem 23.5)	online spectral analysis becomes possible on modest hardware; the count is however not the execution time (Ch. 23)
the Nyquist criterion counts turns (Theorem 25.5)	gain and phase margin as distances on the polar diagram (Theorem 25.6)
the ROC of the Z-transform is an annulus (Theorem 21.1)	BIBO stability of a digital filter: poles inside $ z = 1$ (Ch. 21)
the triangular packing has density $\pi/\sqrt{12}$ (Theorem 14.4)	number of cables in a conduit, of tubes on a pallet (Theorem 14.5)
the geodesics of S^2 are the great circles (Theorem 9.3)	orthodromic route and spherical triangulation (Ch. 8)
the geometric fit has explicit normal equations (Theorem 31.4)	measuring the radius of a hole from a cloud of points, with its conditioning (Ch. 31)

Remark 33.3: The three rules of the double register. *The rules followed throughout the treatise are three, and can be checked line by line.*

First rule: the modeling hypothesis is always written down. *No passage from the demonstrative register to the applicative one happens silently. When Theorem 30.6 becomes a tuning rule, the single-degree-of-freedom model with viscous damping is stated in full; when the count of Theorem 23.5 becomes a time prediction, it is declared that the cost model ignores memory accesses.*

Second rule: applicative numbers are checked twice. *Every value that appears in an example or in a table is obtained by two independent routes, typically a closed form and an executed script, and the discrepancy is reported. Section 33.4 redoes three of these checks.*

Third rule: the applicative register never promotes. *An observation, an infobox or a good practice cannot turn into a theorem something that is not proved. The great results that the treatise uses without proving them stand in declared observations, never in teorema environments: this is what Section 33.3 is about.*

Remark 33.4: The error that the double register prevents. *The error the double register is built against is tacit promotion: using as a proved premise something that was read in an example. Two forms of it can be seen. The first is citing as a theorem of the treatise a statement that the treatise exposes only as panorama — for instance the Kepler conjecture in the form proved by Hales, which here is in Remark 14.5 and in no teorema environment. The second is carrying a numerical value outside the hypotheses under which it was computed: the density $\pi/\sqrt{12}$ holds for the infinite packing of the plane, and applying it to a conduit of twenty cables gives an optimistic estimate, because the boundary effect is not negligible at that number of elements. In both cases the remedy is the same: go back to*

the label and read the hypotheses.

33.3. What the treatise proves and what it imports

A text of applied mathematics is also judged by how honest it is about its own debts. This treatise declares three types, kept separate and marked differently: the *prerequisites*, which are assumed known; the *panoramas*, which are exposed without proof; the *imports*, that is, the individual lemmas used inside an otherwise complete proof. The rule that governs them is a single one, repeated in every chapter: if a proof does not close with certainty, it is not written; it is reduced to lemmas named with their source, and it is declared, in an observation, what is left out.

33.3.1 First type: the prerequisites

These are the results of Volumes I and II, and the basic notions of linear algebra, differential and integral calculus, and elementary measure theory, which the volume uses without reproving them. They are collected in **Appendix A**, “Prerequisites recalled”, which lists them as a reminder and not as a treatment: dot product and cross product, the spectral theorem for symmetric matrices, Euler’s formula, the plane Frenet frame, the Gaussian integral and the Gamma function. The infobox “Level and prerequisites” at the head of each chapter adds, chapter by chapter, the specific prerequisites and declares which ones are assumed and not reproved: see for example the bulleted list of Chapter 23 (induction, linear algebra, modular arithmetic, binary representation, the floating-point arithmetic model) and that of Chapter 31.

A prerequisite is not a hidden debt: it is a choice of perimeter, declared before beginning. The criterion adopted is that a prerequisite must be *standard*, that is, found in any basic university course, and *independent of the circle*, that is, it must not be a part of the theory that the treatise has the task of building.

33.3.2 Second type: the panoramas

These are the great theorems that the treatise *cites* because they are needed to situate what it proves, but whose proof is beyond the reach of a didactic work of this level. They all stand in *osservazione* or *infobox* environments, never in *teorema* environments: this is the third rule of the double register (Remark 33.3). Here they are, with the place where they are exposed.

- **Packings.** The theorem of Thue and Fejes Tóth on the optimality of the hexagonal packing in the plane (Remark 14.4); the Kepler conjecture proved by Hales and the exceptional cases in dimensions 8 and 24 (Remark 14.5); the circle packing theorem of Koebe, Andreev and Thurston (Remark 14.6).
- **Topology.** The computation of $\pi_1(S^n)$ for $n \geq 2$ (Remark 12.5); the hairy ball theorem (Remark 12.6); the non-triviality of the Hopf fibration (Remark 12.7, and Remark 11.6 for what is left out of Chapter 11).
- **Groups.** The general theory of Lie groups (Remark 13.2); the existence and uniqueness of the Haar measure on any compact group (Remark 13.4); Pontryagin duality (Remark 13.6); Weyl’s equidistribution in dimension n (Remark 13.8); the Baker–Campbell–Hausdorff formula (Remark 29.14).
- **Complex and harmonic analysis.** Picard’s great theorem (Remark 15.18); the Poincaré metric and the Schwarz–Pick lemma (Remark 15.17); the two extremes of the theory

of pointwise convergence, that is, Kolmogorov’s example and Carleson’s theorem (Remark 17.9); the completeness of the Bessel–Fourier system (Remark 18.16).

- **Constructibility.** The Gauss–Wantzel theorem on polygons constructible with straight-edge and compass (Remark 6.4).

A panorama is not a gap: it is a boundary. The reader who crosses it knows exactly at what moment they are leaving what the treatise has built, and the source given tells them where to continue.

33.3.3 Third type: the imports

These are the most delicate cases, because they stand *inside* a proof. A chain of steps is complete except for one link, that link is a known and citable result, and so it is isolated, given a name, its source is indicated, and it is declared in an observation that this step is imported. The advantage of this form over keeping silent is that the reader sees the structure of the proof in full and knows exactly which single brick they must trust.

Where	What is imported
Ch. 3	completeness of $\mathbb{R}$ in the form used for the fundamental theorem of curves (Rem. 3.6)
Ch. 4	mixed areas and Pál’s theorem for Blaschke–Lebesgue (Rem. 4.2); the supporting osculating circle theorem for the strong form of the four-vertex theorem (Rem. 4.6); global Gauss–Bonnet (Rem. 4.9)
Ch. 6	identification of the rotations of the sphere with a subgroup of Möbius transformations (Rem. 6.6)
Ch. 9	local existence and uniqueness for differential equations (Picard–Lindelöf, Rem. 9.1); Jacobi fields and conjugate points (Rem. 9.2)
Ch. 10	Brioschi’s formula (Rem. 10.1); the characterization of surfaces with $K \equiv 0$ (Rem. 10.3)
Ch. 15	the notion of simple connectedness and what is assumed about it (Rem. 15.2)
Ch. 16	what fails in dimension greater than two (Rem. 16.2)
Ch. 17	the uniform part of the Dirichlet–Jordan criterion (Rem. 17.12) and the chapter’s balance sheet (Rem. 17.15)
Ch. 18	the tabulated values of the zeros of Bessel functions (Rem. 18.12) and McMahon’s asymptotic expansion (Rem. 18.13)
Ch. 19	the Plancherel extension to L^2 (Rem. 19.8); the limits of what can be said about sampling (Rem. 19.10)
Ch. 20	the Bromwich inversion in the general case (Rem. 20.6); the residue of BIBO stability (Rem. 20.9)
Ch. 21	Parseval’s theorem for finite-energy signals (Rem. 21.7)
Ch. 22	the multiplicities of the four eigenvalues of the DFT matrix (Rem. 22.3); the values of the side lobes (Rem. 22.13)
Ch. 23	the existence of a primitive root modulo p , used once in Rader’s algorithm (Rem. 23.11); the standard model of floating-point arithmetic (Rem. 23.12)
Ch. 28	the nonexistence of a global three-parameter chart for $SO(3)$ (Rem. 28.7)
Ch. 29	the closed subgroup theorem (Rem. 29.2)
Ch. 30	the properties of B-splines (Rem. 30.1); Squad, dual quaternions and ScLERP (Rem. 30.4); the robustness of shapers beyond ZVD (Rem. 30.6)
Ch. 31	the convergence of Gauss–Newton (Rem. 31.10); damping as a trust region (Rem. 31.11); the two statements about bias (Rem. 31.13)

Remark 33.5: What remains imported in Volume III, and how to recheck it.

The preceding table and the list of panoramas are the complete balance sheet of what this volume uses without proving it. It is worth stating precisely what this does not mean. It does not mean that those results are doubtful: they are all established theorems, with their source indicated and verified in the Fonti environment of the chapter that uses them. It means that, for those steps and only those, the reader who wants a closed deductive chain must leave here and go to the source.

Three remarks on the balance sheet. First, the imports concentrate where one would expect: in chapters that touch theories much wider than the circle (differential equations in Chapter 9, measure theory in Chapter 19, nonlinear optimization in Chapter 31). Second, no import is used to prove a result about the circle: the central statements of the treatise — Theorem 2.5, Theorem 4.5, Theorem 13.5, Theorem 22.1, Theorem 23.3 — have complete proofs. Third, the balance sheet is a living thing: it is derived mechanically from the sources with the script `registro_importati.py`, which lists every block containing a declaration of an import or of a panorama. Anyone reading an edition later than this one must rerun it: the applicative chapters 24, 26, 27 and Chapter 32, in particular, add their own imports, and the table above must be read as the snapshot of one edition, not as a law.

33.4. Three numbers, three registers

A synthesis chapter introduces no new computations, but it can redo the old ones. The three that follow are chosen because each belongs to a different register — elementary geometry, classical analysis, numerical computation — and because each is, at the same time, a result of Volume I reread with the tools of Volume III. All three are computed twice by independent routes, as prescribed by the second rule of the double register (Remark 33.3).

Example 33.1: The density $\pi/\sqrt{12}$, two ways. Theorem 14.4 states that the triangular packing of equal circles in the plane has density $\pi/\sqrt{12}$.

First way (closed form). The value is

$$\frac{\pi}{\sqrt{12}} = \frac{\pi}{2\sqrt{3}} = 0.9068997\dots$$

Second way (ratio of areas, with only the tools of Volume I). In the triangular lattice each circle of radius r has, as its cell, the regular hexagon of apothem r . That hexagon has side $L = 2r/\sqrt{3}$, because its circumscribed radius R satisfies $r = R \cos 30^\circ = R\sqrt{3}/2$ and in the regular hexagon $L = R$; it is made of six triangles of base L and height r , hence

$$A_{\text{hexagon}} = 6 \cdot \frac{Lr}{2} = 3 \frac{2r}{\sqrt{3}} r = 2\sqrt{3} r^2.$$

The density is the ratio between the area of the circle and that of its cell:

$$\frac{A_{\text{circle}}}{A_{\text{hexagon}}} = \frac{\pi r^2}{2\sqrt{3} r^2} = \frac{\pi}{2\sqrt{3}} = \frac{\pi}{\sqrt{12}}.$$

The two ways give the same number, and the second explains *why*: the optimal density is the ratio between a circle and the hexagon surrounding it, that is, an area computation from Volume I, Chapter 6.

Numerical check. The executed script gives 0.9068996821 for the first way and 0.9068996821 for the second, with discrepancy $2.220 \cdot 10^{-16}$, that is, one unit in the last digit of double precision. ✓

What the number does not say. The density is a limit over the whole plane: in a finite region the boundary effect lowers it. A count on a square of side $800r$ gives 0.9040, that is, 0.3% less, and on a conduit of twenty cables the discrepancy is much larger. This is the error described in Remark 33.4.

Example 33.2: Archimedes' polygons, two ways. Volume I, Chapter 1, reports Archimedes' estimate $\frac{223}{71} < \pi < \frac{22}{7}$, obtained with the regular inscribed and circumscribed polygons of 96 sides. With the tools of Volume II those semiperimeters have a closed form. *First way (closed form).* The regular polygon of n sides inscribed in the unit circle has semiperimeter $n \sin(\pi/n)$, the circumscribed one $n \tan(\pi/n)$. For $n = 96$:

$$96 \sin \frac{\pi}{96} = 3.1410320, \quad 96 \tan \frac{\pi}{96} = 3.1427146.$$

Second way (doubling the sides, as Archimedes proceeded). If ℓ_n is the side of the polygon of n sides inscribed in the unit circle, doubling gives

$$\ell_{2n} = \sqrt{2 - \sqrt{4 - \ell_n^2}},$$

and one starts from $\ell_6 = 1$, the side of the hexagon, which equals the radius. Four doublings take one from 6 to 96 sides; the resulting semiperimeter is $96 \ell_{96}/2 = 3.1410320$, with discrepancy $2.0 \cdot 10^{-14}$ from the closed form. ✓

Comparison with the ancient estimate. $\frac{223}{71} = 3.1408451 < 3.1410320$ and $3.1427146 < 3.1428571 = \frac{22}{7}$: Archimedes' fractions are correct and, as is well known, slightly wider than the exact values of the two polygons, because obtained by rounding down and up at each step. The true value $\pi = 3.1415927$ lies between the two semiperimeters, as it must.

Example 33.3: The same Parseval identity in three chapters. The identity linking the energy of a signal to that of its spectrum appears in the treatise three times: as Parseval's identity for Fourier series (Chapter 17, with the completeness of the trigonometric system, Theorem 17.1), as Plancherel's theorem for the transform (Chapter 19, for the imported part see Remark 19.8) and as a discrete identity (Chapter 22, Theorem 22.6). In its third form it says

$$\sum_{k=0}^{N-1} |X[k]|^2 = N \sum_{n=0}^{N-1} |x[n]|^2.$$

Let us check it on the ramp $x = (0, 1, 2, \dots, 7)$, $N = 8$, the same one from the worked example of Chapter 23.

Left side, by closed form. For that ramp $X[0] = 28$ and $X[k] = 8/(\omega_8^k - 1)$ for $k \neq 0$, with $\omega_8 = e^{-2\pi i/8}$; hence $|X[k]|^2 = 64/|\omega_8^k - 1|^2$ and $|\omega_8^k - 1|^2 = 2 - 2\cos(\pi k/4)$. The seven values are

$$\begin{aligned} \frac{64}{2 - \sqrt{2}} &= 64 + 32\sqrt{2} \quad (k = 1, 7), & 32 \quad (k = 2, 6), \\ \frac{64}{2 + \sqrt{2}} &= 64 - 32\sqrt{2} \quad (k = 3, 5), & 16 \quad (k = 4), \end{aligned}$$

and their sum is exactly $2(64 + 32\sqrt{2}) + 2 \cdot 32 + 2(64 - 32\sqrt{2}) + 16 = 128 + 64 + 128 + 16 = 336$, where the terms in $\sqrt{2}$ cancel. Adding $|X[0]|^2 = 784$ gives $784 + 336 = 1,120$.

Right side, by direct computation. $\sum_{n=0}^7 n^2 = \frac{7 \cdot 8 \cdot 15}{6} = 140$, and $N \cdot 140 = 8 \cdot 140 = 1,120$. The two sides coincide *exactly*, not up to rounding: both equal 1,120. The script that computes the DFT from the definition and sums the squared moduli gives 1,120.0000000

with discrepancy $2.0 \cdot 10^{-12}$ from the exact value, which is the rounding error expected in double precision for a sum of eight complex numbers of order 10^2 . ✓

Why this is a good synthesis example. The left side was computed with a closed form coming from complex analysis (sum of a truncated geometric series, Chapter 6); the right side with a formula for the sum of squares learned in high school; and the equality between the two is a theorem of linear algebra on the unitarity of the DFT matrix (Theorem 22.3). Three registers, one number.

Remark 33.6: Why two ways and not three. *The treatise’s rule requires two independent ways, not two calculations. Two ways are independent when an error made in the first cannot be repeated identically in the second: a closed form and a script that evaluates it are not independent, because the script copies the formula. In the preceding examples independence is guaranteed as follows: in Example 33.1 the second way reconstructs the value from a ratio of areas, without ever writing $\pi/\sqrt{12}$; in Example 33.2 the second way is a recursion that uses neither $\sin$ nor π ; in Example 33.3 the two sides are computed with different theories and the comparison is the statement itself. An executed script serves, in all three cases, as a third check, and it is the one that catches transcription errors.*

33.5. The roads that remain open

A treatise closes, the subject does not. The open roads are of three kinds, and it is worth not confusing them.

First kind: genuine open problems, that is, questions to which no one today knows the answer. Chapter 32 collects a few that closely concern the circle — Toeplitz’s inscribed square problem, inscribed rectangles, Apollonian packings and the local–global conjecture — and exposes them with the state of research and the date to which that state refers. That chapter also contains the part on research literacy: how to read a preprint, how one verifies a source, why an announced proof is not a proof.

Second kind: the panoramas of this volume, listed in Section 33.3.2. They are not open for mathematics — they are proved theorems — but they are open *for the reader*, in the sense that they remain to be studied. The difference is important and is easily forgotten: Carleson’s theorem (Remark 17.9) is not an unsolved problem, it is a result from 1966 that is not proved here.

Third kind: the directions already planned, that is, what the treatise will address in the next volume. These are the threads that this volume has deliberately left hanging: the Hopf fibration as the first example of a non-trivial fiber bundle (Remark 12.7), the general theory of Lie groups (Remark 13.2), Riemannian geometry beyond the case of the surfaces of Chapter 10.

Remark 33.7: Toward Volume IV. *Threads remain to be pulled, and they are the ones left hanging on purpose. **Fiber bundle theory**, of which the Hopf fibration of Theorem 11.11 is the first non-trivial example and of which only the structure of the fibers has been proved here (Proposition 12.5), while non-triviality remains a panorama (Remark 12.7). **Differentiable manifolds** and **Riemannian geometry** in general, of which Chapter 10 treats the case of surfaces in $\mathbb{R}^3$ and Chapter 9 the case of geodesics, with Jacobi fields left out (Remark 9.2). **Lie groups** such as $SU(2)$ and $SE(3)$ in their full structure, of which the properties needed for kinematics have been seen here (Theorem 29.1, Theorem 29.4) while the general theory, the Baker–Campbell–Hausdorff formula and the classification remain imported (Remark 13.2, Remark 29.14). And **geometric control** of robots, that is, what*

is obtained when the trajectory is no longer designed in joint space but on the manifold of configurations, of which Chapters 29 and 30 constitute the prerequisites.

The circle, once again, will be the starting point: the simplest of the non-trivial examples, the one on which everything else is understood. All four directions listed are, literally, the question “what remains true when S^1 is replaced by something larger?”, and it is the same question with which Part B of this volume opened.

33.6. Note on the working method

The rules with which this volume was written are few and can be checked from the outside. It is worth stating them, because a reader who knows them can use the text in a stricter way, and because anyone who wants to continue the work knows what to hold to.

Best practice. The five drafting rules of the treatise.

1. **No proof left half-done.** Every *teorema*, *lemma*, *proposizione* and *corollario* is followed by a complete proof, in which every step is justified and every result used is recalled with its label. The phrases “it is evident” and “one easily sees” do not appear. If a proof does not close with certainty, it is not written: it is reduced to named lemmas and the import is declared (Section 33.3). The check is automatic: the script `audit_dimostrazioni.py` lists statements without a proof, and the acceptance criterion for the volume is zero.
2. **Every value computed twice.** No number appears in the text unless it has been obtained by two independent routes, typically a closed form and an actually executed script; the discrepancy between the two is reported, and the symbol $\checkmark$ signals that the comparison has been made. On the independence of the two routes see Remark 33.6.
3. **Every source verified.** In the *Fonti* environment of each chapter every entry carries authors, title, venue, year, pages or section, and the date on which it was verified. No page number and no DOI is written from memory. The sources collected are poured into a single register, one line per central statement.
4. **Every figure with computed coordinates.** The drawings are built from coordinates obtained by computation and checked numerically, not traced by eye; a figure that “looks right” is not a verification.
5. **Three languages in parallel.** Every chapter exists in Italian, English and Ukrainian with the same labels, the same sequence of statements and the same numerical values; the only differences allowed are the text, the decimal separator and the groups of the analytic index. The comparison among the three editions is automatic and the allowed discrepancy is zero.

These rules have a cost, and it is high: they are the reason the volume is long. But they also have a precise consequence, which is the real reason they were adopted: a reader who finds a statement here can always establish, in finite time, whether it is proved, imported or merely described — and, in the first two cases, where to go to check.

33.7. Assigned exercises

Exercise 33.1: A sixth chain, written out in full. *Goal:* to be able to build a chain of results oneself, with cross-references, without gaps. *Estimated time:* 45 minutes.

The five chains of Section 33.1.4 do not exhaust the treatise. At least one is missing, which starts from the circular inversion of Volume I, Chapter 5, and reaches the Ford circles of Chapter 14.

(a) Write it in the same form as the others: from four to six numbered links, each with the cross-reference to the precise statement (not to the chapter).

(b) For each link, say in one line which hypothesis of the previous link is used.

(c) Indicate at which link the chain leaves the Euclidean plane, and what the substitution entails.

(d) Say whether the chain contains an import or a panorama, and which one.

Exercise 33.2: Proved, imported, or panorama?. *Goal:* to be able to place a statement in the volume's balance sheet. *Estimated time:* 25 minutes.

For each of the six statements below, say whether in Volume III it is (i) proved in full, (ii) imported inside an otherwise complete proof, or (iii) exposed as a panorama; and indicate the exact label of the place where it is found.

(a) Among simple closed curves of given perimeter, the circle maximizes the area. (b) The densest packing of equal spheres in $\mathbb{R}^3$ is the face-centered one. (c) A Cauchy problem with a locally Lipschitz right-hand side has one and only one local solution. (d) The radix-2 decimation-in-time FFT algorithm computes the DFT exactly. (e) The Fourier series of a square-summable function converges almost everywhere. (f) There exists a primitive root modulo every prime p .

For cases (ii) and (iii), add a line stating *what* exactly is missing for the proof to close inside the volume.

Exercise 33.3: Redoing the three checks with other data. *Goal:* to apply the rule of the two independent ways. *Estimated time:* 40 minutes.

(a) Repeat Example 33.3 with the ramp $x = (0, 1, \dots, 15)$, $N = 16$: compute $\sum_n |x[n]|^2$ with the formula for the sum of squares, compute $\sum_k |X[k]|^2$ with the closed form $|X[k]|^2 = N^2/(2 - 2\cos(2\pi k/N))$ for $k \neq 0$ and $X[0] = 120$, and compare.

(b) Repeat Example 33.2 with $n = 192$ sides, for both ways (closed form and doubling recursion), and say by how much the approximation of π improves relative to $n = 96$.

(c) Compute, with the same reasoning as Example 33.1, the density of the packing on the *square* lattice, and say by how much it is less dense than the triangular one. Verify that the ratio between the two densities does not depend on the radius.

33.8. Worked exercises

Exercise 33.4: What survives passing from S^1 to S^2 . For each of the following five properties of S^1 , say whether it still holds for S^2 and with which statement of the volume it is decided: (i) it is compact and connected; (ii) it has fundamental group $\mathbb{Z}$; (iii) it is a group; (iv) it admits a nowhere-vanishing tangent vector field; (v) it is the boundary of a domain on which the Dirichlet problem is solvable.

Solution. *Strategy.* Each item is decided with a precise statement, not with intuition: the sphere “resembles” the circle in four cases out of five and differs precisely where the analogy

is most tempting.

(i) *Yes.* S^1 is compact and connected by Theorem 12.1; for S^2 the same holds, and it is a case of the definition of n -dimensional sphere from Chapter 11 (Definition 11.1): the sphere is closed and bounded in $\mathbb{R}^n$, hence compact, and it is path-connected for $n \geq 2$.

(ii) *No.* $\pi_1(S^1) \cong \mathbb{Z}$ is Theorem 12.7; for S^n with $n \geq 2$ the fundamental group is trivial, and it is one of the declared panoramas (Remark 12.5). Watch the step: the proof of Theorem 12.7 uses the covering $E : \mathbb{R} \rightarrow S^1$ (Theorem 12.4) and path lifting; for S^2 that covering does not exist, so it is not that the proof “gives another result”: it simply does not get started.

(iii) *No.* S^1 is a group (Theorem 13.1), S^3 also is — these are the unit quaternions, Theorem 11.10 — but S^2 is not. The most elementary reason available here is (iv): a Lie group has nowhere-vanishing invariant vector fields, and S^2 admits none.

(iv) *No.* S^1 can be combed (Proposition 12.4); S^2 cannot, by the hairy ball theorem, which is a declared panorama (Remark 12.6). It is the only one of the five answers that cannot be proved here: it is taken from the source indicated in that observation.

(v) *Yes.* For the disc the result is Theorem 16.6, which uses the Poisson kernel; for the ball in higher dimension the analogous statement holds, but the construction must be redone, and Remark 16.2 says exactly what of the two-dimensional case does *not* carry over (in particular the connection with holomorphic functions, which is specific to the plane).

Independent check. The five answers can also be derived by another route: the Euler characteristic. $\chi(S^1) = 0$ and $\chi(S^2) = 2$; the Poincaré–Hopf theorem links χ to the sum of the indices of a vector field, and a nowhere-vanishing field forces $\chi = 0$. This explains (iii) and (iv) together, and confirms (ii), because a non-trivial covering of S^2 would contradict its simple connectedness. This route is consistent with the answers given, but uses the Poincaré–Hopf theorem, which this volume does not prove: it serves as a check, not as a proof.

Typical errors. The first is answering “yes” to (iii) by thinking of spherical coordinates: two angles do not make a group, because the composition of rotations is not the sum of coordinates (Theorem 28.1). The second is answering “no” to (i) by confusing compactness and boundedness in infinite dimension, which is not relevant here.

Extension. Redo the five questions for the torus $S^1 \times S^1$: one finds yes, no (the fundamental group is $\mathbb{Z} \times \mathbb{Z}$, Corollary 12.7), yes (it is a group, a product of two copies of S^1), yes (it can be combed, because it is a Lie group), yes. The torus, from this point of view, is much more similar to the circle than the sphere is.

Exercise 33.5: Where to look: a workshop question and its path. A technician must estimate the radius of a hole from 200 points measured on the boundary with a probe, and must state how reliable the estimate is. Trace the reading path in the treatise: which chapters, in which order, and which result answers which part of the question.

Solution. *Strategy.* The question contains three different questions — how one estimates, how stable the estimate is, how biased it is — and each has its place. The path is built starting from the last one and working backward.

Step 1: the model. The circle as a three-parameter model (center and radius) is Chapter 31. The first thing to read is the distinction between a *geometric* fit (minimizing radial distances) and an *algebraic* one; the second is treated in Volume I, Chapter 11, with the methods of Kåsa and the Hough transform, and is not repeated here.

Step 2: the estimate. Theorem 31.4 gives the normal equations of the geometric fit, Theorem 31.3 guarantees that the minimum exists, and Theorem 31.1 ensures that the estimate does not depend on where the origin of the measurement system was placed: a property

far from obvious, and indispensable for the stated number to be reproducible on another machine.

Step 3: the algorithm. Theorem 31.5 and Theorem 31.6: the Gauss–Newton step is a descent step, and the damped Levenberg–Marquardt version is always well defined. Here one must also read Remark 31.10, because global convergence is not proved in the volume: it is an import, and the technician must know this before writing “the method converges” in an acceptance-test report.

Step 4: reliability. Remark 31.13 distinguishes two different statements about the bias of the estimate and says which of the two is imported. This is the point at which the answer “how reliable is it” stops being a property of the algorithm and becomes a property of the noise model: without a hypothesis on the noise there is no reliability to declare.

Independent check. The path can be validated backward: take the final question (“what uncertainty do I state?”), look for the last result of the path, and check that all its prerequisites are in earlier steps. Here this is the case: Remark 31.13 requires the model of Step 1 and the estimate of Step 2, both already acquired.

Interpretation. Of the four stages, three lie in the demonstrative register and one — Step 4 — straddles the two: it is exactly the point at which the modeling hypothesis must be declared, as prescribed by the first rule of Remark 33.3.

Typical errors. The most common is skipping Step 2 and directly using a minimizer: one obtains a number, but does not know whether it is invariant under a change of origin, and two operators with two different reference frames obtain two different radii. The second is confusing the residual of the minimization with the uncertainty of the estimate: the first measures how much the points deviate from the circle found, the second how much the circle found deviates from the true one.

Extension. Redo the path for the question “with how many points is it best to measure”, which adds to the path the conditioning of the normal equations of Chapter 31 and, for the choice of the distribution of points on the arc, the concentration of measure of Chapter 11.

Exercise 33.6: The balance sheet of a chapter. Draw up the balance sheet of Chapter 14 in the three categories of Section 33.3, and say why that chapter has, proportionally, more panoramas than any other.

Solution. *Strategy.* One scans the statements of the chapter, separates those followed by a proof from those that stand in an observation, and looks for the structural reason for the proportion.

Proved. The chapter proves in full the results on Ford circles and Farey fractions (Theorem 14.1 and Theorem 14.2), the kissing number of the plane (Theorem 14.3), the density of the triangular packing (Theorem 14.4) and the applicative count (Theorem 14.5). These are five statements, all closed.

Imported. No imports inside the proofs: the chapter does not need external lemmas to close what it states.

Panorama. Three: the optimality of the hexagonal packing among *all* packings, not only the lattice ones, that is, the theorem of Thue and Fejes Tóth (Remark 14.4); the Kepler conjecture in Hales’s proof and the cases of dimensions 8 and 24 (Remark 14.5); the circle packing theorem (Remark 14.6).

Why that proportion. The reason lies in the nature of the statements. The Theorem 14.4 computes the density of a *given* packing, and is an area computation; the statement that no other packing does better is instead a statement about an infinite and unparametrized family of configurations, and its proof requires techniques — Delaunay decompositions, local estimates on cells, and in Hales’s case a computer-assisted verification — that are out of

scale for a chapter. The treatise’s rule then requires one to state, not to prove: and to say so.

Independent check. The same balance sheet is obtained mechanically by running the script `registro_importati.py` on the volume and reading the lines relating to that chapter: the result is the three observations listed, and no others. The automatic check and the manual count agree.

Typical errors. Counting among the panoramas results that are merely *mentioned* in a sentence of context: a panorama is an explicit declaration of what is not proved, not a mention. And counting among the proved results the applicative count of the tubes without noting that it holds under the declared hypothesis that the pallet be much larger than the radius.

Extension. Repeat the balance sheet for Chapter 13, which has the opposite proportion: many statements proved about the circle and four panoramas, all relating to generalizations (Remarks 13.2, 13.4, 13.6, 13.8).

33.9. Self-assessment quiz

- (Definition) In this treatise a *panorama* is
 - a result whose proof is deferred to an appendix
 - a theorem exposed in an observation or in an infobox, not proved here, with the source indicated
 - an exercise left to the reader
 - a synthesis chapter like this one
- (Hypothesis) Which property of S^1 is the ultimate reason why Part C can develop the Fourier series, the transform, the DFT and the FFT in the form used?
 - compactness, alone
 - being an *abelian* group, as well as compact and connected
 - being a differentiable manifold of dimension 1
 - having fundamental group $\mathbb{Z}$
- (Symbolic computation) Derived as the ratio between the area of the circle of radius r and that of the regular hexagon of apothem r , the density of the triangular packing equals
 - $\frac{\pi}{2\sqrt{3}}$
 - $\frac{\pi}{4}$
 - $\frac{\pi}{4\sqrt{3}}$
 - $\frac{2\pi}{3\sqrt{3}}$
- (Numerical computation) For the ramp $x = (0, 1, \dots, 15)$ with $N = 16$, the sum $\sum_k |X[k]|^2$ equals
 - 1,240
 - 19,840
 - 1,120
 - 240
- (Proof step) In Example 33.3 the sum of the seven terms $|X[k]|^2$ with $k \neq 0$ equals 336 because
 - the seven terms are all equal
 - the pairs $k = 1, 7$ and $k = 3, 5$ give $2(64 + 32\sqrt{2}) + 2(64 - 32\sqrt{2}) = 256$, in which the terms in $\sqrt{2}$ cancel, and $32 + 32 + 16 = 80$ remain
 - $336 = 8 \cdot 42$
 - Parseval’s identity forces that value
- (Error diagnosis) A report states that, “as is proved in Volume III, the densest way to arrange equal spheres in space is the face-centered one.” The error is that
 - there is no error
 - the volume exposes it as a panorama, without proving it
 - the statement is false
 - the statement concerns only $\mathbb{R}^2$
- (Transfer) To establish whether a digital filter is stable, and then whether it remains so once a feedback loop is closed, the correct reading path is

- A) Chapter 31, then Chapter 11 B) Chapter 21 (region of convergence and poles inside $|z| = 1$), then Chapter 25 (argument principle and Nyquist criterion) C) Chapter 23, then Chapter 22 D) Chapter 12, then Chapter 13
8. (Source and metacognition) The *up-to-date* list of what Volume III imports and of what it exposes as panorama is obtained
- A) by reading the analytic index B) by running on the sources the script that lists the blocks in which an import or a panorama is declared C) from the volume's general bibliography D) from Appendix A of the prerequisites

33.10. Teacher's key

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 1–4).

1) **B.** *Rationale:* this is the third rule of the double register (Remark 33.3): results not proved here stand in *osservazione* or *infobox* environments, never in *teorema* environments, and carry the source. The complete list is in Section 33.3.2. *Distractors:* A confuses the panorama with an internal cross-reference, and Appendix A contains prerequisites, not panoramas; C confuses what the text does not prove with what it asks the reader to do; D confuses a category of statements with a type of chapter. *Diagnosed error:* not distinguishing the three forms of the text's debt (prerequisite, panorama, import). *Source:* Section 33.3. *Prerequisite:* none. *Recovery:* open three observations from the list in Section 33.3.2 and check that each names the result, says that it does not prove it, and indicates where to find it.

2) **B.** *Rationale:* commutativity is what makes the characters complex-valued functions (Theorem 13.5), hence the coefficients numbers and not matrices; this is the content of Remark 33.1. *Distractors:* A is necessary — it is needed to have a finite Haar measure, Theorem 13.4 — but not sufficient, as $SO(3)$ shows, which is compact and non-abelian; C is also true for the line, which has no Fourier series; D is a topological property that plays no role in the construction of harmonic analysis. *Diagnosed error:* mistaking a necessary condition for the decisive one. *Source:* Chapter 13. *Prerequisite:* Theorem 13.5. *Recovery:* reread Remark 33.1 and say which step of Chain D would break if the group were not abelian.

3) **A.** *Rationale:* the hexagon of apothem r has side $L = 2r/\sqrt{3}$ and area $6 \cdot \frac{Lr}{2} = 2\sqrt{3}r^2$; the ratio with πr^2 is $\pi/(2\sqrt{3}) = \pi/\sqrt{12} = 0.9068997$ (Example 33.1, Theorem 14.4). *Distractors:* B is the density of the *square* lattice, that is, the ratio between the circle and the circumscribed square, and equals 0.7853982; C equals 0.4534498 and is obtained by forgetting the factor $\frac{1}{2}$ in the area of the six triangles, that is, writing $A_{\text{hexagon}} = 6Lr = 4\sqrt{3}r^2$; D equals 1.2091996 and arises from swapping apothem and side (hexagon of side r , of area $\frac{3\sqrt{3}}{2}r^2$), and must be discarded without computation because a density cannot exceed 1. *Diagnosed error:* getting the lattice cell wrong, confusing apothem and side, or getting the area of the regular polygon wrong. *Source:* Chapter 14. *Prerequisite:* area of the regular hexagon (Volume I, Chapter 6). *Recovery:* redo the computation drawing the cell and marking which segment equals r .

4) **B.** *Rationale:* $\sum_{n=0}^{15} n^2 = \frac{15 \cdot 16 \cdot 31}{6} = 1,240$ and Theorem 22.6 gives $\sum_k |X[k]|^2 = N \sum_n |x[n]|^2 = 16 \cdot 1,240 = 19,840$; this is item (a) of Exercise 33.3. *Distractors:* A is $\sum_n |x[n]|^2$, that is, the *right* side without the factor N ; C is the value for $N = 8$ from Example 33.3, reported without redoing the computation; D is $2 \sum_n x[n] = 2 \cdot 120 = 240$, that is, twice $X[0]$: a number that appears in the computation but is neither of the two

sides. *Diagnosed error*: forgetting the factor N in the discrete form of the identity. *Source*: Theorem 22.6. *Prerequisite*: sum of the first squares. *Recovery*: check the case $N = 8$ of Example 33.3, where $140 \cdot 8 = 1,120$, and then redo $N = 16$.

BEST PRACTICE

Quiz — answers, rationale and diagnosis (items 5–8).

5) **B**. *Rationale*: the four terms with $k \in \{1, 3, 5, 7\}$ are, in pairs, $64 + 32\sqrt{2}$ and $64 - 32\sqrt{2}$, and add up to 256 because the irrational parts cancel; the three remaining give $32 + 32 + 16 = 80$; in total 336 (Example 33.3). *Distractors*: A is false, the terms equal 109.2548, 32, 18.7452 and 16; C is a true arithmetic remark but with no content, which does not explain where 336 comes from; D is the circular answer, that is, using the thesis as the reason: it is exactly what verification by two independent ways is meant to avoid (Remark 33.6). *Diagnosed error*: accepting as a check a piece of reasoning that presupposes the result to be checked. *Source*: Example 33.3. *Prerequisite*: rationalization of $64/(2 \pm \sqrt{2})$. *Recovery*: redo the computation writing out the seven values in full and adding them in the order $k = 1, \dots, 7$.

6) **B**. *Rationale*: the result is true and proved — by Hales — but not in this volume, which exposes it as a panorama in Remark 14.5; writing “as proved in Volume III” attributes to the text a proof that it declares it does not give. This is the *tacit promotion* of Remark 33.4. *Distractors*: A is the answer of someone who does not distinguish the registers; C is false, the Kepler conjecture is a theorem; D is false, the volume also treats the three-dimensional case, but precisely as a panorama. *Diagnosed error*: citing as proved what was read in an observation. *Source*: Chapter 14. *Prerequisite*: Section 33.3.2. *Recovery*: rewrite the sentence in correct form, with the primary source in place of the volume.

7) **B**. *Rationale*: the stability of the isolated filter is read on the region of convergence (Theorem 21.1) and on the position of the poles relative to $|z| = 1$; the stability of the closed loop is the Nyquist criterion (Theorem 25.5), which is the argument principle (Theorem 25.4) applied to the transfer function. This is Chain E of Section 33.1.4. *Distractors*: A concerns the estimation of parameters from data, not stability; C concerns the *computation* of the transform, not its region of convergence — a very frequent confusion; D contains the conceptual tool (the winding number) but not the operational criterion, and by itself does not answer. *Diagnosed error*: looking for the answer in the chapter that contains the right word rather than in the one that contains the right statement. *Source*: Chapters 21 and 25. *Prerequisite*: Theorem 21.6. *Recovery*: go through Chain E link by link, saying, at each step, which question that link solves.

8) **B**. *Rationale*: the balance sheet is generated from the sources, not transcribed by hand; this is stated explicitly in Remark 33.5, which also warns that the printed table is the snapshot of one edition. *Distractors*: A gives the occurrences of terms, not the status of what is proved; C lists the works cited, not what the volume assumes; D contains the *prerequisites*, which are the first of the three categories and not the other two. *Diagnosed error*: confusing the bibliographic apparatus with the epistemic balance sheet of the text. *Source*: Remark 33.5. *Prerequisite*: none. *Recovery*: run the script and compare its result with the table of Section 33.3.3, noting the differences.

BEST PRACTICE

Assigned exercises — answers.

Exercise 33.1. A correct answer has five links. (1) Volume I, Chapter 5: circular inversion, which sends circles and lines to circles and lines. (2) Volume II, Chapter 3, and Chapter 6, Theorem 6.6: the Möbius transformations send generalized circles to generalized circles; the link uses from the previous one the fact that a line and a circle must be treated as a single

object. (3) Chapter 7, Theorem 7.6: the stereographic projection is conformal and sends circles to circles or lines; it uses from the previous one the notion of generalized circle, and realizes that notion as a “circle on the sphere.” Here the chain leaves the Euclidean plane, item (c): the line stops being a degenerate case and becomes the circle passing through the pole. (4) Chapter 14, Theorem 14.2: two Ford circles are tangent or disjoint; tangency is a contact condition preserved by the transformations of item (2). (5) Theorem 14.1: tangent Ford circles correspond to consecutive fractions in the Farey sequence, that is, to $|ad - bc| = 1$. For item (d): the chain contains a panorama, the circle packing theorem of Remark 14.6, and an import concerning the rotations of the sphere as Möbius transformations (Remark 6.6).

Exercise 33.2. (a) Proved: Theorem 4.5. (b) Panorama: Remark 14.5; the entire proof by Hales is missing, in particular the computer-assisted part. (c) Imported: Remark 9.1; the proof of the Picard–Lindelöf theorem is missing, used for the local existence and uniqueness of geodesics. (d) Proved: Theorem 23.3, by complete induction. (e) Panorama: Remark 17.9; the proof of Carleson’s theorem is missing, and the chapter instead proves convergence in L^2 (Theorem 17.1) and pointwise convergence under the hypothesis of bounded variation (Theorem 17.4). (f) Imported: Remark 23.11; the proof of the cyclicity of the multiplicative group $(\mathbb{Z}/p\mathbb{Z})^*$ is missing, used once in Rader’s algorithm.

Exercise 33.3. (a) $\sum_{n=0}^{15} n^2 = \frac{15 \cdot 16 \cdot 31}{6} = 1,240$, hence the right side equals $16 \cdot 1,240 = 19,840$. The left side, with $X[0] = 120$ and $|X[k]|^2 = 256/(2 - 2\cos(\pi k/8))$, gives 14,400 from the term $k = 0$ and 5,440 from the other fifteen, in total 19,840. The script confirms 19,840.000000 with discrepancy $2.9 \cdot 10^{-11}$. ✓ (b) $192 \sin(\pi/192) = 3.1414525$ and $192 \tan(\pi/192) = 3.1418730$; the doubling recursion, starting from $\ell_6 = 1$ and doubling five times, gives the same 3.1414525. The gap between the two semiperimeters goes from $3.1427146 - 3.1410320 = 1.68 \cdot 10^{-3}$ for $n = 96$ to $3.1418730 - 3.1414525 = 4.21 \cdot 10^{-4}$ for $n = 192$: it shrinks by a factor 4.0008, that is, 4 to within one part in a thousand, as it must, because the width of the gap is $O(n^{-2})$ and the number of sides doubles. ✓ (c) In the square lattice the cell of each circle of radius r is the square of side $2r$, of area $4r^2$; the density is $\pi r^2/(4r^2) = \pi/4 = 0.7853982$. The ratio between the two densities is $\frac{\pi/\sqrt{12}}{\pi/4} = \frac{4}{\sqrt{12}} = \frac{2}{\sqrt{3}} = 1.1547005$: the triangular lattice is denser by 15.47%. The ratio does not depend on r because both densities are ratios between areas that scale as r^2 , and the factor r^2 cancels: it is the same invariance under similarity that Volume I attributes to π .

33.11. Chapter formulary

The five chains, one line each.

A — Measure $\ell = r\theta$, $A = \pi r^2 \rightarrow L^2 \geq 4\pi A \rightarrow \text{vol}(B^n) \rightarrow 0 \rightarrow \pi/\sqrt{12}$.

B — Group $e^{i(\alpha+\beta)} = e^{i\alpha}e^{i\beta} \rightarrow \mathbb{T} \cong SO(2) \rightarrow \chi_n(z) = z^n \rightarrow S^3 \rightarrow SO(3) \rightarrow SE(3)$, screw motion.

C — Curvature $\kappa \equiv 1/r \rightarrow \kappa \text{ constant} \Rightarrow \text{circle} \rightarrow (\kappa, \tau) \text{ determines the curve} \rightarrow \int \kappa ds \in 2\pi\mathbb{Z} \rightarrow G02/G03$.

D — Fourier orthogonality of the roots $\rightarrow$ characters of $S^1 \rightarrow$ completeness in $L^2 \rightarrow$ Poisson and Dirichlet $\rightarrow$ transform $\rightarrow$ DFT $\rightarrow$ FFT $\rightarrow$ OFDM.

E — Stability phasor $\rightarrow$ residues $\rightarrow$ half-plane $\text{Re } s < 0 \rightarrow$ annulus $|z| < 1 \rightarrow$ turns of the Nyquist diagram = winding number.

The chapter’s three check numbers.

$$\frac{\pi}{\sqrt{12}} = \frac{\pi}{2\sqrt{3}} = \frac{A_{\text{circle}}}{A_{\text{hexagon of apothem } r}} = 0.9068997, \quad \frac{\pi}{4} = 0.7853982 \text{ (square lattice),}$$

$$n \sin \frac{\pi}{n} < \pi < n \tan \frac{\pi}{n}, \quad \ell_{2n} = \sqrt{2 - \sqrt{4 - \ell_n^2}}, \quad \ell_6 = 1;$$

$$96 \sin \frac{\pi}{96} = 3.1410320, \quad 96 \tan \frac{\pi}{96} = 3.1427146, \quad \frac{223}{71} = 3.1408451, \quad \frac{22}{7} = 3.1428571;$$

$$\sum_{k=0}^{N-1} |X[k]|^2 = N \sum_{n=0}^{N-1} |x[n]|^2 : \quad N = 8 : 1,120 = 8 \cdot 140, \quad N = 16 : 19,840 = 16 \cdot 1,240.$$

For the ramp $x[n] = n$: $X[0] = \frac{N(N-1)}{2}$ and $|X[k]|^2 = \frac{N^2}{2 - 2 \cos(2\pi k/N)}$ for $k \neq 0$.

The balance sheet in three categories.

Category	Where it stands	What it guarantees
Prerequisite	Appendix A, infobox	standard, independent of the circle
Panorama	<i>osservazione</i> , <i>infobox</i>	statement with source, not proved
Import	<i>osservazione</i> “imported”	proof closed except for one link

Operational rule: *no teorema environment without a complete proof*; the check is `audit_dimostrazioni.py`, the census of imports is `registro_importati.py`.

The five drafting rules. (1) No proof left half-done; what does not close is declared imported. (2) Every value by two independent ways, with the discrepancy reported and the sign ✓. (3) Every source with authors, title, venue, year, pages and date of verification. (4) Every figure with computed and checked coordinates. (5) Three languages with the same labels, the same statements and the same numbers.

Sources and bibliography

[1] The statements of this chapter are statements *about the treatise*: each is verifiable by opening the place indicated by the label. The external sources of the results cited stand in the *Fonti* environments of the chapters that prove or declare them, and are not repeated here; the complete list, one line per central statement, is in the source register of Volume III, which collects author, title, venue, year, pages and date of verification for every entry cited in the volume. *Verified on 7 September 2026*.

[2] *Master Plan — The Circle: complete guidelines*, a project document of the treatise. It is the source of the perimeter of the work and of the correspondence between its chapters and the three volumes, used in Section 33.1. *Verified on 7 September 2026* (chapter-by-chapter correspondence rechecked against the volume’s list of sources).

[3] *Executive Plan of Volumes II and III*, a project document of the treatise, §3.4 (content and origin of each chapter of Volume III) and §6.1 (apparatuses of the volume, including this epilogue with the map of the three volumes). It is the source of the structure in six Parts and of the division of contents between Volume II and Volume III described in Sections 33.1.2 and 33.1.3. *Verified on 7 September 2026*.

[4] *Structure and compilation of the treatise*, a maintenance document of the repository: writing conventions (decimal separator, identical labels across the three languages), the list of the model’s environments and of the checking tools (`audit_dimostrazioni.py`, `registro_importati.py`, `parita_lingue.py`, `verifica_coerenza.py`). It is the source of the five drafting rules of Section 33.6. *Verified on 7 September 2026*.

[5] The three numerical checks of Section 33.4 and the answers to Exercise 33.3 were carried

out with a Python script in double precision, which computes each value by the two ways described in the text and prints the discrepancy; the discrepancies reported ($2.2 \cdot 10^{-16}$, $2.0 \cdot 10^{-14}$, $2.0 \cdot 10^{-12}$ and $2.9 \cdot 10^{-11}$) are those actually obtained. *Executed and verified on 7 September 2026.*

A further chain: from motion to control

Rigid-body kinematics describes motion; the mass matrix in Proposition 36.1 measures its energy. Theorem 36.3 connects forces and coordinates, while Theorem 36.4 reduces the ideal error to a linear system. Kalman's rank criterion, Theorem 34.1, decides whether its state can be controlled. The recursion in Theorem 35.1 reconstructs the state from noisy data under its stated assumptions. Finally, Theorem 37.1 gives the sampled model and Theorem 37.3 provides synthesis in the unit disk. The disk as a universal conformal domain is now Theorem 15.21; lattice points remain a boundary between proved results and open research, not a promise of a solution.

Part G

State, estimation, dynamics and digital control

State-space control

INFO

Level C–D. Prerequisites: real and complex linear algebra, Cayley–Hamilton, quadratic forms, matrix integrals and series. Linear dynamics connects to the rotation exponential in Chapter 28; discrete synthesis connects to the Z transform in Chapter 21, not the DFT in Chapter 22. The physical model is assumed; reachability, estimation and optimality consequences are proved. References for comparison: [2, 3].

34.1. The model and its solution

Definition 34.1: Continuous-time linear system. The state $x(t) \in \mathbb{R}^n$, input $u(t) \in \mathbb{R}^m$ and output $y(t) \in \mathbb{R}^p$ satisfy

$$\dot{x} = Ax + Bu, \quad y = Cx + Du.$$

The matrices are constant and real. On finite intervals inputs belong to L^2 , hence also to L^1 . State equations hold almost everywhere for absolutely continuous functions.

Proposition 34.1: Variation of constants.

$$x(t) = e^{At}x_0 + \int_0^t e^{A(t-s)}Bu(s)ds.$$

This is the unique solution with $x(0) = x_0$.

Proof. In a submultiplicative norm, $e^{At} = \sum_{j \geq 0} A^j t^j / j!$ converges uniformly on bounded intervals, dominated by $e^{\|A\||t|}$. The differentiated series also converges uniformly and gives $(e^{At})' = Ae^{At}$. The product $e^{-At}e^{At}$ has derivative zero and initial value I , so it equals I . Multiply the state equation by e^{-At} and differentiate the product:

$$\frac{d}{dt}(e^{-At}x(t)) = e^{-At}Bu(t).$$

Integrate and multiply by e^{At} to obtain the formula. Conversely, differentiation verifies the equation and initial condition. For two solutions with the same data, e^{-At} times their difference has derivative zero and initial value zero: the difference vanishes. $\square$

34.2. Controllability and observability

Theorem 34.1: Kalman rank criterion. Fix any $T > 0$. Every final state is reachable from zero at time T if and only if

$$\text{rank } \mathcal{C} = n, \quad \mathcal{C} = [B \ AB \ \cdots \ A^{n-1}B].$$

In this case every transfer between two states is possible in the same time.

Proof. 1. Gramian. Set

$$W_T = \int_0^T e^{As} B B^\top e^{A^\top s} ds, \quad v^\top W_T v = \int_0^T \|B^\top e^{A^\top s} v\|^2 ds.$$

Thus W_T is symmetric positive semidefinite. If the last quantity vanishes, its continuous nonnegative integrand vanishes for every s . Differentiation at $s = 0$ gives $v^\top A^j B = 0$ for all $j \geq 0$. Conversely, if these equalities hold for $0 \leq j < n$, Cayley–Hamilton extends them to every power: A^n is a combination of preceding powers, and induction applies. The exponential series then gives $B^\top e^{A^\top s} v = 0$. Consequently

$$\ker W_T = \ker \mathcal{C}^\top, \quad W_T > 0 \iff \text{rank } \mathcal{C} = n.$$

2. Necessity. If the rank is less than n , take $v \neq 0$ in $\ker \mathcal{C}^\top$. For any input, the solution formula gives $v^\top x(T) = 0$ when $x_0 = 0$. The state v cannot be reached because $v^\top v > 0$.

3. Constructive sufficiency. If $W_T > 0$, for target x_f and initial state x_0 set $d = x_f - e^{AT} x_0$ and choose

$$u_*(s) = B^\top e^{A^\top(T-s)} W_T^{-1} d.$$

Substitution in the solution, with $r = T - s$, makes the integral equal $W_T W_T^{-1} d = d$. Hence $x(T) = x_f$. The input is continuous and belongs to $L^2[0, T]$. $\square$

Corollary 34.1: Minimum transfer energy. Among all inputs realizing that transfer, u_* uniquely minimizes $\int_0^T \|u\|^2 ds$, and the minimum is $d^\top W_T^{-1} d$.

Proof. Write $u = u_* + v$. The difference leaves the final state unchanged, so $\int_0^T e^{A(T-s)} B v(s) ds = 0$. Hence

$$\int_0^T u_*^\top v ds = d^\top W_T^{-1} \int_0^T e^{A(T-s)} B v(s) ds = 0.$$

Expanding the square gives $\|u\|_{L^2}^2 = \|u_*\|_{L^2}^2 + \|v\|_{L^2}^2$. Substituting u_* makes the first term $d^\top W_T^{-1} d$; equality requires $v = 0$ almost everywhere. $\square$

Theorem 34.2: Observability and duality. With known input, the initial state is uniquely determined by the output on $[0, T]$, $T > 0$, if and only if

$$\text{rank } \mathcal{O} = n, \quad \mathcal{O} = \begin{bmatrix} C \\ CA \\ \vdots \\ CA^{n-1} \end{bmatrix}.$$

This is exactly controllability of the dual pair $(A^\top, C^\top)$.

Proof. Subtract from y the known-input response, including Du , to obtain $\tilde{y}(t) = Ce^{At}x_0$. Define

$$W_o = \int_0^T e^{A^\top t} C^\top C e^{At} dt.$$

Theorem 34.1, applied to $(A^\top, C^\top)$, gives $W_o > 0$ exactly when $\mathcal{O}$ has full rank. If $W_o > 0$,

$$x_0 = W_o^{-1} \int_0^T e^{A^\top t} C^\top \tilde{y}(t) dt.$$

If W_o is singular, a vector $v \neq 0$ in its kernel satisfies $Ce^{At}v = 0$ for every t , by the same nonnegative integral identity. The states x_0 and $x_0 + v$ produce identical outputs and cannot be distinguished. $\square$

34.3. Pole placement: a construction, not a promise

Theorem 34.3: Ackermann's formula for one input. If (A, b) is controllable and $p(\lambda) = \lambda^n + \sum_{j=0}^{n-1} d_j \lambda^j$ has real coefficients, the feedback $u = -Kx$ with

$$K = e_n^\top C^{-1} p(A)$$

makes p the characteristic polynomial of $A - bK$.

Proof. Let $r = e_n^\top C^{-1}$. Then $rA^j b = 0$ for $j < n-1$ and $rA^{n-1}b = 1$. Form S with rows $r, rA, \dots, rA^{n-1}$. The product SC has zeros before the antidiagonal and ones on it, so it is invertible, as is S . In coordinates $z = Sx$, $Sb = e_n$. The first $n-1$ rows of SAS^{-1} shift a coordinate to the next one. If $\det(\lambda I - A) = \lambda^n + \sum a_j \lambda^j$, Cayley–Hamilton gives last row $(-a_0, \dots, -a_{n-1})$.

$$SAS^{-1} = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & & & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ -a_0 & -a_1 & -a_2 & \cdots & -a_{n-1} \end{bmatrix}.$$

Feedback in the new basis, $u = -\sum (d_j - a_j)z_{j+1}$, replaces the last row by $(-d_0, \dots, -d_{n-1})$. Expanding $\det(\lambda I - A_c)$ recursively along the first column of the companion matrix gives $p(\lambda)$. Returning to x ,

$$K = \sum_{j=0}^{n-1} (d_j - a_j) r A^j = r \left(A^n + \sum_{j=0}^{n-1} d_j A^j \right) = r p(A).$$

The last equality again uses Cayley–Hamilton. A desired multiset of roots closed under conjugation has a real monic polynomial; conjugate complex poles and repeated poles are both included. $\square$

Theorem 34.4: Extension to multiple inputs. If (A, B) is controllable, every real monic polynomial of degree n is the characteristic polynomial of $A - BK$ for some real matrix K .

Proof. Choose $b = B\beta \neq 0$ and build a basis $v_1 = b, v_2, \dots, v_n$ with $v_{j+1} = Av_j + Bu_j$. Suppose $k < n$ independent vectors have been constructed and let $V_k = \text{span}(v_1, \dots, v_k)$. If no choice of u_k produces a vector outside V_k , then $Av_k \in V_k$ and $\text{im } B \subset V_k$. The preceding relations also give $Av_j = v_{j+1} - Bu_j \in V_k$ for $j < k$. Thus V_k is A -invariant and contains $\text{im } B$, hence every column of $\mathcal{C}$, contradicting rank n . The basis can therefore be completed.

Define F by $Fv_j = u_j$ for $j < n$ and choose any value on v_n . Then $(A + BF)^{j-1}b = v_j$ for $1 \leq j \leq n$, so $(A + BF, b)$ is single-input controllable. Theorem 34.3 gives a row k assigning the polynomial to $A + BF - bk$. Since $b = B\beta$, set $K = \beta k - F$. $\square$

Corollary 34.2: Observer and separation principle. *If (A, C) is observable, the poles of $A - LC$ can be assigned arbitrarily. With*

$$\dot{\hat{x}} = A\hat{x} + Bu + L(y - C\hat{x} - Du), \quad u = -K\hat{x},$$

the combined poles are those of $A - BK$ and $A - LC$, counted with multiplicity.

Proof. Apply pole placement to the dual pair $(A^\top, C^\top)$ and transpose the gain. With $e = x - \hat{x}$, subtracting the equations gives $\dot{e} = (A - LC)e$ and

$$\frac{d}{dt} \begin{bmatrix} x \\ e \end{bmatrix} = \begin{bmatrix} A - BK & BK \\ 0 & A - LC \end{bmatrix} \begin{bmatrix} x \\ e \end{bmatrix}.$$

The determinant of a block triangular matrix is the product of its diagonal-block determinants. $\square$

34.4. Finite-horizon LQR

Lemma 34.1: Local existence for the Riccati equation. *A matrix equation $\dot{P} = F(P)$ with polynomial F has a unique local solution for every initial value. A solution bounded on a finite interval extends to its endpoint.*

Proof. On a closed ball around P_0 , F is bounded by M and Lipschitz with constant L , because its derivative is continuous and bounded. Choose h with hM smaller than the radius and $hL < 1$. The operator $\mathcal{T}P(t) = P_0 + \int_0^t F(P(s))ds$ maps continuous functions in the ball to themselves and contracts the uniform distance by hL . Differences of successive iterates are dominated by a geometric series, so the iterates converge uniformly. The limit solves the integral equation and hence the differential equation. The same contraction gives uniqueness. If P stays bounded, so does $F(P)$; thus P is uniformly Lipschitz in time and has a limit at the endpoint. Restart the local construction from that limit. $\square$

Theorem 34.5: Riccati and completion of the square. *Let $Q = Q^\top \geq 0$, $R = R^\top > 0$, $S = S^\top \geq 0$ and $T < \infty$. For the state system, the cost*

$$J_T(u) = x(T)^\top Sx(T) + \int_0^T (x^\top Qx + u^\top Ru) dt$$

has minimum $x_0^\top P(0)x_0$, uniquely attained by $u_ = -R^{-1}B^\top P(t)x$, where*

$$-\dot{P} = A^\top P + PA - PBR^{-1}B^\top P + Q, \quad P(T) = S.$$

This equation has a symmetric positive semidefinite solution on all of $[0, T]$.

Proof. 1. Identity. Begin with the local solution of Lemma 34.1, integrated backwards. Its transpose solves the same equation with the same data, so $P = P^\top$. Set $K = R^{-1}B^\top P$.

Differentiate $x^\top Px$ and substitute the two equations:

$$\begin{aligned}\frac{d}{dt}(x^\top Px) &= x^\top (\dot{P} + A^\top P + PA)x + 2x^\top PBu \\ &= -x^\top Qx + x^\top K^\top RKx + 2x^\top K^\top Ru \\ &= -x^\top Qx - u^\top Ru + (u + Kx)^\top R(u + Kx).\end{aligned}$$

Integrating from t to T ,

$$J_{[t,T]}(u) = x(t)^\top P(t)x(t) + \int_t^T (u + Kx)^\top R(u + Kx) ds.$$

The choice $u = -Kx$ makes the integral zero; every other choice makes it positive unless equality holds almost everywhere. The closed linear system has a unique solution, so the optimal input is unique.

2. No Riccati blow-up. The cost is nonnegative, so the optimal choice shows $P(t) \geq 0$ wherever the solution exists. The cost of $u = 0$ gives, for every initial vector ξ ,

$$0 \leq \xi^\top P(t)\xi \leq \xi^\top \left[e^{A^\top(T-t)} S e^{A(T-t)} + \int_0^{T-t} e^{A^\top s} Q e^{As} ds \right] \xi.$$

The bracketed matrix is uniformly bounded for $0 \leq t \leq T$. For symmetric positive semidefinite matrices, this also bounds the norm of P . The continuation lemma extends the solution to zero. The identity in step 1 therefore holds over the entire interval. $\square$

34.5. Infinite horizon: hypotheses and existence proved

Definition 34.2: Stabilizability and detectability. A matrix is Hurwitz when every eigenvalue has negative real part. The pair (A, B) is stabilizable if some F makes $A - BF$ Hurwitz. The pair (H, A) is detectable if some L makes $A - LH$ Hurwitz. Here $H = Q^{1/2}$, the symmetric positive semidefinite square root of Q .

Theorem 34.6: Stabilizing solution of the algebraic Riccati equation. Under stabilizability and detectability, with $Q \geq 0$ and $R > 0$, there is a symmetric solution $P \geq 0$ of

$$A^\top P + PA - PBR^{-1}B^\top P + Q = 0.$$

The matrix $A - BR^{-1}B^\top P$ is Hurwitz. Feedback $u_* = -R^{-1}B^\top Px$ minimizes $J_\infty = \int_0^\infty (x^\top Qx + u^\top Ru)dt$, with value $x_0^\top Px_0$. The stabilizing solution is unique. Positive definiteness $P > 0$ is not asserted without an additional hypothesis.

Proof. 1. Monotone limit. Let P_T be the initial value matrix of the finite problem with terminal weight $S = 0$. Extending the horizon adds nonnegative cost, so $x_0^\top P_T x_0$ increases with T for every x_0 . Stabilizing feedback $u = -Fx$ provides the upper bound

$$P_T \leq \bar{P} = \int_0^\infty e^{(A-BF)^\top t} (Q + F^\top RF) e^{(A-BF)t} dt.$$

The integral converges: Jordan form shows that the exponential of a Hurwitz matrix is bounded by $Me^{-\alpha t}$, absorbing polynomial block factors into a slightly slower exponential. Bounded monotone quadratic forms have limits. Applying this to basis vectors and their sums yields, by polarization, a matrix limit $P \geq 0$.

2. Algebraic equation. By time invariance, P_T , regarded as a function of T , satisfies

$$\frac{dP_T}{dT} = A^\top P_T + P_T A - P_T B R^{-1} B^\top P_T + Q, \quad P_0 = 0.$$

The right-hand side converges to the same expression in P . If any limiting component were nonzero, the corresponding derivative would eventually have fixed sign and modulus bounded away from zero, preventing that component of P_T from converging. The limiting right-hand side is therefore zero, giving the algebraic equation.

3. Stability. Set $K = R^{-1} B^\top P$ and $A_c = A - BK$. Riccati implies

$$A_c^\top P + P A_c = -Q - K^\top R K.$$

If $A_c v = \lambda v$ for a nonzero complex vector,

$$2 \operatorname{Re} \lambda v^* P v = -\|Hv\|^2 - \|R^{1/2} K v\|^2.$$

For $\operatorname{Re} \lambda \geq 0$, the left side is nonnegative and the right side nonpositive, so $Hv = Kv = 0$. Then $Av = \lambda v$ and $(A - LH)v = \lambda v$, contradicting detectability. Thus A_c is Hurwitz.

4. The boundary term cannot be ignored. For an input of finite cost, u and Hx belong to $L^2[0, \infty)$. Write

$$\dot{x} = (A - LH)x + v(t), \quad v = Bu + LHx \in L^2.$$

Variation of constants gives $x(t) \rightarrow 0$. Specifically, split the convolution into $[0, S]$ and $[S, t]$. The first integral tends to zero by exponential kernel decay and integrability of v on $[0, S]$. Cauchy–Schwarz bounds the second by $(\int_0^\infty M^2 e^{-2\alpha s} ds)^{1/2} \|v\|_{L^2(S, \infty)}$. First let $t \rightarrow \infty$, then $S \rightarrow \infty$. Thus $x(t)^\top P x(t) \rightarrow 0$. Integrating the completed-square identity with constant P gives

$$J_\infty(u) = x_0^\top P x_0 + \int_0^\infty (u + Kx)^\top R(u + Kx) dt.$$

The input $u_* = -Kx$ has finite cost since A_c is Hurwitz, and makes the integral zero. Infinite-cost inputs cannot improve it.

5. Stabilizing uniqueness. For two symmetric stabilizing solutions P_1, P_2 , set $G = BR^{-1}B^\top$ and $D = P_1 - P_2$. Subtracting their Riccati equations gives

$$(A - GP_1)^\top D + D(A - GP_2) = 0.$$

The derivative of $e^{(A-GP_1)^\top t} D e^{(A-GP_2)t}$ is zero, so this product always equals D . Stability makes it tend to zero; hence $D = 0$. $\square$

Remark 34.1: Semidefinite does not mean definite. For $A = -1$, $B = 1$, $Q = 0$, $R = 1$, the system is stabilizable and detectable, but $P = 0$ and the minimum cost is zero with $u = 0$. Thus the plan's assertion $P > 0$ needs correction. If $(Q^{1/2}, A)$ is observable instead, $x_0^\top P x_0 = 0$ forces, under the optimum, $u = 0$ and $Q^{1/2} e^{At} x_0 = 0$ for every t . Observability forces $x_0 = 0$, hence $P > 0$.

34.6. Discrete time and a checkable example

Proposition 34.2: Discrete reachability and observability. For $x_{k+1} = Ax_k + Bu_k$, $y_k = Cx_k + Du_k$, we have

$$x_N = A^N x_0 + \sum_{j=0}^{N-1} A^{N-1-j} Bu_j.$$

Reachability from zero in n steps is equivalent to full rank of $\mathcal{C}$; observability from $y_0, \dots, y_{n-1}$ is equivalent to full rank of $\mathcal{O}$. Pole-placement theorems remain unchanged because they are algebraic.

Proof. The formula for x_N follows by induction: multiply the formula for N by A and add Bu_N . For $N = n$, the final vector from zero is $\mathcal{C}(u_{n-1}^\top, \dots, u_0^\top)^\top$, so it is arbitrary exactly when $\mathcal{C}$ is onto. For $N > n$, Cayley–Hamilton prevents growth of the reachable space. Subtract known-input contributions from the outputs; the stacked vector is $\mathcal{O}x_0$, which identifies x_0 exactly when $\ker \mathcal{O} = \{0\}$. $\square$

In discrete time, driving every state to zero is not synonymous with reachability from zero: with $A = 0$, $B = 0$, every state disappears in one step, but no nonzero state is reachable from zero. Asymptotic stability requires $|\lambda(A)| < 1$; Jordan form proves this because $k^j |\lambda|^k \rightarrow 0$, while an eigenvector with $|\lambda| \geq 1$ prevents decay.

Example 34.1: An oscillator, two pole checks. Consider $\ddot{q} + \dot{q} + 4q = u$, with $x = (q, \dot{q})^\top$ and output q . Parameters are $\omega_n = 2$ and $\zeta = 1/4$, using the elastic-mode conventions of Chapter 30.

$$A = \begin{bmatrix} 0 & 1 \\ -4 & -1 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \quad C = \begin{bmatrix} 1 & 0 \end{bmatrix}, \quad \mathcal{C} = \begin{bmatrix} 0 & 1 \\ 1 & -1 \end{bmatrix}, \quad \mathcal{O} = I.$$

The determinant of $\mathcal{C}$ is -1 . For poles $-3, -4$, the desired polynomial is $s^2 + 7s + 12$. With $K = (k_1, k_2)$, the closed polynomial is $s^2 + (1 + k_2)s + 4 + k_1$, hence $K = (8, 6)$. Ackermann's formula, calculated separately, gives the same result. Finally

$$A - BK = \begin{bmatrix} 0 & 1 \\ -12 & -7 \end{bmatrix}, \quad \det(sI - A + BK) = (s + 3)(s + 4).$$

The code also computes the numerical eigenvalues directly, rather than inferring them only from the coefficients.

34.7. Assigned and worked exercises

Exercise 34.1: Complete scalar LQR. For $\dot{x} = u$, $Q = R = 1$, $S = 0$, derive $P(t)$, $x_*(t)$ and the cost.

Solution. Riccati is $-\dot{P} = 1 - P^2$, with $P(T) = 0$. Separating variables gives $\operatorname{artanh} P = T - t$, hence $P(t) = \tanh(T - t)$. Integrating $\dot{x} = -P(t)x$ gives

$$x_*(t) = x_0 \frac{\cosh(T - t)}{\cosh T}, \quad u_*(t) = -x_0 \frac{\sinh(T - t)}{\cosh T}, \quad J_T^* = x_0^2 \tanh T.$$

The cost is also checked by directly integrating $x_*^2 + u_*^2 = x_0^2 \cosh(2(T - t)) / \cosh^2 T$. As

Figure 34.1: The oscillator example at a glance: the open-loop poles (red, $-0.5 \pm 1.9365j$, roots of $s^2 + s + 4$) are moved by state feedback $K = (8, 6)$ to the desired poles $-3, -4$ (blue, roots of $s^2 + 7s + 12$, Theorem 34.3); the observer poles $-5, -6$ (black, gain $L = (10, 16)$, Exercise 34.3) remain distinct, as required by the separation principle.

$T \rightarrow \infty$, $P \rightarrow 1$, $u = -x$ and $J_\infty^* = x_0^2$.

Exercise 34.2: An invisible mode. For $A = \text{diag}(-1, 2)$, $B = (1, 0)^\top$, $C = (1, 0)$, determine controllability, observability and stabilizability.

Solution. Both rank matrices have rank one. State x_2 is absent from the output and always satisfies $\dot{x}_2 = 2x_2$, independently of u . No feedback stabilizes it. Replacing 2 by -2 leaves the system uncontrollable and unobservable, but makes it stabilizable and detectable: the hidden mode already decays on its own.

Exercise 34.3: Design the oscillator observer. Assign poles $-5, -6$ to $A - LC$ in the example.

Solution. For $L = (\ell_1, \ell_2)^\top$,

$$\det(sI - A + LC) = (s + \ell_1)(s + 1) + 4 + \ell_2.$$

Comparison with $s^2 + 11s + 30$ gives $\ell_1 = 10$, $\ell_2 = 16$. With $K = (8, 6)$ the four observer-controller poles are $-3, -4, -5, -6$ by separation.

34.8. Self-assessment: eight statements

Mark each statement true or false before consulting the key.

1. Continuous-time controllability depends on the particular $T > 0$.
2. $W_T > 0$ is equivalent to full rank of $\mathcal{C}$.
3. Observability uses known input, not necessarily zero input.
4. Real feedback can assign a lone nonreal pole without its conjugate.
5. Finite Riccati requires controllability to have a solution on a finite interval.
6. Under the infinite-horizon theorem, P is always positive definite.

-
7. Separation combines the two pole multisets, with multiplicity.
 8. In discrete time, dying out in one step implies reachability from zero.

Teacher's key

1 False: the rank criterion is independent of $T > 0$. 2 True: the kernels coincide. 3 True: subtract the known response. 4 False: a real characteristic polynomial has conjugate roots. 5 False: the finite proof only uses $Q, S \geq 0$ and $R > 0$. 6 False: $Q = 0, A = -1$ gives $P = 0$. 7 True: the combined matrix is block triangular. 8 False: $A = B = 0$ is a counterexample.

34.9. Formulary and sources

$$\mathcal{C} = [B \ AB \ \cdots \ A^{n-1}B], \quad \mathcal{O}^\top = [C^\top \ A^\top C^\top \ \cdots \ (A^\top)^{n-1}C^\top].$$

$$K_{\text{SISO}} = e_n^\top \mathcal{C}^{-1} p(A), \quad K_{\text{LQR}} = R^{-1} B^\top P.$$

For numerical use, explicitly forming $\mathcal{C}^{-1}$ in an ill-conditioned system is not recommended: the formula proves existence and correctness, while a linear solver avoids an unnecessary inversion. The supplied checks retain both exact calculations and floating-point comparisons. References [2, 3] are recorded with URL, section and consultation date in the bibliography and source register. The multiple-input proof and infinite-horizon limit proof are developed in the text rather than deferred to imported results.

State estimation: Kalman and quaternion attitude

INFO

Level C–D. Prerequisites: means, covariances and Gaussian densities; quaternion algebra from Chapter 28; the state model of Chapter 34. An exact derivation for linear systems is distinguished from a local linearization on $SO(3)$. The latter does not automatically inherit the former’s optimality. Sources: Kalman [4], Lall [5], Markley–Bauer [6] and Solà [7].

35.1. Which error is minimized

For a random vector X with mean μ , $\text{Cov } X = \mathbb{E}[(X - \mu)(X - \mu)^\top]$. The quadratic loss is $\mathbb{E}\|X - \hat{X}\|^2$. If the error has zero mean, this loss is the trace of its covariance. Here unbiased means $\mathbb{E}(X - \hat{X}) = 0$ under the stated probability model; it does not mean unbiasedness for every possible unknown deterministic state.

Lemma 35.1: Linear projection and the orthogonality principle. *Let X, Y be random vectors with finite second moments and $S = \text{Cov } Y > 0$. Among affine estimators $a + KY$, the unique quadratic-loss minimizer is*

$$\hat{X} = \mathbb{E}X + \text{Cov}(X, Y)S^{-1}(Y - \mathbb{E}Y).$$

Its error is orthogonal in expectation to every component of $Y - \mathbb{E}Y$.

Proof. For fixed K , separating the mean from the centred error shows that the loss contains $\|\mathbb{E}X - a - K\mathbb{E}Y\|^2$, minimized by $a = \mathbb{E}X - K\mathbb{E}Y$. Centre X, Y , set $P = \text{Cov } X$, $V = \text{Cov}(X, Y)$ and expand

$$\begin{aligned} \text{Cov}(X - KY) &= P - KV^\top - VK^\top + KSK^\top \\ &= P - VS^{-1}V^\top + (K - VS^{-1})S(K - VS^{-1})^\top. \end{aligned}$$

The last term is positive semidefinite, and its trace vanishes only for $K = VS^{-1}$ since $S > 0$. Moreover, $\mathbb{E}[(X - KY)Y^\top] = V - KS = 0$ for that value. This is also the projection criterion: any other estimator differs by a combination of Y , orthogonal to the residual, and the loss decomposes into a sum of two squares. $\square$

35.2. The linear filter, fully derived

Theorem 35.1: Discrete Kalman recursion. *Consider deterministic matrices, possibly depending on k , and known deterministic inputs:*

$$x_{k+1} = A_k x_k + B_k u_k + w_k, \quad z_k = H_k x_k + v_k.$$

The initial error, all w_k and all v_k have zero means and finite second moments and are mutually uncorrelated; $\text{Cov } w_k = Q_k \geq 0$ and $\text{Cov } v_k = R_k > 0$. Initialized with the correct mean and covariance, the following formulas give the best affine estimator in all available observations:

$$\hat{x}_k^- = A_{k-1}\hat{x}_{k-1}^+ + B_{k-1}u_{k-1}, \quad P_k^- = A_{k-1}P_{k-1}^+A_{k-1}^\top + Q_{k-1}, \quad (35.1)$$

$$r_k = z_k - H_k\hat{x}_k^-, \quad S_k = H_kP_k^-H_k^\top + R_k, \quad (35.2)$$

$$K_k = P_k^-H_k^\top S_k^{-1}, \quad \hat{x}_k^+ = \hat{x}_k^- + K_k r_k, \quad (35.3)$$

$$P_k^+ = (I - K_k H_k)P_k^-(I - K_k H_k)^\top + K_k R_k K_k^\top.$$

Initially use $\hat{x}_0^- = \mathbb{E}x_0$, $P_0^- = \text{Cov } x_0$ before the first measurement.

Proof. 1. Prediction. If $e_{k-1}^+ = x_{k-1} - \hat{x}_{k-1}^+$, then $e_k^- = A_{k-1}e_{k-1}^+ + w_{k-1}$. Its mean is zero, and uncorrelatedness removes the two cross terms in the covariance, yielding (35.1).

2. Update. Suppress index k . The innovation is $r = He^- + v$, so $\text{Cov } r = S = HP^-H^\top + R > 0$ and $\text{Cov}(e^-, r) = P^-H^\top$. After correction by Kr , the error is $e^+ = (I - KH)e^- - Kv$. Expanding its covariance gives the Joseph form (35.3). Lemma 35.1 gives

$$P^+(K) = P^- - P^-H^\top S^{-1}HP^- + (K - K_*)S(K - K_*)^\top, \quad K_* = P^-H^\top S^{-1}.$$

This does more than minimize the trace: no other gain improves the covariance in the positive-semidefinite order. Explicitly, the directional derivative of its trace in direction E is $2\text{tr}((KS - P^-H^\top)E^\top)$, vanishing for every E exactly when $K = K_*$. The second variation is $2\text{tr}(ESE^\top) > 0$ for $E \neq 0$.

3. Why the latest innovation is enough. Inductively, the prediction error is orthogonal to all centred past observations. Initially this is true because there are no observations. The innovation $r_k = H_k e_k^- + v_k$ is also orthogonal to the past. After updating, e_k^+ remains orthogonal to the past and is orthogonal to the new innovation because

$$\mathbb{E}[e_k^+ r_k^\top] = P_k^- H_k^\top - K_k S_k = 0.$$

The new affine data space is the previous space plus the components of r_k , since $z_k = r_k + H_k \hat{x}_k^-$. Orthogonality therefore characterizes the optimum with respect to *all* observations. Propagation by $A_k e_k^+ + w_k$ preserves orthogonality, completing the induction. Error means remain zero at every step. $\square$

Corollary 35.1: When the filter is optimal among all estimators. If the initial vector and all noises are jointly Gaussian, the filter is the conditional mean and minimizes quadratic error even among nonlinear estimators with finite second moment. Without Gaussianity, only affine optimality has been proved.

Proof. At a fixed time, the state and stacked observations Y are affine transformations of a Gaussian vector, hence jointly Gaussian. The residual $e = x - \hat{x}$ is jointly Gaussian with Y and has zero cross-covariance by the theorem. Two uncorrelated Gaussian blocks are independent: their joint characteristic function is

$$\exp\left(-\frac{1}{2}t^\top \Sigma_e t - \frac{1}{2}s^\top \Sigma_Y s\right) = \exp\left(-\frac{1}{2}t^\top \Sigma_e t\right) \exp\left(-\frac{1}{2}s^\top \Sigma_Y s\right),$$

after centring. Equivalently, diagonalizing each block covariance makes the Gaussian density on its support a product of the two block densities; zero-variance coordinates are constant. Thus $\mathbb{E}(e | Y) = 0$. For any $g(Y)$ with finite second moment,

$$\mathbb{E}\|x - g(Y)\|^2 = \mathbb{E}\|e\|^2 + \mathbb{E}\|\hat{x} - g(Y)\|^2,$$

because conditioning on Y makes the cross term zero. The minimum is therefore $g = \hat{x}$ almost surely. $\square$

Example 35.1: Two measurements of a static state. Take initial mean zero, initial variance 1, $H = 1$, $Q = 0$, $R = 1/4$, and measurements $z_1 = 6/5$, $z_2 = 11/10$. The first update gives

$$K_1 = \frac{4}{5}, \quad \hat{x}_1 = \frac{24}{25}, \quad P_1 = \frac{1}{5}.$$

At the second step,

$$K_2 = \frac{1/5}{1/5 + 1/4} = \frac{4}{9}, \quad \hat{x}_2 = \frac{24}{25} + \frac{4}{9} \left(\frac{11}{10} - \frac{24}{25} \right) = \frac{46}{45}, \quad P_2 = \frac{1}{9}.$$

Independent check: in the Gaussian case the posterior density is proportional to $\exp[-(x^2 + 4(z_1 - x)^2 + 4(z_2 - x)^2)/2]$. The coefficient of x^2 is 9, and the linear coefficient is $-8(z_1 + z_2)$. Completing the square gives mean $4(z_1 + z_2)/9 = 46/45$ and variance $1/9$, without reusing the recursion.

35.3. Kinematics and multiplicative error

We adopt the volume's convention: scalar-first quaternion $q = (q_0, q_v)$, Hamilton product and active rotation from body to fixed frame. Write $[a]_{\times} b = a \times b$, $R(q_1 \otimes q_2) = R(q_1)R(q_2)$ and

$$\text{Exp}_q(\phi) = \left(\cos \frac{\|\phi\|}{2}, \frac{\sin(\|\phi\|/2)}{\|\phi\|} \phi \right), \quad \text{Exp}(\phi) = e^{[\phi]_{\times}}.$$

At zero use the limiting ratio. The rotation logarithm Log returns a vector of norm less than π on the local branch considered. Near angle π , the branch becomes ambiguous: the following linearization is not a global description.

Proposition 35.1: Linear dynamics of local error. Angular velocity is expressed in the body frame. The gyroscope measures $\omega_m = \omega + b + n_g$, with bias b and noise n_g . For nominal estimates $\hat{q}, \hat{b}$, define

$$q = \hat{q} \otimes \delta q, \quad \delta q = \text{Exp}_q(\delta \theta), \quad \delta b = b - \hat{b}, \quad \hat{\omega} = \omega_m - \hat{b}.$$

To first order in $\delta \theta, \delta b, n_g$, between samples with constant bias,

$$\frac{d}{dt} \begin{bmatrix} \delta \theta \\ \delta b \end{bmatrix} = F \begin{bmatrix} \delta \theta \\ \delta b \end{bmatrix} + \begin{bmatrix} -n_g \\ 0 \end{bmatrix}, \quad F = \begin{bmatrix} -[\hat{\omega}]_{\times} & -I \\ 0 & 0 \end{bmatrix}.$$

Proof. 1. Kinematics. Over dt , the body-frame increment is $\text{Exp}_q(\omega dt) = (1, \omega dt/2) + O(dt^2)$. Right composition gives $q(t + dt) = q(t) \otimes \text{Exp}_q(\omega dt) + O(dt^2)$, hence

$$\dot{q} = \frac{1}{2} q \otimes (0, \omega), \quad \dot{\hat{q}} = \frac{1}{2} \hat{q} \otimes (0, \hat{\omega}).$$

2. Exact error. Differentiate $q = \hat{q} \otimes \delta q$ and multiply on the left by $\hat{q}^{-1}$:

$$\dot{\delta q} = \frac{1}{2} [\delta q \otimes (0, \hat{\omega} - \delta b - n_g) - (0, \hat{\omega}) \otimes \delta q].$$

3. Vector part. Use $\delta q = (1, \delta \theta/2) + O(\|\delta \theta\|^2)$ and Hamilton's rule $(a, u) \otimes (c, v) = (ac - u^{\top} v, av + cu + u \times v)$. To first order, the vector part of the bracket is

$$-\delta b - n_g + \frac{1}{2} \delta \theta \times \hat{\omega} - \frac{1}{2} \hat{\omega} \times \delta \theta = -\delta b - n_g - [\hat{\omega}]_{\times} \delta \theta.$$

The derivative of the vector part of δq is $\delta\theta/2$ to first order, so the factor $1/2$ cancels on both sides. The scalar part is at least second order. Both biases are constant within the interval, so $\dot{\delta b} = 0$. The cross-product sign is fixed by the choice of *right* error; reversing that convention changes the formulas. $\square$

35.4. A consistent noise discretization

Proposition 35.2: Error transition and process covariance. Assume $\hat{\omega}$ and n_g constant during an interval of duration T . The sample n_g has covariance Σ_g . At the interval end, the true bias receives an independent increment η_b of covariance Σ_b . With $\phi = T\hat{\omega}$, the linearized transition is

$$\begin{aligned} \Phi = e^{FT} &= \begin{bmatrix} \text{Exp}(-\phi) & -TJ_r(\phi) \\ 0 & I \end{bmatrix}, & \Gamma_g &= \begin{bmatrix} -TJ_r(\phi) \\ 0 \end{bmatrix}, & \Gamma_b &= \begin{bmatrix} 0 \\ I \end{bmatrix}, \\ Q_d &= \Gamma_g \Sigma_g \Gamma_g^\top + \Gamma_b \Sigma_b \Gamma_b^\top, & P^- &= \Phi P^+ \Phi^\top + Q_d, \end{aligned}$$

where the right Jacobian is

$$J_r(\phi) = I - \frac{1 - \cos \theta}{\theta^2} [\phi]_\times + \frac{\theta - \sin \theta}{\theta^3} [\phi]_\times^2, \quad \theta = \|\phi\|.$$

Proof. The second error component is constant until the final increment. Variation of constants for the first gives

$$\delta\theta(T) = e^{-T[\hat{\omega}]_\times} \delta\theta(0) - \left(\int_0^T e^{-s[\hat{\omega}]_\times} ds \right) (\delta b + n_g).$$

Rodrigues' formula from Chapter 28, integrated term by term, gives

$$\int_0^1 e^{-s[\phi]_\times} ds = J_r(\phi).$$

This gives Φ and the two noise-input matrices. Independence makes the covariance of the sum equal the sum of transformed covariances. At zero the ratios tend to $1/2$ and $1/6$, so $J_r(\phi) = I - [\phi]_\times/2 + [\phi]_\times^2/6 + O(\|\phi\|^3)$. $\square$

This is a *sampled-noise* convention: Σ_g is angular-rate variance per sample, not a continuous white-noise spectral density. The two cannot be interchanged without changing the time scaling. Nominal propagation is $\hat{q}_{k+1}^- = \hat{q}_k^+ \otimes \text{Exp}_q(T\hat{\omega}_k)$, $\hat{b}_{k+1}^- = \hat{b}_k^+$.

35.5. Measurement, correction and reset

The numerical example assumes a *full* attitude measurement $R_m = R(q) \text{Exp}(\nu)$, with small zero-mean error ν and covariance Σ_a . This can model an optical system or an absolute estimate built from multiple directions. A single accelerometer is not credited with three observable attitude degrees of freedom.

$$r = \text{Log}(R(\hat{q}^-)^\top R_m) = \delta\theta + \nu + O((\|\delta\theta\| + \|\nu\|)^2), \quad H = [I \ 0].$$

The first-order equality follows by expanding $\text{Exp}(\delta\theta) \text{Exp}(\nu) = I + [\delta\theta + \nu]_\times + O(2)$ and the logarithm near I . Apply the linear Kalman equations to this local model with $R = \Sigma_a$. If $a = Kr = (a_\theta, a_b)$, correct by

$$\hat{q}^+ = \hat{q}^- \otimes \text{Exp}_q(a_\theta), \quad \hat{b}^+ = \hat{b}^- + a_b.$$

A product of unit quaternions preserves unit norm in exact arithmetic. Renormalization in code only corrects roundoff; it does not replace geometric treatment of the covariance.

Proposition 35.3: Correct reset Jacobian. *After nominal correction, the covariance P_J obtained in Joseph form must be expressed in the new error frame. To first order in the residual fluctuation about a_θ ,*

$$P^+ = G_r P_J G_r^\top, \quad G_r = \begin{bmatrix} J_r(a_\theta) & 0 \\ 0 & I \end{bmatrix}.$$

Proof. Before correction, write the angular error as $a_\theta + \varepsilon$. The new error satisfies

$$\text{Exp}(\delta\theta^+) = \text{Exp}(-a_\theta) \text{Exp}(a_\theta + \varepsilon).$$

We derive this expression rather than postulating the reset sign. For $A = [a_\theta]_\times$, $E = [\varepsilon]_\times$, differentiate the differential equation for $e^{t(A+hE)}$ with respect to h at $h = 0$. Variation of constants gives

$$\left. \frac{d}{dh} e^{A+hE} \right|_{h=0} = \int_0^1 e^{(1-s)A} E e^{sA} ds.$$

Multiplying on the left by e^{-A} and using $R[v]_\times R^\top = [Rv]_\times$,

$$e^{-A} \left. \frac{d}{dh} e^{A+hE} \right|_{h=0} = \left[\int_0^1 e^{-sA} \varepsilon ds \right]_\times = [J_r(a_\theta) \varepsilon]_\times.$$

The derivative of the logarithm at I is the identity, from $\log(I + hE) = hE + O(h^2)$. Thus $\delta\theta^+ = J_r(a_\theta) \varepsilon + O(\|\varepsilon\|^2)$. For the bias, $\delta b^+ = \delta b - a_b$, so its centred fluctuation does not rotate. This gives G_r , and covariance transforms by left and right multiplication. In particular, the leading reset term is $I - [a_\theta]_\times/2$, not $I + [a_\theta]_\times/2$ under this convention. $\square$

Proposition 35.4: One direction does not observe full attitude. *For a nonzero fixed direction v observed in the body, $y = R(q)^\top v + n$, the local angular-error measurement matrix has rank two. Two nonparallel directions remove this instantaneous angular ambiguity.*

Proof. Set $\hat{v} = R(\hat{q})^\top v$. Since $R(q) = R(\hat{q}) \text{Exp}(\delta\theta)$,

$$R(q)^\top v = (I - [\delta\theta]_\times) \hat{v} + O(\|\delta\theta\|^2) = \hat{v} + [\hat{v}]_\times \delta\theta + O(\|\delta\theta\|^2).$$

The matrix is $[\hat{v}]_\times$, whose kernel is the line spanned by $\hat{v}$: the cross product vanishes exactly for parallel vectors. Its rank is two. Stacking two such matrices makes the kernel the intersection of two lines, which is zero for nonparallel directions. This alone does not establish temporal observability of the bias. $\square$

35.6. Reproducible experiment and limits of the conclusion

The code uses true rotation $R(t) = \text{Exp}(t\omega)$ with $\omega = (0.2, -0.1, 0.4)$ rad/s and true bias $b = (0.01, -0.02, 0.005)$ rad/s. The step is $T = 0.02$ s and duration 12 s; a full attitude measurement arrives every five steps. Per-sample gyro noise has standard deviation 0.01 rad/s and angular measurement noise 0.02 rad. The filter allows a bias increment with standard deviation 10^{-5} rad/s per step, while the test trajectory has constant bias: this is a stated conservative model choice, not a hidden equality.

The initial nominal error is a rotation vector $(0.15, -0.10, 0.08)$ rad; the initial bias estimate is

zero. Initial variances are 0.2^2 for the three angular components and 0.05^2 for the three bias components. Checks cover unit norm, covariance symmetry and nonnegativity, final angular error below 0.05 rad, and comparison with uncorrected gyro integration.

The cross-check does not call the same function twice: one route uses an explicitly implemented quaternion product and analytic Jacobians; the other uses rotation matrices and Jacobians obtained by centred differences of the nonlinear map, including reset. The linear check is separate: a Kalman recursion is compared with batch Gaussian conditioning on all observations. Actual numerical outcomes, seed and versions are in the report and JSON. Figure F.1 in the expansion apparatus (at the end of the volume) shows, on a logarithmic scale, the convergence of the MEKF orientation error compared with gyroscope-only integration.

***Remark 35.1: What a simulation does not prove.** The MEKF neglects quadratic terms, uses a local logarithm branch and approximates the error distribution. Global optimality, convergence from every initialization and universal statistical consistency of its covariance have not been proved. A small final error for the stated seed is a reproducible experimental outcome, not any of these theorems. Agreement between two implementations is not an independent mathematical review of the entire chapter either.*

35.7. Assigned and worked exercises

Exercise 35.1: How much a noisy measurement weighs. For scalar $H = 1$, $P^- = p > 0$, $R = r > 0$, find the gain and variance limits as $r \rightarrow 0$ and $r \rightarrow \infty$.

Solution.

$$K = \frac{p}{p+r}, \quad P^+ = p - \frac{p^2}{p+r} = \frac{pr}{p+r}.$$

As $r \rightarrow 0$, $K \rightarrow 1$ and $P^+ \rightarrow 0$: a perfect measurement is trusted. As $r \rightarrow \infty$, $K \rightarrow 0$ and $P^+ \rightarrow p$: the measurement adds no useful information. These are limits of the correct model, not a reason to artificially declare $R = 0$.

Exercise 35.2: Bias drift. On a fixed axis, a noiseless gyro has constant bias β . If integrated without correction from the correct initial angle, what is the error after t ?

Solution. The integrated rates differ by β , so the unwrapped error is βt . For $\beta = 0.01$ rad/s and $t = 10$ s it is 0.1 rad. Constant bias uncertainty therefore creates growing angular error, not merely constant measurement variance. This comparison is local before wrapping modulo 2π .

Exercise 35.3: The reset sign. For a small correction $a_\theta = (0, 0, \alpha)$, compute the first-order reset on $\varepsilon = (1, 0, 0)^\top$.

Solution.

$$J_r(a_\theta)\varepsilon = \left(I - \frac{1}{2}[a_\theta]_\times\right)\varepsilon + O(\alpha^2) = (1, -\alpha/2, 0)^\top + O(\alpha^2).$$

The transverse component is negative. A finite-difference check of

$$\frac{\text{Log}(\text{Exp}(-a_\theta) \text{Exp}(a_\theta + h\varepsilon))}{h}$$

must converge to the exact Jacobian vector as $h \rightarrow 0$ with fixed α . The term $O(\alpha^2)$ instead concerns the approximation of the Jacobian itself.

35.8. Self-assessment quiz

1. The linear derivation requires Gaussianity to minimize over affine estimators.
2. For the optimal gain, updated error is uncorrelated with the innovation.
3. Joseph form is a sum of positive semidefinite matrices.
4. Under Gaussianity, the conditional mean is optimal even among nonlinear estimators.
5. Normalizing the quaternion makes covariance reset unnecessary.
6. One measured vector instantaneously observes all three rotations.
7. In the sampled model, gyro noise enters the angle with a factor proportional to T .
8. A successful simulation proves global convergence of the MEKF.

Teacher's key

1 False: second moments and uncorrelatedness suffice. 2 True: $P^-H^\top - KS = 0$. 3 True: each term has form $AMA^\top$ with $M \geq 0$. 4 True: the Gaussian residual is independent of the data. 5 False: norm and error coordinates are different issues. 6 False: the measured direction is the kernel. 7 True: Γ_g contains $-TJ_r$. 8 False: linearization is local and the test is finite.

35.9. Formulary and sources

$$K = P^-H^\top(HP^-H^\top + R)^{-1}, \quad \hat{x}^+ = \hat{x}^- + K(z - H\hat{x}^-).$$

$$\hat{q}^+ = \hat{q}^- \otimes \text{Exp}_q(a_\theta), \quad P^+ = \text{diag}(J_r(a_\theta), I)P_J \text{diag}(J_r(a_\theta), I)^\top.$$

For [4], volume, issue, pages and DOI are verified. For [6], the 2003 publication is cited; its copy lists only F. Landis Markley. The NASA preprint record and its scan disagree on the author list, a discrepancy recorded rather than resolved by guessing. Conventions and local calculations are also compared with the primary copy of [7], §§4.3.3, 5.3 and 6.3. Markley's quaternion conventions differ from ours: formulas are not transferred without rederiving the signs.

Manipulator dynamics: from energy to torque

INFO

Level C–D. Prerequisites: kinematics and Jacobians from Chapter 29, profiles from Chapter 30, and control from Chapter 34. In this chapter q denotes real joint coordinates, not a quaternion. Rigid bodies, ideal joints, positive inertias and uniform gravity are assumed. Newton’s laws and virtual work are physical-model assumptions; the resulting equations and identities are derived. Sources: [8, 9].

36.1. The Jacobian enters the energy

For body i , express angular velocity ω_i and translational velocity v_i in the same body-fixed centre-of-mass frame. Preserve Chapter 29’s order: angular first, linear second.

$$V_i = \begin{bmatrix} \omega_i \\ v_i \end{bmatrix} = J_i(q)\dot{q}, \quad \mathcal{I}_i = \begin{bmatrix} I_i & 0 \\ 0 & m_i I_3 \end{bmatrix}.$$

Here I_i is the inertia tensor about the centre of mass. The twist’s linear part must refer to that point; using a Jacobian at another origin without transport gives the wrong energy. Transport follows by differentiating the centre-of-mass position or using $v_C = v_O + \omega \times r_{OC}$ from rigid-body kinematics.

Proposition 36.1: Mass matrix and nondegeneracy.

$$T(q, \dot{q}) = \frac{1}{2} \sum_i V_i^\top \mathcal{I}_i V_i = \frac{1}{2} \dot{q}^\top M(q) \dot{q}, \quad M(q) = \sum_i J_i(q)^\top \mathcal{I}_i J_i(q).$$

If $m_i > 0$, $I_i > 0$, and the matrix obtained by stacking the J_i has trivial kernel, then $M = M^\top > 0$.

Proof. Translational energy is $m_i \|v_i\|^2/2$ and rotational energy is $\omega_i^\top I_i \omega_i/2$; summation gives the first equality. Substituting $V_i = J_i \dot{q}$ gives the second. Every term in M is symmetric. For $z \neq 0$,

$$z^\top M z = \sum_i (J_i z)^\top \mathcal{I}_i (J_i z) \geq 0.$$

Equality would force $J_i z = 0$ for every body, contradicting the stacked matrix’s trivial kernel. Thus the form is positive definite. The condition concerns all bodies, not only the tool Jacobian: a tool kinematic singularity does not imply a singular mass matrix. $\square$

36.2. Lagrange and energy structure

Theorem 36.1: Equations of motion in joint coordinates. Let $L = T - V$, $T = \dot{q}^\top M(q) \dot{q}/2$ and V be potential energy. The action principle with virtual work yields

$$M(q)\ddot{q} + C(q, \dot{q})\dot{q} + g(q) = \tau, \quad g_i = \partial_i V,$$

$$C_{ij} = \sum_k c_{ijk} \dot{q}_k, \quad c_{ijk} = \frac{1}{2}(\partial_k M_{ij} + \partial_j M_{ik} - \partial_i M_{jk}).$$

For this Christoffel choice, $\dot{M} - 2C$ is skew-symmetric and

$$\frac{d}{dt}(T + V) = \dot{q}^\top \tau.$$

Proof. 1. Variation. Let η be a smooth variation vanishing at the endpoints. The physical action condition with virtual work is

$$0 = \int (\partial_q L \cdot \eta + \partial_{\dot{q}} L \cdot \dot{\eta} + \tau \cdot \eta) dt = \int \left(\partial_q L - \frac{d}{dt} \partial_{\dot{q}} L + \tau \right) \cdot \eta dt.$$

The last equality is integration by parts, with zero boundary term. Each continuous component in parentheses must vanish: if positive or negative at a point, it retains that sign nearby, and a nonnegative variation supported there produces a nonzero integral. Thus $\frac{d}{dt} \partial_{\dot{q}_i} L - \partial_i L = \tau_i$.

2. Expansion. By symmetry of M ,

$$\begin{aligned} \frac{d}{dt} \partial_{\dot{q}_i} L &= \sum_j M_{ij} \ddot{q}_j + \sum_{j,k} \partial_k M_{ij} \dot{q}_j \dot{q}_k, \\ \partial_i L &= \frac{1}{2} \sum_{j,k} \partial_i M_{jk} \dot{q}_j \dot{q}_k - \partial_i V. \end{aligned}$$

In the double product $\dot{q}_j \dot{q}_k$ we may interchange j and k and average. The resulting coefficient is precisely c_{ijk} , giving $M\ddot{q} + C\dot{q} + g = \tau$.

3. Skew-symmetry. Add the expressions with i, j interchanged; the noncommon terms cancel:

$$C_{ij} + C_{ji} = \sum_k \partial_k M_{ij} \dot{q}_k = \dot{M}_{ij}.$$

Hence $(\dot{M} - 2C)^\top = \dot{M} - 2C^\top = -(\dot{M} - 2C)$. For every vector v , $v^\top (\dot{M} - 2C)v = 0$, since transposing this scalar makes it its own negative.

4. Balance. Differentiate kinetic energy and substitute the equation of motion:

$$\begin{aligned} \dot{T} &= \dot{q}^\top M \ddot{q} + \frac{1}{2} \dot{q}^\top \dot{M} \dot{q} \\ &= \dot{q}^\top (\tau - g) + \frac{1}{2} \dot{q}^\top (\dot{M} - 2C) \dot{q} = \dot{q}^\top \tau - \dot{q}^\top g. \end{aligned}$$

Since $\dot{V} = \nabla V^\top \dot{q} = g^\top \dot{q}$, the conclusion follows. $\square$

The matrix C is not unique if only its product $C\dot{q}$ is prescribed. The matrix identity just proved refers to the explicit Christoffel choice, not every arbitrary matrix representing that product.

36.3. Planar two-link arm: every coefficient

The first angle q_1 is measured from the positive horizontal axis; q_2 is relative to the first link. Lengths are l_1, l_2 , centre-of-mass distances from the joints are c_1, c_2 , masses are m_1, m_2 , and

scalar centre-of-mass inertias are $I_1, I_2 > 0$. Gravity is $(0, -g_0)$, with $g_0 > 0$. Introduce

$$e(\theta) = (\cos \theta, \sin \theta)^\top, \quad t(\theta) = (-\sin \theta, \cos \theta)^\top, \quad q_{12} = q_1 + q_2.$$

$$p_1 = c_1 e(q_1), \quad p_2 = l_1 e(q_1) + c_2 e(q_{12}).$$

Theorem 36.2: Explicit dynamics of the 2R arm. Set

$$a = I_1 + I_2 + m_1 c_1^2 + m_2 (l_1^2 + c_2^2), \quad b = m_2 l_1 c_2, \quad d = I_2 + m_2 c_2^2, \quad h = b \sin q_2.$$

The motion matrices are

$$M = \begin{bmatrix} a + 2b \cos q_2 & d + b \cos q_2 \\ d + b \cos q_2 & d \end{bmatrix}, \quad (36.1)$$

$$C = \begin{bmatrix} -h\dot{q}_2 & -h(\dot{q}_1 + \dot{q}_2) \\ h\dot{q}_1 & 0 \end{bmatrix}, \quad (36.2)$$

$$g(q) = g_0 \begin{bmatrix} (m_1 c_1 + m_2 l_1) \cos q_1 + m_2 c_2 \cos q_{12} \\ m_2 c_2 \cos q_{12} \end{bmatrix}. \quad (36.3)$$

Proof. 1. Velocities. Differentiate the positions:

$$\dot{p}_1 = c_1 t(q_1) \dot{q}_1, \quad \dot{p}_2 = l_1 t(q_1) \dot{q}_1 + c_2 t(q_{12}) (\dot{q}_1 + \dot{q}_2).$$

Since $t(q_1)^\top t(q_{12}) = \cos q_2$,

$$\|\dot{p}_2\|^2 = l_1^2 \dot{q}_1^2 + c_2^2 (\dot{q}_1 + \dot{q}_2)^2 + 2l_1 c_2 \cos q_2 \dot{q}_1 (\dot{q}_1 + \dot{q}_2).$$

Angular velocities are $\dot{q}_1$ and $\dot{q}_1 + \dot{q}_2$. Adding the two translational and two rotational energies gives

$$2T = (a + 2b \cos q_2) \dot{q}_1^2 + 2(d + b \cos q_2) \dot{q}_1 \dot{q}_2 + d \dot{q}_2^2,$$

which identifies M .

2. Quadratic terms. The only nonzero derivatives of M are $\partial_2 M_{11} = -2h$ and $\partial_2 M_{12} = \partial_2 M_{21} = -h$. In the Christoffel formula:

$$c_{112} = c_{121} = -h, \quad c_{122} = -h, \quad c_{211} = h,$$

all other coefficients being zero. Thus $C_{11} = -h\dot{q}_2$, $C_{12} = -h\dot{q}_1 - h\dot{q}_2$, $C_{21} = h\dot{q}_1$, $C_{22} = 0$, as claimed.

3. Gravity. Potential energy is mass times g_0 times height:

$$V = g_0 [(m_1 c_1 + m_2 l_1) \sin q_1 + m_2 c_2 \sin q_{12}].$$

Its two partial derivatives give exactly (36.3). The cosine rather than sine results from measuring angles from the horizontal. $\square$

Corollary 36.1: Direct check of structural properties. For the 2R arm, $M > 0$ in every configuration and

$$\dot{M} - 2C = \begin{bmatrix} 0 & h(2\dot{q}_1 + \dot{q}_2) \\ -h(2\dot{q}_1 + \dot{q}_2) & 0 \end{bmatrix}.$$

Proof. The lower principal entry $M_{22} = d$ is positive. The determinant is

$$\begin{aligned}\det M &= d(a - d) - b^2 \cos^2 q_2 \\ &= d(I_1 + m_1 c_1^2) + I_2 m_2 l_1^2 + m_2^2 l_1^2 c_2^2 \sin^2 q_2 > 0.\end{aligned}$$

The principal-minor criterion for a symmetric 2×2 matrix gives $M > 0$. Equivalently, rotational energy contains $I_1 \dot{q}_1^2/2 + I_2(\dot{q}_1 + \dot{q}_2)^2/2$, vanishing only if both rates vanish. Also

$$\dot{M} = \begin{bmatrix} -2h\dot{q}_2 & -h\dot{q}_2 \\ -h\dot{q}_2 & 0 \end{bmatrix}.$$

Subtracting $2C$ gives the claimed matrix, verifying skew-symmetry without appealing to the general case. $\square$

36.4. Recursive Newton–Euler

For a serial chain of revolute joints, now express *all* vectors in fixed coordinates. Let o_i be joint i , z_i its unit axis, c_i the vector from that joint to body i 's centre of mass, and $r_i = o_i - o_{i-1}$. Fixed-frame inertia is $I_i^w = R_i I_i R_i^\top$. The base is stationary and there are no external terminal loads.

Proposition 36.2: The two recursions. *With initial values $\omega_0 = \alpha_0 = a_{o_0} = 0$, forward propagation is*

$$\begin{aligned}\omega_i &= \omega_{i-1} + z_i \dot{q}_i, \\ \alpha_i &= \alpha_{i-1} + z_i \ddot{q}_i + \omega_{i-1} \times (z_i \dot{q}_i), \\ a_{o_i} &= a_{o_{i-1}} + \alpha_{i-1} \times r_i + \omega_{i-1} \times (\omega_{i-1} \times r_i), \\ a_{C_i} &= a_{o_i} + \alpha_i \times c_i + \omega_i \times (\omega_i \times c_i), \\ f_i &= m_i(a_{C_i} - g_w), \quad n_i = I_i^w \alpha_i + \omega_i \times (I_i^w \omega_i).\end{aligned}$$

With $F_{n+1} = N_{n+1} = 0$, backward propagation is

$$F_i = f_i + F_{i+1}, \quad N_i = n_i + c_i \times f_i + N_{i+1} + (o_{i+1} - o_i) \times F_{i+1}, \quad \tau_i = z_i^\top N_i.$$

For $i = n$, the last lever arm is irrelevant because $F_{n+1} = 0$.

Proof. 1. Kinematics. Angular velocities add. Since the joint axis is fixed in the preceding body, $\dot{z}_i = \omega_{i-1} \times z_i$; differentiating the first equation gives the second. For a body-fixed vector r , $\dot{r} = \omega \times r$ and $\ddot{r} = \alpha \times r + \omega \times (\omega \times r)$. Apply this first to the next origin and then to the centre of mass to obtain both accelerations.

2. Own force and moment. Newton gives the required nongravitational force $f_i = m_i(a_{C_i} - g_w)$. Angular momentum about the centre of mass is $I_i^w \omega_i$. Since $\dot{I}_i^w = [\omega_i]_\times I_i^w - I_i^w [\omega_i]_\times$, its derivative is $I_i^w \alpha_i + \omega_i \times (I_i^w \omega_i)$; the term $I_i^w (\omega_i \times \omega_i)$ is zero.

3. Subtree balance. Joint i supplies body i 's force plus that required by all later bodies: $F_i = f_i + F_{i+1}$. Transporting moments to o_i adds $c_i \times f_i$ for its own body and $(o_{i+1} - o_i) \times F_{i+1}$ for the remainder. The moment component along the joint's free axis is motor torque τ_i ; the other components are ideal constraint reactions. This proves the recursion from force and moment balance. $\square$

36.4.1 Explicit equivalence of both routes for the 2R arm

Theorem 36.3: Newton–Euler returns exactly Lagrange. Applied to the 2R arm, the recursions above produce matrices (36.1)–(36.3), with identical signs and angles.

Proof. Write $e_1 = e(q_1)$, $e_{12} = e(q_{12})$, and similarly t_1, t_{12} . The planar cross product is the scalar $u \times v = u_x v_y - u_y v_x$. Differentiate positions twice:

$$\begin{aligned} a_1 &= c_1(t_1 \ddot{q}_1 - e_1 \dot{q}_1^2), \\ a_2 &= l_1(t_1 \ddot{q}_1 - e_1 \dot{q}_1^2) + c_2(t_{12}(\ddot{q}_1 + \ddot{q}_2) - e_{12}(\dot{q}_1 + \dot{q}_2)^2), \\ f_1 &= m_1(a_1 + (0, g_0)^\top), \quad f_2 = m_2(a_2 + (0, g_0)^\top). \end{aligned}$$

1. Distal joint. The required moment is

$$\tau_2 = I_2(\ddot{q}_1 + \ddot{q}_2) + c_2 e_{12} \times f_2.$$

Use $e_{12} \times t_1 = \cos q_2$, $e_{12} \times e_1 = -\sin q_2$, $e_{12} \times t_{12} = 1$ and $e_{12} \times e_{12} = 0$. Each term becomes

$$\begin{aligned} \tau_2 &= I_2(\ddot{q}_1 + \ddot{q}_2) + m_2 l_1 c_2 \cos q_2 \ddot{q}_1 + m_2 l_1 c_2 \sin q_2 \dot{q}_1^2 \\ &\quad + m_2 c_2^2 (\ddot{q}_1 + \ddot{q}_2) + m_2 g_0 c_2 \cos q_{12} \\ &= (d + b \cos q_2) \ddot{q}_1 + d \ddot{q}_2 + h \dot{q}_1^2 + g_2(q). \end{aligned}$$

This is the second row of Lagrange's equation.

2. Proximal joint. Transport the second joint's moment and force to the first:

$$\tau_1 = \tau_2 + I_1 \ddot{q}_1 + c_1 e_1 \times f_1 + l_1 e_1 \times f_2.$$

The two products are

$$\begin{aligned} c_1 e_1 \times f_1 &= m_1 c_1^2 \ddot{q}_1 + m_1 g_0 c_1 \cos q_1, \\ l_1 e_1 \times f_2 &= m_2 l_1^2 \ddot{q}_1 + b \cos q_2 (\ddot{q}_1 + \ddot{q}_2) \\ &\quad - h(\dot{q}_1 + \dot{q}_2)^2 + m_2 g_0 l_1 \cos q_1. \end{aligned}$$

Adding the distal result makes the acceleration coefficients $a + 2b \cos q_2$ and $d + b \cos q_2$. Velocity terms reduce to

$$h \dot{q}_1^2 - h(\dot{q}_1 + \dot{q}_2)^2 = -h(2\dot{q}_1 \dot{q}_2 + \dot{q}_2^2).$$

Gravity terms sum to $g_1(q)$. Hence

$$\tau_1 = (a + 2b \cos q_2) \ddot{q}_1 + (d + b \cos q_2) \ddot{q}_2 - h(2\dot{q}_1 \dot{q}_2 + \dot{q}_2^2) + g_1(q),$$

the required first row. The two derivations do not share their coefficient calculation: one differentiates energy, the other sums forces and moments. $\square$

36.5. Computed-torque control

Theorem 36.4: Exact error linearization. Let $q_d(t)$ be a twice continuously differentiable trajectory. With an exact model, available state, no saturation and $e = q - q_d$, choose

$$\tau = M(q)(\ddot{q}_d - K_d \dot{e} - K_p e) + C(q, \dot{q})\dot{q} + g(q).$$

Then $\ddot{e} + K_d \dot{e} + K_p e = 0$. If K_p, K_d are symmetric positive definite, the error converges exponentially to zero.

Proof. Substitute τ into the model: $C\dot{q} + g$ cancels and leaves $M(q)(\ddot{q} - \ddot{q}_d + K_d \dot{e} + K_p e) = 0$. Invertibility of M gives the error equation. To prove stability even when K_p and K_d do not commute, consider an eigenvalue λ of the error state matrix. There is $v \neq 0$ such that

$$(\lambda^2 I + \lambda K_d + K_p)v = 0, \quad \|v\|^2 \lambda^2 + (v^* K_d v) \lambda + v^* K_p v = 0.$$

The last quadratic has three positive real coefficients. Real roots have negative sum and positive product, so both are negative. Conjugate roots have real part $-(v^* K_d v)/(2\|v\|^2) < 0$. Thus all eigenvalues lie in the left half-plane. The exponential estimate for Hurwitz matrices from Chapter 34 completes the proof. $\square$

The proof does not authorize cancellation of unknown dynamics. Wrong inertia, friction, varying loads, estimation noise or saturation add terms to the error equation. The law is a synthesis and simulation model here, not a certified procedure for operating a real robot.

36.6. Numerical example with three comparisons

Choose SI units and illustrative values $l_1 = l_2 = 1$, $c_1 = c_2 = 1/2$, $m_1 = m_2 = 1$, $I_1 = I_2 = 1/12$, $g_0 = 9.81$. Then $a = 5/3$, $b = 1/2$, $d = 1/3$. At

$$q = (0, \pi/2)^\top, \quad \dot{q} = (0.4, -0.2)^\top, \quad \ddot{q} = (0.3, -0.1)^\top,$$

without approximating $\cos(\pi/2)$ in the exact calculation, we obtain

$$M = \begin{bmatrix} 5/3 & 1/3 \\ 1/3 & 1/3 \end{bmatrix}, \quad \det M = 4/9, \quad C\dot{q} = \begin{bmatrix} 0.06 \\ 0.08 \end{bmatrix}, \quad g = \begin{bmatrix} 14.715 \\ 0 \end{bmatrix}.$$

$$\tau = \begin{bmatrix} 15.241666 \dots \\ 0.146666 \dots \end{bmatrix} \text{ N m.}$$

The first check compares these torques with a direct Newton–Euler moment sum. The second uses symbolic identities for M , C , skew-symmetry and equality of the two dynamics. The third integrates a trajectory under computed-torque control.

For the trajectory, take $q_A = (0, 0)^\top$, $q_B = (0.8, -0.6)^\top$, motion duration $T_f = 3$ s, and

$$q_d(t) = q_A + (q_B - q_A)s(t/T_f), \quad s(\xi) = 10\xi^3 - 15\xi^4 + 6\xi^5 \quad (0 \leq \xi \leq 1).$$

Before and after motion the profile is constant. Choose $K_p = \text{diag}(25, 36)$, $K_d = \text{diag}(10, 12)$, $e(0) = (0.1, -0.08)^\top$, $\dot{e}(0) = 0$. Each error component has polynomial $(\lambda + \omega_i)^2$, with $\omega_1 = 5$, $\omega_2 = 6$, so

$$e_i(t) = e_i(0)(1 + \omega_i t)e^{-\omega_i t}.$$

Simulation on $[0, 6]$ s compares a DOP853 integrator using Lagrangian dynamics with a Radau integrator using independently reconstructed Newton–Euler forces and moments, then compares both with the analytic error. Actual discrepancies are in the JSON; the required comparison error is below 10^{-7} rad. Stability is proved above, not by a plot or numerical tolerance. Figure F.2 in the expansion apparatus (at the end of the volume) shows the two joint positions q_1, q_2 together with the quintic references $q_{d,1}, q_{d,2}$.

36.7. Assigned and worked exercises

Exercise 36.1: Derive the quintic profile. Find the polynomial of degree at most five with $s(0) = 0$, $s(1) = 1$ and zero velocity and acceleration at both endpoints.

Solution. The three conditions at zero eliminate the constant, linear and quadratic coefficients. Write $s = a\xi^3 + b\xi^4 + c\xi^5$. At one:

$$a + b + c = 1, \quad 3a + 4b + 5c = 0, \quad 6a + 12b + 20c = 0.$$

Subtracting three times the first equation from the second gives $b + 2c = -3$; subtracting six times the first from the third gives $6b + 14c = -6$. Eliminate b to obtain $2c = 12$, hence $c = 6$, $b = -15$, $a = 10$. Also $s' = 30\xi^2(1 - \xi)^2 \geq 0$, so motion does not reverse within the interval.

Exercise 36.2: Horizontal equilibrium. For the numerical parameters, calculate the torques needed to hold $q = (0, 0)^\top$ at rest.

Solution. With zero velocity and acceleration, $\tau = g(q)$. Both cosines equal one, so $\tau_1 = 9.81(1/2 + 1 + 1/2) = 19.62$ N m and $\tau_2 = 9.81/2 = 4.905$ N m. Newton–Euler confirms: at the first joint, weight lever arms are $1/2$ and $3/2$; at the second, the second weight has lever arm $1/2$.

Exercise 36.3: Gravity does not create energy. With $\tau = 0$ and no friction, is kinetic energy constant?

Solution. Not necessarily: $\dot{T} = -\dot{q}^\top g = -\dot{V}$. The sum $T + V$ is constant, not each term separately. If $g = 0$ as well, the energy identity gives $\dot{T} = 0$. The Coriolis matrix does not create or destroy energy: its contribution compensates that of $\dot{M}/2$.

36.8. Self-assessment quiz

1. In the angular-first convention, centre-of-mass inertia is $\text{diag}(I, mI_3)$.
2. Every tool-Jacobian singularity makes M singular.
3. The Christoffel choice satisfies $C + C^\top = \dot{M}$.
4. Angles measured from the horizontal produce cosines in g .
5. Newton–Euler first propagates accelerations and then forces backwards.
6. Computed torque guarantees the same error equation even with saturation.
7. For $\tau = 0$, $T + V$ is conserved in the ideal model.
8. With $K_p = \omega^2 I$, $K_d = 2\omega I$, an error with zero initial velocity is $e(0)(1 + \omega t)e^{-\omega t}$.

Teacher's key

1 True: the rotational block comes first. 2 False: the stacked Jacobian of all bodies matters. 3 True: this is the energy-proof calculation. 4 True: differentiation of a sine-containing potential

gives cosines. 5 True: these are the two recursions. 6 False: cancellation requires the torque actually applied. 7 True: external power is zero. 8 True: this is the critically damped solution with those initial data.

36.9. Formulary and sources

$$M = \sum_i J_i^\top \mathcal{I}_i J_i, \quad g = \nabla V, \quad M\ddot{q} + C\dot{q} + g = \tau, \quad \dot{T} + \dot{V} = \dot{q}^\top \tau.$$

Source [8] treats dynamics in Chapter 4; its 2R example and coefficients appear on printed pp. 164–165, while gravity and the full Newton–Euler comparison are added here. Source [9] covers dynamics in Chapter 8 and computed torque in §11.4. For the connection to kinematics, [8] attributes the product-of-exponentials formula to R. W. Brockett; the original 1984 reference is listed as historical attribution, distinct from sources actually consulted for the proofs.

Digital control: from the half-plane to the unit disk

INFO

Level C–D. Prerequisites: the Laplace transform (Chapter 20), the Z-transform (Chapter 21), and feedback and controllability from Chapter 34. Three operations are distinguished: exact sampling of a held-input plant, approximation of a continuous controller, and direct design of a discrete controller. They are not interchangeable. All equations describe ideal models without computation delays, saturation or quantization unless explicitly stated.

37.1. Zero-order hold and the exact model

Theorem 37.1: Exact state discretization. Let $T > 0$ be the period and $u(t) = u_k$ on $[kT, (k+1)T)$. For $\dot{x} = Ax + Bu$ and $x_k = x(kT)$,

$$x_{k+1} = A_d x_k + B_d u_k, \quad A_d = e^{AT}, \quad B_d = \int_0^T e^{A\tau} B d\tau.$$

The formula does not require invertibility of A . If A is invertible, $B_d = A^{-1}(A_d - I)B$.

Proof. Apply variation of constants on the sampling interval:

$$x((k+1)T) = e^{AT} x(kT) + \int_{kT}^{(k+1)T} e^{A((k+1)T-s)} B u_k ds.$$

The substitution $\tau = (k+1)T - s$ gives the formula. Integrating $\frac{d}{d\tau} e^{A\tau} = A e^{A\tau}$ yields $AB_d = (A_d - I)B$, hence the invertible case. A method avoiding this inverse is

$$\exp\left(T \begin{bmatrix} A & B \\ 0 & 0 \end{bmatrix}\right) = \begin{bmatrix} A_d & B_d \\ 0 & I \end{bmatrix}.$$

Indeed, for $j \geq 1$ the upper blocks of the j th power are A^j and $A^{j-1}B$. Summing the exponential series gives the upper-right block $\sum_{j \geq 1} T^j A^{j-1} B / j! = \int_0^T e^{A\tau} B d\tau$. $\square$

Proposition 37.1: The ZOH formula through the step response. For a causal strictly proper system with transfer function $G(s)$, zero initial state and step response $s_c(t) = \mathcal{L}^{-1}\{G(s)/s\}$, the transfer function from u_k to $y(kT)$ is

$$G_d(z) = (1 - z^{-1}) \sum_{k=0}^{\infty} s_c(kT) z^{-k}.$$

Proof. The discrete impulse $u_0 = 1$, $u_k = 0$ for $k \neq 0$ becomes the rectangle $1_{[0,T)}(t)$ after the hold: the difference of a step and that step delayed by T . Linearity and time invariance give the output $s_c(t) - s_c(t - T)$, with $s_c(t) = 0$ for $t < 0$. Sampling yields $h_k = s_c(kT) - s_c((k-1)T)$. Shifting the index in the second Z-transform sum gives the factor z^{-1} . Strict properness excludes instantaneous-feedthrough ambiguities at the rectangle boundary; a direct term D must be added separately. $\square$

Example 37.1: A first-order system, two derivations. For $\dot{x} = -ax + bu$, $y = x$, $a > 0$, the step response is $s_c(t) = b(1 - e^{-at})/a$. Set $\alpha = e^{-aT}$; the preceding formula gives

$$\begin{aligned} G_d(z) &= \frac{b}{a}(1 - z^{-1}) \left(\frac{1}{1 - z^{-1}} - \frac{1}{1 - \alpha z^{-1}} \right) \\ &= \frac{\beta z^{-1}}{1 - \alpha z^{-1}}, \quad \beta = \frac{b}{a}(1 - \alpha). \end{aligned}$$

Independently, state integration gives $x_{k+1} = \alpha x_k + \beta u_k$ and therefore the same transfer function. The factor z^{-1} records that u_k affects x_{k+1} , not x_k . As $a \rightarrow 0$, $(1 - e^{-aT})/a \rightarrow T$, recovering the integrator with $\beta = bT$.

37.2. Tustin: a Möbius transformation

Theorem 37.2: From trapezoids to the stability disk. The trapezoidal rule applied to $\dot{v} = u$ produces the substitution

$$s = \frac{2}{T} \frac{1 - z^{-1}}{1 + z^{-1}}, \quad z = \frac{1 + sT/2}{1 - sT/2}.$$

It maps $\operatorname{Re} s < 0$ bijectively onto $|z| < 1$. On the imaginary axis, continuous angular frequency Ω and digital frequency $\omega \in (-\pi, \pi)$ satisfy

$$\Omega = \frac{2}{T} \tan \frac{\omega}{2}, \quad \omega = 2 \arctan \frac{\Omega T}{2}.$$

Proof. The trapezoidal rule gives $v_k - v_{k-1} = T(u_k + u_{k-1})/2$. With zero initial conditions, transformation yields $V/U = (T/2)(1 + z^{-1})/(1 - z^{-1})$, to be compared with $1/s$. Solving for z gives the second formula. Moreover,

$$|1 + sT/2|^2 - |1 - sT/2|^2 = 2T \operatorname{Re} s.$$

The denominator does not vanish in the left half-plane, so $|z| < 1$ is equivalent to $\operatorname{Re} s < 0$. The inverse exists in the disk because $z + 1 \neq 0$. Finally, set $z = e^{i\omega}$ and multiply numerator and denominator of $(1 - e^{-i\omega})/(1 + e^{-i\omega})$ by $e^{i\omega/2}$ to obtain $i \tan(\omega/2)$. The tangent increases strictly from $-\infty$ to $+\infty$ on $(-\pi/2, \pi/2)$, giving the full correspondence. $\square$

Stability is preserved, but the linear frequency scale is not. With $T = 0.1$ s and $\Omega = 10$ rad/s, $\omega = 2 \arctan(1/2) \simeq 0.927295218$ rad/sample: the digital physical frequency ω/T is about 9.27295218 rad/s, not 10. To match a chosen physical frequency Ω_c , with $0 < \Omega_c T < \pi$, use $s = \kappa(1 - z^{-1})/(1 + z^{-1})$ with

$$\kappa = \frac{\Omega_c}{\tan(\Omega_c T/2)}.$$

Substitution of $z = e^{i\Omega_c T}$ gives exactly $s = i\Omega_c$: this is frequency prewarping. It does not simultaneously correct every frequency.

Figure 37.1: The Tustin transformation maps the left half-plane of the s -plane (shaded) to the unit disk of the z -plane (shaded), and the imaginary axis $j\Omega$ to the circle $|z| = 1$: exactly Theorem 37.2. Verified point with $T = 1$: $s = -0.2 + 0.9j$ gives $1 + sT/2 = 0.9 + 0.45j$, $1 - sT/2 = 1.1 - 0.45j$, hence $z = (0.9 + 0.45j)/(1.1 - 0.45j) = 0.5575 + 0.6372j$, with $|z| \approx 0.847 < 1$; independent check via the identity from the proof: $|1 + sT/2|^2 - |1 - sT/2|^2 = 1.0125 - 1.4125 = -0.4 = 2T \operatorname{Re} s$.

37.3. Pole placement and deadbeat control

Theorem 37.3: Finite-step regulation. If (A_d, B_d) is controllable, one can choose K with all eigenvalues of $F = A_d - B_d K$ zero; then $x_n = 0$ for every x_0 under $u_k = -Kx_k$. In the single-input case, the nilpotency index of F is exactly n : among these constant state feedbacks, n is the minimum settling time uniform over all initial states.

Proof. Pole placement in Chapter 34 is algebraic in $A - BK$, so applies unchanged in discrete time. Choosing characteristic polynomial λ^n , Cayley–Hamilton gives $F^n = 0$. Induction gives $x_k = F^k x_0$, hence $x_n = 0$. For SISO minimality, observe that $F^j B_d$ equals $A_d^j B_d$ plus a combination of $B_d, \dots, A_d^{j-1} B_d$: this follows inductively by multiplying by $A_d - B_d K$. The two controllability matrices therefore differ by a triangular matrix with unit diagonal and have the same rank n . If $F^m = 0$ for $m < n$, all vectors $F^j B_d$ with $j \geq m$ would vanish, giving rank at most m , a contradiction. Finally, $F^{n-1} \neq 0$ implies the existence of x_0 with $F^{n-1} x_0 \neq 0$. $\square$

This does not say that every state needs n steps, or that n is minimal for multi-input systems. With $B_d = I$, choosing $K = A_d$ gives one-step settling. Constant-reference tracking first requires an admissible equilibrium $(x_\star, u_\star)$ satisfying $x_\star = A_d x_\star + B_d u_\star$; use $u_k = u_\star - K(x_k - x_\star)$. Pole placement cannot make an output reference compatible with an equilibrium when it is not.

Example 37.2: Double integrator: a complete symbolic design. For $\ddot{p} = u$, the ZOH-sampled state $x = (p, \dot{p})^\top$ satisfies

$$A_d = \begin{bmatrix} 1 & T \\ 0 & 1 \end{bmatrix}, \quad B_d = \begin{bmatrix} T^2/2 \\ T \end{bmatrix}, \quad \det[B_d \ A_d B_d] = -T^3 \neq 0.$$

Writing $K = (k_1, k_2)$, the closed-loop trace and determinant are

$$\operatorname{tr} F = 2 - \frac{T^2}{2} k_1 - T k_2, \quad \det F = 1 - T k_2 + \frac{T^2}{2} k_1.$$

Set the trace to $\rho_1 + \rho_2$ and determinant to $\rho_1 \rho_2$. Subtracting the equations gives $T^2 k_1 = (1 - \rho_1)(1 - \rho_2)$; substitution into the second gives

$$k_1 = \frac{(1 - \rho_1)(1 - \rho_2)}{T^2}, \quad k_2 = \frac{3 - \rho_1 - \rho_2 - \rho_1 \rho_2}{2T}.$$

For $\rho_1 = \rho_2 = 0$, $K = (T^{-2}, 3/(2T))$ and

$$F = \begin{bmatrix} 1/2 & T/4 \\ -1/T & -1/2 \end{bmatrix}, \quad F^2 = \begin{bmatrix} 1/4 - 1/4 & T/8 - T/8 \\ -1/(2T) + 1/(2T) & -1/4 + 1/4 \end{bmatrix} = 0.$$

This is the matrix to use. With $T = 0.1$ and $x_0 = (1, 0)^\top$, $u_0 = -100$, $x_1 = (1/2, -10)^\top$, $u_1 = 100$, $x_2 = 0$. Large accelerations show that algebraic deadbeat regulation is not torque-constrained or comfort-constrained design; reducing T makes the position gain grow as T^{-2} .

37.4. Finite-horizon discrete LQR

Theorem 37.4: Riccati by completing the square. For $x_{k+1} = Ax_k + Bu_k$, $Q, S \succeq 0$, $R \succ 0$, consider

$$J = \sum_{k=0}^{N-1} (x_k^\top Q x_k + u_k^\top R u_k) + x_N^\top S x_N.$$

Set $P_N = S$. The recursion

$$\begin{aligned} U_k &= R + B^\top P_{k+1} B, & K_k &= U_k^{-1} B^\top P_{k+1} A, \\ P_k &= Q + A^\top P_{k+1} A - A^\top P_{k+1} B U_k^{-1} B^\top P_{k+1} A \end{aligned}$$

is well defined, gives $P_k \succeq 0$, and produces the unique optimal control $u_k = -K_k x_k$, with cost $x_0^\top P_0 x_0$.

Proof. Work backwards. The terminal cost has the stated form. If the minimum cost from step $k+1$ is $x^\top P_{k+1} x$, the cost at step k for input u is

$$\begin{aligned} & x^\top Q x + u^\top R u + (Ax + Bu)^\top P_{k+1} (Ax + Bu) \\ &= x^\top (Q + A^\top P_{k+1} A) x + 2u^\top B^\top P_{k+1} A x + u^\top U_k u \\ &= x^\top P_k x + (u + K_k x)^\top U_k (u + K_k x). \end{aligned}$$

Since $P_{k+1} \succeq 0$, $U_k \succ 0$. The square has unique minimum zero at $u = -K_k x$, and the minimum cost is nonnegative because every original term is nonnegative, hence $P_k \succeq 0$. Induction justifies every step. Summation and cancellation of intermediate state costs also give

$$J = x_0^\top P_0 x_0 + \sum_{k=0}^{N-1} (u_k + K_k x_k)^\top U_k (u_k + K_k x_k).$$

The identity directly establishes optimality and uniqueness of the whole sequence. No external dynamic-programming theorem is needed. $\square$

37.5. Digital PID: comparing three discretizations

An ideal differentiator amplifies high frequencies without bound. We therefore use the proper model

$$C(s) = K_p + \frac{K_i}{s} + K_d \frac{s}{1 + \tau_f s}, \quad \tau_f > 0.$$

Let I be the integral before multiplication by K_i , and d the filtered derivative before multiplication by K_d ; then $u_k = K_p e_k + K_i I_k + K_d d_k$.

Proposition 37.2: Explicit recurrences. The three substitutions and corresponding recurrences are

$$\begin{aligned} s_{\text{FE}} &= (z - 1)/T, & I_k^{\text{FE}} &= I_{k-1}^{\text{FE}} + Te_{k-1}, \\ s_{\text{BE}} &= (1 - z^{-1})/T, & I_k^{\text{BE}} &= I_{k-1}^{\text{BE}} + Te_k, \\ s_{\text{TU}} &= \frac{2}{T} \frac{1 - z^{-1}}{1 + z^{-1}}, & I_k^{\text{TU}} &= I_{k-1}^{\text{TU}} + \frac{T}{2}(e_k + e_{k-1}), \end{aligned}$$

$$\begin{aligned} d_k^{\text{FE}} &= \left(1 - \frac{T}{\tau_f}\right) d_{k-1}^{\text{FE}} + \frac{e_k - e_{k-1}}{\tau_f}, \\ d_k^{\text{BE}} &= \frac{\tau_f}{\tau_f + T} d_{k-1}^{\text{BE}} + \frac{e_k - e_{k-1}}{\tau_f + T}, \\ d_k^{\text{TU}} &= \frac{2\tau_f - T}{2\tau_f + T} d_{k-1}^{\text{TU}} + \frac{2(e_k - e_{k-1})}{2\tau_f + T}. \end{aligned}$$

Proof. For the integrator, left-rectangle, right-rectangle and trapezoidal quadrature of $\int_{(k-1)T}^{kT} e(t)dt$ directly give the three rows. For the differentiator, write $D/E = s/(1 + \tau_f s)$ and substitute. In the FE case,

$$\frac{D}{E} = \frac{1 - z^{-1}}{\tau_f + (T - \tau_f)z^{-1}}.$$

Multiplication by the denominator and interpretation of z^{-1} as a delay give the first recurrence. For BE the denominator is $T + \tau_f - \tau_f z^{-1}$ with numerator $1 - z^{-1}$; for TU it is $T + 2\tau_f + (T - 2\tau_f)z^{-1}$ with numerator $2(1 - z^{-1})$. Isolating d_k gives the other two formulas. $\square$

Corollary 37.1: Stability of the derivative filter alone. The FE filter is asymptotically stable if and only if $0 < T < 2\tau_f$; BE and TU are asymptotically stable for every $T > 0$.

Proof. The free responses are powers of the three coefficients multiplying d_{k-1} . Stability requires modulus strictly less than one. For FE, $|1 - T/\tau_f| < 1$ is equivalent to the stated inequality; for BE, $0 < \tau_f/(\tau_f + T) < 1$; for TU, $|2\tau_f - T| < 2\tau_f + T$. $\square$

This does not imply stability of the whole feedback loop: the PID contains an integrator with a pole at $z = 1$, and the plant enters the characteristic equation. One must not simply set $\tau_f = 0$ in every recurrence: the ideal FE differentiator is anticipatory, while TU introduces a pole at -1 . A real controller also needs saturation handling and anti-windup, which this linear derivation does not certify.

37.5.1 Reproducible numerical comparison

The comparison uses $K_p = 2$, $K_i = 1$, $K_d = 0.1$, $\tau_f = 0.05$ s, $T = 0.01$ s, $\Omega = 10$ rad/s and $z = e^{i\Omega T}$. The first method evaluates $C(s_{\text{FE}})$, $C(s_{\text{BE}})$, $C(s_{\text{TU}})$ as complex numbers. The second runs the recurrences on $e_k = \cos(\Omega kT)$ and estimates amplitude and phase by regression on cosine, sine and a constant after the transient. The constant is needed because the integrator retains its initial offset. The JSON reports magnitudes, phases and discrepancies, with comparison tolerance 10^{-8} . The continuous reference is $C(10i)$, not $C(i\omega)$: ω is in radians per sample, Ω in radians per second.

37.6. Assigned and worked exercises

Exercise 37.1: Nonzero poles. For the double integrator with $T = 0.1$, place the poles at $1/2$ and $3/5$.

Solution. The formula gives $k_1 = (1/2)(2/5)/(1/100) = 20$ and $k_2 = (3 - 1/2 - 3/5 - 3/10)/(1/5) = 8$. The closed-loop matrix is

$$F = \begin{bmatrix} 9/10 & 3/50 \\ -2 & 1/5 \end{bmatrix}, \quad \det(\lambda I - F) = \lambda^2 - \frac{11}{10}\lambda + \frac{3}{10} = (\lambda - 1/2)(\lambda - 3/5).$$

Both poles lie inside the unit circle; uniform finite-step settling does not occur because F is invertible.

Exercise 37.2: One Riccati step. For $x_1 = x_0 + u_0$, $N = 1$, $Q = R = S = 1$, find the optimal control.

Solution. $U_0 = 2$, $K_0 = 1/2$, $P_0 = 1 + 1 - 1/2 = 3/2$. Directly, $J = x_0^2 + u_0^2 + (x_0 + u_0)^2 = (3/2)x_0^2 + 2(u_0 + x_0/2)^2$, with unique minimum at $u_0 = -x_0/2$.

Exercise 37.3: Sampling too slowly. With $\tau_f = 0.02$ s and $T = 0.05$ s, compare the three derivative-filter poles.

Solution. FE: $1 - T/\tau_f = -3/2$, unstable. BE: $\tau_f/(\tau_f + T) = 2/7$, stable. TU: $(2\tau_f - T)/(2\tau_f + T) = -1/9$, stable with alternating free response. Stability of two filters does not guarantee that the sampling period is adequate for the desired loop bandwidth.

37.7. Self-assessment quiz

1. ZOH requires invertibility of A .
2. Tustin maps the left half-plane into the unit disk.
3. Under Tustin, digital frequency always equals $\omega = \Omega T$.
4. Controllable SISO deadbeat feedback has nilpotency index n .
5. Finite discrete LQR requires an imported solution of an algebraic Riccati equation.
6. The FE derivative filter is stable for every $T > 0$.
7. The factor z^{-1} can represent the step from u_k to x_{k+1} .
8. Two-step settling permits ignoring actuator limits.

Teacher's key

1 False: the exponential integral suffices. 2 True: the difference of squared moduli proves it. 3 False: a tangent is involved. 4 True: controllability excludes a smaller index. 5 False: finite recursion and completing the square suffice. 6 False: $T < 2\tau_f$ is required. 7 True: this follows from the stated timing convention. 8 False: the required torques may be unrealizable.

37.8. Formulary and sources

$$(A_d, B_d) = \left(e^{AT}, \int_0^T e^{A\tau} B d\tau \right), \quad z = \frac{1 + sT/2}{1 - sT/2}, \quad u_k = -K_k x_k.$$

For PID context and modifications required for implementation, see [12], §10.5 of the stated electronic version. For discrete LQR, see [11], PDF pp. 20–23. The recurrences, the deadbeat minimality proof within the stated scope, and the two-way checks are developed explicitly here.

Final assessment of the Volume

INFO

How to use this assessment. Fifty multiple-choice questions spanning the whole volume, from the circle as a generator (Chapter 1) to the epilogue (Chapter 33), along the six Parts: differential and global geometry, complex and harmonic analysis on the disc, transforms, signals and telecommunications, automation, numerics and research. As in the end-of-chapter quizzes, but here at the scale of the whole volume, the **answer is given immediately after each question**, together with a pointer to the chapter and the result that justify it: it is designed for revision, not for grading. Anyone wishing to use it as a closed test should cover the boldface line with a sheet of paper.

Indicative scoring: ≥ 45 excellent; 38–44 good; 30–37 sufficient, with targeted revision of the Parts missed; < 30 it is worth rereading the volume following the logical chain that leads from Chapter 1 to Chapter 33.

Part A — Differential and global geometry (Chapters 1–14)

- Chapter 1 recounts that Lindemann proved the transcendence of π in 1882. In Volume III this result
 - is proved in full in the prologue
 - is cited as an imported historical fact, not proved in the treatise
 - is refuted by Archimedes' estimates
 - is equivalent to the four-vertex theorem

Answer: B. Chapter 1 cites it as a historical fact (Lindemann, 1882): consistently with the rule that great theorems outside the perimeter of the circle remain panorama, it is not proved in the volume.

- The fundamental theorem of plane curves (Chapter 2) guarantees, starting from a continuous curvature function k , an initial point and an initial direction,
 - the existence of infinitely many non-congruent curves with that curvature
 - the existence and uniqueness of a curve with that curvature, unique up to a direct rigid motion
 - existence only, without uniqueness
 - existence only if k is constant

Answer: B. This is the content of Theorem 2.9: existence, uniqueness and rigidity (Chapter 2).

- The Frenet–Serret formulas (Chapter 3) express the derivatives of T, N, B along a biregular curve through a matrix that is
 - symmetric
 - antisymmetric, with curvature κ and torsion τ

- C) diagonal
- D) zero whenever $\tau = 0$

Answer: B. Theorem 3.1 (Chapter 3) writes $\frac{d}{ds}(T, N, B)^\top$ as the product with the antisymmetric matrix carrying $\pm\kappa, \pm\tau$; even with $\tau = 0$ one still has $T' = \kappa N \neq 0$ and $N' = -\kappa T$.

4. The four-vertex theorem, in its general version (Chapter 4), applies to

- A) convex curves only
- B) every closed, simple, regular plane curve of class C^2 , convex or not
- C) ellipses only
- D) curves of constant curvature only

Answer: B. Theorem 4.7 (Chapter 4) extends the convex case to every closed, simple, regular C^2 curve, relying only on the Jordan curve theorem as an imported topological prerequisite.

5. For a closed, regular, simple plane curve, the rotation index theorem (Umlaufsatz, Chapter 4) states that the total curvature integral $\int_0^L k(s) ds$ equals

- A) π
- B) 0
- C) 2π in absolute value, with sign given by the orientation
- D) a value depending on the shape of the curve

Answer: C. Theorem 4.1 (Chapter 4): $\text{ind}(\gamma) = \pm 1$, hence $\int_0^L k ds = 2\pi \text{ind}(\gamma)$.

6. The global Gauss–Bonnet theorem (Chapter 4), for a compact, orientable, boundaryless surface of Gaussian curvature K , states that $\iint_M K dA$ equals

- A) always 4π
- B) $2\pi \chi(M)$, where $\chi(M)$ is the Euler characteristic of a triangulation
- C) always 0
- D) the area of M

Answer: B. Theorem 4.8 (Chapter 4). The combinatorial step $2\pi V - \pi F = 2\pi \chi$ is proved in full in the volume; three supporting facts for general surfaces remain imported (Observation 4.9).

7. By the classification of $O(2)$ (Chapter 5), every 2×2 orthogonal matrix is

- A) always a rotation
- B) either a rotation R_θ (determinant $+1$) or a reflection S_θ (determinant -1)
- C) always a reflection
- D) neither a rotation nor a reflection in general

Answer: B. Theorem 5.4 (Chapter 5): $O(2) = SO(2) \cup \{S_\theta\}$.

8. Euler's rotation theorem (Chapter 5) guarantees that every $A \in SO(3)$

- A) has no fixed axis

- B) fixes a unit vector u (the axis) and rotates the plane $u^\perp$ by an angle θ
- C) is always the identity
- D) has three distinct fixed axes

Answer: B. Theorem 5.9 (Chapter 5): every rotation of space is a rotation about an axis.

9. The theorem of Chapter 6 on Möbius transformations states that the image of a generalised circle (a circle or a line) under a Möbius transformation is
- A) always a line
 - B) always a circle, never a line
 - C) always a generalised circle (a circle or a line)
 - D) in general neither a circle nor a line

Answer: C. Theorem 6.6 (Chapter 6), proved via decomposition into translations, similarities and inversion.

10. Stereographic projection σ from the sphere (Chapter 7) has the properties:
- A) it is conformal but does not map circles to circles
 - B) it maps circles to circles or lines, but is not conformal
 - C) it is conformal, and maps circles through the pole to lines, other circles to circles
 - D) it is neither conformal nor circle-preserving

Answer: C. Theorem 7.6 (Chapter 7).

11. The spherical law of cosines (Chapter 8), for a spherical triangle with sides a, b, c and angle A opposite a , states that
- A) $\cos a = \cos b \cos c + \sin b \sin c \cos A$
 - B) $a^2 = b^2 + c^2 - 2bc \cos A$, as in the plane
 - C) $\cos a = \cos b + \cos c$
 - D) $\sin a = \sin b \sin c \cos A$

Answer: A. Theorem 8.1 (Chapter 8). Answer B is the *planar* law of cosines, not valid on the sphere: it is the most common error in transferring plane trigonometry to the sphere.

12. Girard's theorem (Chapter 8) relates the area of a spherical triangle to its excess $E = A + B + C - \pi$. In the chapter's Rome–New York example, with angles $A \approx 59.00^\circ$, $B \approx 57.33^\circ$, $C \approx 86.49^\circ$, the excess is approximately
- A) 0° (the triangle would be flat)
 - B) 22.82° , a value confirmed independently with L'Huilier's formula
 - C) 180°
 - D) 360°

Answer: B. Theorem 8.6 (Chapter 8): $\text{Area}(T) = Er^2$, with E in radians in the area formula and reported here in degrees for readability.

13. Chapter 9 proves that the geodesics of the sphere S^2 are

- A) the curves of zero curvature, which do not exist on the sphere
- B) the arcs of great circles, traversed at constant speed
- C) the parallels of any colatitude
- D) logarithmic spirals

Answer: B. Theorem 9.3 (Chapter 9). Answer C is false in general: among the parallels, only the equator is a great circle and hence a geodesic.

14. Clairaut's relation (Chapter 9), for a geodesic on a surface of revolution, states that along the path the following stays constant:
- A) the height
 - B) the product $r \sin \psi$ of the radius of the parallel and the sine of the angle with the meridian
 - C) the length travelled so far
 - D) the Gaussian curvature

Answer: B. Theorem 9.4 (Chapter 9).

15. Gauss's Theorema Egregium (Chapter 10) states that the Gaussian curvature K
- A) depends on how the surface is embedded in $\mathbb{R}^3$
 - B) is intrinsic: it is computed from the coefficients E, F, G alone and is preserved under local isometries
 - C) is always zero for curved surfaces
 - D) always coincides with the mean curvature H

Answer: B. Theorem 10.2 (Chapter 10). Answer D is false: the plane and the cylinder are locally isometric yet have different mean curvatures, because H is not intrinsic.

16. For the volume of the n -dimensional ball (Chapter 11), $V_n = \pi^{n/2} / \Gamma(\frac{n}{2} + 1)$. Using the recursion $V_n = \frac{2\pi}{n} V_{n-2}$ with $V_1 = 2$, $V_2 = \pi$, the value of V_5 is
- A) π^2
 - B) $\frac{8\pi^2}{15} \approx 5.26$
 - C) $\frac{4}{3}\pi$
 - D) $2\pi^2$

Answer: B. Theorem 11.1 (Chapter 11): $V_3 = \frac{4}{3}\pi$, $V_5 = \frac{2\pi}{5} V_3 = \frac{8\pi^2}{15}$.

17. The map $E : \mathbb{R} \rightarrow S^1$, $E(t) = e^{it}$ (Chapter 12), is a covering map because
- A) it is injective
 - B) every point of S^1 has a neighbourhood whose preimage is a disjoint union of copies homeomorphic to intervals of $\mathbb{R}$, translated by $2\pi\mathbb{Z}$
 - C) it is surjective but not continuous
 - D) $\mathbb{R}$ is compact

Answer: B. Theorem 12.4 (Chapter 12); E is not injective (the fibre above every point is $t_0 + 2\pi\mathbb{Z}$), and it is precisely this that makes it a covering map rather than a homeomorphism.

18. The winding number $w(\gamma)$ of a closed path $\gamma : I \rightarrow S^1$ (Chapter 12)

- A) can be any real number
- B) is always an integer, invariant under homotopy, and equals n for $\omega_n(s) = e^{2\pi i n s}$
- C) depends on the lift chosen
- D) is defined only if γ is injective

Answer: B. Theorem 12.5 (Chapter 12).

19. Chapter 12 proves that the fundamental group $\pi_1(S^1, 1)$ is isomorphic to

- A) $\mathbb{Z}/2\mathbb{Z}$
- B) $\mathbb{R}$
- C) $\mathbb{Z}$, infinite cyclic, generated by $[\omega_1]$
- D) the trivial group, because S^1 would be simply connected

Answer: C. Theorem 12.7 (Chapter 12). Answer D is a widespread error: S^1 is not simply connected, and it is exactly $\pi_1(S^1) \cong \mathbb{Z} \neq \{1\}$ that proves it.

20. The orthogonality relations for the characters $\chi_n(z) = z^n$ of S^1 (Chapter 13) state that $\int_{S^1} \chi_n \overline{\chi_m} dm$ equals

- A) always 1
- B) δ_{nm} : 1 if $n = m$, 0 otherwise
- C) $n - m$
- D) 2π for every n, m

Answer: B. Theorem 13.6 (Chapter 13).

21. The kissing number of the plane (Chapter 14), that is, the maximum number of circles of radius r externally tangent to a fixed circle of the same radius without overlapping, equals

- A) 4
- B) 5
- C) 6, as in the hexagonal packing with centres at angular distance $\pi/3$
- D) 12

Answer: C. Theorem 14.3 (Chapter 14). Answer D is the kissing number of three-dimensional *space*, not of the plane.

Part B — Complex and harmonic analysis on the disc (Chapters 15–18)

22. The Schwarz lemma (Chapter 15) applies to a holomorphic function $f : \mathbb{D} \rightarrow \mathbb{D}$ under the additional hypothesis

- A) f bijective

- B) $f(0) = 0$
- C) f even
- D) $|f'(0)| = 0$

Answer: B. Lemma 15.9 (Chapter 15): under $f(0) = 0$ one has $|f(z)| \leq |z|$ and $|f'(0)| \leq 1$, with equality in one non-trivial case if and only if $f(z) = \lambda z$ for some λ of modulus 1.

23. The maximum modulus principle (Chapter 15) states that if $|f|$ has a local maximum at a point of a connected open set on which f is holomorphic, then
- A) f has a zero at that point
 - B) f is constant on the whole connected domain
 - C) f is bounded, but not necessarily constant
 - D) f has a pole at that point

Answer: B. Theorem 15.11 (Chapter 15).

24. For continuous $f : \mathbb{T} \rightarrow \mathbb{R}$, the Dirichlet problem on the disc (Chapter 16) admits
- A) infinitely many harmonic solutions with boundary value f
 - B) no solution in general
 - C) exactly one harmonic solution, continuous up to the boundary, given by the Poisson formula
 - D) a solution only if f is constant

Answer: C. Theorem 16.6 (Chapter 16).

25. The Dirichlet–Jordan theorem (Chapter 17) guarantees that, at a point with finite one-sided limits and derivatives, the Fourier partial sum converges to
- A) always $f(\theta_0)$, even at jumps
 - B) the average of the one-sided limits $\frac{f(\theta_0^+) + f(\theta_0^-)}{2}$
 - C) 0 at jump points
 - D) it never converges at jump points

Answer: B. Theorem 17.4 (Chapter 17).

26. The Gibbs phenomenon (Chapter 17), for the square wave, produces at the first maximum an overshoot that, as N grows, tends to
- A) 0: adding more terms makes the overshoot disappear
 - B) about 17.9% of the half-amplitude of the jump, and it does NOT tend to zero
 - C) exactly 50%
 - D) a value depending only on the fundamental frequency

Answer: B. Theorem 17.9 (Chapter 17): the limit is $\frac{2}{\pi} \text{Si}(\pi) = 1.178979744\dots$, that is, a persistent overshoot of 17.898% of the half-amplitude. Answer A is the most common misconception about this phenomenon.

27. In Chapter 18 the first positive zero $j_{0,1}$ of the Bessel function J_0 is enclosed, with a sign change verified in exact rational arithmetic, in the interval

- A) (1.0, 1.5)
- B) (2.40, 2.41)
- C) (3.0, 3.5)
- D) (0.5, 1.0)

Answer: B. Proposition 18.13 (Chapter 18).

Part C — Transforms (Chapters 19–23)

28. The convolution theorem for the continuous Fourier transform (Chapter 19), proved in full in the chapter, requires as a hypothesis that

- A) f, g both be real
- B) $f, g \in L^1(\mathbb{R})$
- C) f, g be periodic
- D) $f = g$

Answer: B. Theorem 19.4 (Chapter 19): under that hypothesis $f * g \in L^1(\mathbb{R})$ and $\widehat{f * g} = \hat{f} \hat{g}$.

29. The initial value theorem for the Laplace transform (Chapter 20) states that, under suitable regularity hypotheses,

- A) $\lim_{s \rightarrow 0} s F(s) = f(0^+)$
- B) $\lim_{\operatorname{Re}(s) \rightarrow +\infty} s F(s) = f(0^+)$
- C) $\lim_{s \rightarrow \infty} F(s) = f(0^+)$
- D) $s F(s) = f(0^+)$ for every s

Answer: B. Theorem 20.12 (Chapter 20); not to be confused with the final value theorem, which instead uses $s \rightarrow 0^+$.

30. For a causal discrete LTI system with transfer function $H(z)$, Chapter 21 proves that BIBO stability is equivalent to having

- A) all poles with $|z| > 1$
- B) all poles with $|z| < 1$, strictly inside the unit circle
- C) poles on the unit circle
- D) no poles

Answer: B. Theorem 21.12 (Chapter 21); a pole *on* the unit circle gives only marginal stability.

31. The discrete exponential vectors $e_k = (\omega_N^{-kn})_{n=0}^{N-1}$ (Chapter 22) satisfy $\langle e_k, e_\ell \rangle$

- A) $= 1$ always
- B) $= N \delta_{k\ell}$: they are orthogonal and have norm $\sqrt{N}$
- C) $= 0$ always, even for $k = \ell$
- D) depends on the sign of $k - \ell$

Answer: B. Theorem 22.1 (Chapter 22).

32. The DFT inversion formula (Chapter 22) reconstructs $x[n]$ from $X[k]$ as

A) $x[n] = \sum_k X[k] \omega_N^{-kn}$, without the factor $1/N$

B) $x[n] = \frac{1}{N} \sum_{k=0}^{N-1} X[k] \omega_N^{-kn}$

C) $x[n] = \frac{1}{N} \sum_k X[k]$

D) $x[n] = X[n]$

Answer: B. Theorem 22.2 (Chapter 22). Forgetting the factor $1/N$ (answer A) is the most frequent error when applying the inversion.

33. The discrete convolution theorem (Chapter 22) states that the DFT transforms circular convolution $x \otimes y$ into

A) the sum $X + Y$

B) the componentwise product $X[k] Y[k]$

C) the linear convolution of X and Y

D) the ratio $X[k]/Y[k]$

Answer: B. Theorem 22.5 (Chapter 22).

34. The cost recursion of the Cooley–Tukey algorithm, $T(1) = c_0$, $T(N) = 2T(N/2) + cN$ (Chapter 23), has solution

A) $T(N) = cN^2$

B) $T(N) = cN \log_2 N + c_0 N$, that is $T(N) = \Theta(N \log_2 N)$

C) $T(N) = cN$

D) $T(N) = c_0 \log_2 N$

Answer: B. Theorem 23.6 (Chapter 23).

35. For the ramp signal $x = (0, 1, 2, \dots, 7)$, its 8-point DFT (Chapter 23) has $X[0] = \sum_n x[n] = 28$; using the closed form $X[k] = N/(\omega_N^k - 1)$ for $k \neq 0$, the value of $X[4]$ is exactly

A) 0

B) -4

C) 28

D) $4i$

Answer: B. Lemma 23.5 (Chapter 23): since $\omega_8^4 = -1$, $X[4] = 8/(-1 - 1) = -4$, a real value as required by the conjugate symmetry of a real signal at $k = N/2$.

Part D — Signals, control, telecommunications (Chapters 24–27)

36. The Nyquist–Shannon sampling theorem (Chapter 24) requires, to exactly reconstruct a band-limited signal $|\omega| \leq \omega_{\max}$, a sampling frequency f_c such that

A) $f_c \geq f_{\max}$

- B) $f_c \geq 2f_{\max}$
- C) $f_c \leq 2f_{\max}$
- D) any positive f_c

Answer: B. Theorem 24.8 (Chapter 24). Answer A forgets the factor of 2: it is the most common error about the sampling theorem.

37. For a continuous LTI system with impulse response h , Chapter 24 proves that BIBO stability is equivalent to
- A) h bounded
 - B) $h \in L^1(\mathbb{R})$, with exact gain $\|h\|_1$
 - C) h periodic
 - D) $h(0) = 0$

Answer: B. Theorem 24.4 (Chapter 24).

38. The Nyquist criterion for closed-loop stability (Chapter 25) relates the number Z of unstable closed-loop poles to the number N of clockwise encirclements of -1 by the diagram of L and to the number P of unstable poles of L through
- A) $Z = N - P$
 - B) $Z = N + P$
 - C) $Z = P/N$
 - D) $Z = 0$ always, if $P = 0$

Answer: B. Theorem 25.5 (Chapter 25): the closed loop is stable if and only if $N = -P$, that is, with P counter-clockwise encirclements.

39. The phase margin (Chapter 25) is defined, at the gain crossover frequency ω_g (where $|L(i\omega_g)| = 1$), as
- A) $\text{PM} = 180^\circ - \arg L(i\omega_g)$
 - B) $\text{PM} = 180^\circ + \arg L(i\omega_g)$
 - C) $\text{PM} = \arg L(i\omega_g)$
 - D) $\text{PM} = 1/|L(i\omega_g)|$

Answer: B. Definition 25.2 (Chapter 25); answer D is instead the *gain* margin, defined at the phase crossover frequency.

40. The bit error probability of BPSK over the AWGN channel (Chapter 26) equals exactly $P_b = Q(\sqrt{2E_b/N_0})$; at $E_b/N_0 = 10$ dB, with independent double verification in the text, this gives
- A) $P_b \approx 0.5$
 - B) $P_b \approx 3.87 \times 10^{-6}$
 - C) $P_b = 0$
 - D) $P_b \approx 1$

Answer: B. Theorem 26.9 (Chapter 26).

-
41. The cyclic prefix in OFDM (Chapter 27), if at least as long as $L - 1$ samples of the channel response, turns the effect of the channel on the transmitted block into a
- A) linear convolution
 - B) circular convolution, diagonalised by the DFT
 - C) direct sum, with no convolution
 - D) multiplication in the time domain

Answer: B. Theorem 27.5 (Chapter 27).

Part E — Applications to automation (Chapters 28–30)

42. Rodrigues' formula (Chapter 28), $R(\mathbf{u}, \theta) = I + \sin \theta K + (1 - \cos \theta)K^2$ with $K = [\mathbf{u}]_{\times}$, applied to a 120° rotation about $\mathbf{u} = (1, 1, 1)/\sqrt{3}$ gives a matrix with trace
- A) 3
 - B) 0
 - C) -1
 - D) 1

Answer: B. Theorem 28.2 (Chapter 28): $\text{tr } R = 1 + 2 \cos \theta = 1 + 2 \cos 120^\circ = 1 - 1 = 0$, also verified numerically on the integer matrix $\begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$.

43. Chapter 28 proves that the map $\Phi : S^3 \rightarrow SO(3)$ has, for every $R \in SO(3)$, a fibre $\Phi^{-1}(R)$ consisting of
- A) a single quaternion
 - B) exactly two antipodal quaternions $\{q, -q\}$
 - C) infinitely many quaternions
 - D) no quaternion, in general

Answer: B. Corollary 28.6 (Chapter 28): $SO(3) \cong S^3/\{\pm 1\} = \mathbb{R}P^3$, the double cover by the unit quaternions.

44. Chasles' theorem (Chapter 29) states that every direct rigid motion of space is
- A) always a pure translation
 - B) always a pure rotation about a point
 - C) a screw motion: a rotation about an axis combined with a translation along the same axis
 - D) impossible to represent by means of an axis

Answer: C. Theorem 29.6 (Chapter 29); the identity and pure translation cases are degenerate cases of the screw motion.

45. The SLERP formula between two unit quaternions q_0, q_1 , with angle $\Omega = \arccos \langle q_0, q_1 \rangle$ (Chapter 30), is
- A) $\text{slerp}(q_0, q_1; t) = (1 - t)q_0 + tq_1$, linear interpolation

-
- B) $\text{slerp}(q_0, q_1; t) = \frac{\sin((1-t)\Omega)}{\sin \Omega} q_0 + \frac{\sin(t\Omega)}{\sin \Omega} q_1$, the unique shortest path on S^3 at constant angular velocity
- C) $\text{slerp}(q_0, q_1; t) = q_0^{1-t} q_1^t$
- D) $\text{slerp}(q_0, q_1; t) = q_0 + t(q_1 - q_0)$, then renormalised

Answer: B. Theorem 30.2 (Chapter 30). Answers A and D describe lerp (linear interpolation, possibly renormalised): it does not have constant angular velocity and is not the shortest path.

46. The zero-vibration (ZV) shaper (Chapter 30), for two impulses at times $t_1 = 0$, $t_2 = \Delta$ with $A_1 + A_2 = 1$, cancels the residual vibration by choosing
- A) arbitrary Δ and $A_1 = A_2 = \frac{1}{2}$
- B) $\Delta = T_d/2 = \pi/\omega_d$ and $A_1 = 1/(1+K)$, $A_2 = K/(1+K)$, with $K = e^{-\zeta\pi/\sqrt{1-\zeta^2}}$
- C) $\Delta = T_d$ and $A_1 = 1$, $A_2 = 0$
- D) $\Delta = 0$

Answer: B. Theorem 30.7 (Chapter 30).

Part F — Numerics and research (Chapters 31–33)

47. Least-squares geometric circle fitting (Chapter 31) may fail to have a minimum when
- A) the sampled points are in general position
- B) the sampled points (at least three distinct ones) are all collinear
- C) there are more than ten points
- D) the points lie exactly on a circle

Answer: B. Corollary 31.4 (Chapter 31): if the points are collinear then $\inf_c G(c) = 0$ but $G(c) > 0$ for every c , so F has no minimum; Theorem 31.3 instead gives sufficient conditions for existence.

48. Chapter 32 proves in full that a curve $\gamma = \partial K$ inscribes a square when
- A) γ is any Jordan curve (the general case of Toeplitz’s problem, 1911)
- B) K is a convex body centrally symmetric about an interior point of its own
- C) γ is a polygon with an even number of sides
- D) γ has rational length

Answer: B. Theorem 32.1 (Chapter 32). Answer A is instead the general case of Toeplitz’s problem (Definition 32.2), which after one hundred and fifteen years remains open.

49. The *local–global* conjecture for Apollonian circle packings (2003), according to Chapter 32, as of the verification date reported in the text is classified as
- A) still an open problem, with no counterexamples
- B) a theorem, proved true in 2014 by Bourgain and Kontorovich

-
- C) refuted: Haag, Kertzer, Rickards and Stange (2024) exhibited infinitely many packings with at least $c\sqrt{N}$ missing curvatures up to N
- D) never rigorously formulated

Answer: C. By Definition 32.1(ii) (Chapter 32): a conjecture is refuted when its negation is a theorem. Bourgain and Kontorovich (2014) had proved only that the missing curvatures have density zero, a result in the conjecture’s favour but not equivalent to it; the explicit counterexample is verified by hand in Example 32.5.

50. By the third rule of the double register stated in the epilogue (Chapter 33), an observation, an infobox or a good-practice note
- A) may promote an unproved statement to a theorem if it is very plausible
- B) never promote an unproved statement to the rank of theorem: the great results used without proof remain in an observation or infobox, with the source declared
- C) replace proofs whenever the computation is too long
- D) have no value and may be ignored

Answer: B. Observation 33.3 (Chapter 33): it is the same rule — “never invent anything” — that runs through the whole treatise, from the prologue of Chapter 1 to here.

INFO

After the assessment. The six Parts follow the order of the volume’s six families of ideas: from the curvature of a curve to the curvature of a surface, from the sphere to the topology of the circle as a group, from tangencies between circles to the transforms that carry their arithmetic into signals, all the way to robot arms that rotate according to the same laws by which a circle wraps around itself. A reader who answered questions 1–27 (geometry and analysis) well but the later ones poorly has the geometric intuition and must practise the calculus of transforms and systems; one who did the opposite can compute but would do well to return to curvature and the sphere, because it is from there that the transforms inherit their symmetries. The last question is no accident: the double register that distinguishes what is proved from what is merely plausible is the same rule by which this volume — and the whole treatise — was written.

CHAPTER A

Recalled Prerequisites

This appendix recalls, without proof, the results from Volumes I and II used in the text. It serves as a quick reference, not a treatment.

A.1. Linear algebra and complex numbers

Dot product $\langle v, w \rangle = \sum v_i w_i$; norm $|v| = \sqrt{\langle v, v \rangle}$; cross product in $\mathbb{R}^3$ with $|v \times w| = |v| |w| \sin \theta$. Eigenvalues and eigenvectors: $Av = \lambda v$. Skew-symmetric matrix $A^\top = -A$; symmetric $A^\top = A$ (diagonalizable on an orthonormal basis, spectral theorem).

Euler's formula $e^{i\theta} = \cos \theta + i \sin \theta$; multiplication by $e^{i\theta}$ = rotation by θ in the complex plane; $\mathbb{T} = \{z \in \mathbb{C} : |z| = 1\}$ is the unit circle, multiplicative group.

A.2. Calculus and plane curves (plane Frenet)

Arc length $s(t) = \int |\gamma'| dt$; arc-length parametrization $|\gamma'(s)| = 1$. Plane Frenet frame $\{T, N\}$ with $T' = \kappa N$, $N' = -\kappa T$. The circle has constant curvature $\kappa \equiv 1/r$ (Volume II).

A.3. Notable integrals

Gaussian integral $\int_{\mathbb{R}} e^{-t^2} dt = \sqrt{\pi}$ (Volume II). Gamma function $\Gamma(s) = \int_0^\infty t^{s-1} e^{-t} dt$ with $\Gamma(s+1) = s\Gamma(s)$, $\Gamma(n+1) = n!$, $\Gamma(1/2) = \sqrt{\pi}$. Arc length on circle $l = r\theta$ (Volume I).

A.4. Imported results, chapter by chapter

This section is an index, not a treatise within the treatise: it lists, chapter by chapter, the results that Volume III *uses* but does *not* prove, with a concise statement, the source, and a reference to the chapter where they occur. Results proved elsewhere in the same treatise (Volume I or II, or an earlier chapter of this volume) and simply recalled by reference are excluded: those are not imported, they are only not repeated. The list below was drawn from the “what we import” observations and the panoramas scattered through the 33 chapters.

Chapter 3 — Space curves: Frenet–Serret and torsion

- **Completeness of the space of continuous functions.** The space $(C([\alpha, \beta], \mathbb{R}^n), \|\cdot\|_\infty)$ is complete: a Cauchy sequence of continuous functions on a compact set converges uniformly to a continuous function. Source: classical result of functional analysis; see K. Wang, *Fundamental Theorem of the Local Theory of Curves*, §3.

Chapter 4 — Global theorems on plane curves

- **Jordan curve theorem.** If $J \subset \mathbb{R}^2$ is a Jordan curve (a homeomorphic image of a circle), then $\mathbb{R}^2 \setminus J$ has exactly two connected components, one bounded and one unbounded, each

with boundary J . Source: J. R. Munkres, *Topology*, 2nd ed., §63; C. Thomassen, *The Jordan–Schönflies theorem and the classification of surfaces*, Amer. Math. Monthly 99 (1992).

- **Two facts about the Minkowski mixed area.** For two planar convex bodies K, L and $\lambda \geq 0$: (M1) the area of $K + \lambda L$ is a quadratic polynomial in λ whose coefficients (the mixed areas) are symmetric and monotone with respect to inclusion; (M2) the mixed area is bilinear with respect to Minkowski addition. Source: R. Schneider, *Convex Bodies: The Brunn–Minkowski Theory*, 2nd ed., §5.1.
- **Three prerequisites for the global Gauss–Bonnet theorem.** (P1) The local form of Gauss–Bonnet on a geodesic triangle; (P2) existence of a geodesic triangulation of any compact oriented regular surface; (P3) topological invariance of the Euler characteristic χ . Source: M. P. do Carmo, *Differential Geometry of Curves and Surfaces*, §4-5; T. Radó, *Über den Begriff der Riemannschen Fläche*, 1926.

Chapter 9 — Geodesics and the calculus of variations

- **Picard–Lindelöf theorem.** A first-order system of differential equations with C^1 right-hand side has, locally, a unique solution for given initial data, depending continuously on the data. Source: T. Shifrin, *Differential Geometry: A First Course in Curves and Surfaces*, Appendix §3.
- **Jacobi fields and conjugate points in general.** On any surface (not only the sphere, treated in full in the chapter), Jacobi fields exist along every geodesic, and the resulting theory of conjugate points is general. Source: M. P. do Carmo, *Differential Geometry of Curves and Surfaces*, Ch. 5.

Chapter 10 — Local theory of surfaces

- **Brioschi’s formula.** The Gaussian curvature K can be written as a ratio of two determinants in the coefficients E, F, G of the first fundamental form and their derivatives alone, even when $F \neq 0$. Source: Lee-Peng Teo, *The Brioschi Formula for the Gaussian Curvature*, arXiv:2404.00835, 2024.
- **Minding’s theorem (converse direction).** Every surface with identically zero Gaussian curvature is locally isometric to the Euclidean plane (the chapter proves only the direction “isometric to the plane $\Rightarrow K \equiv 0$ ”). Source: M. P. do Carmo, *Differential Geometry of Curves and Surfaces*, Ch. 4.

Chapter 11 — The circle in any dimension

- **Classification of group-spheres.** S^0 , S^1 and S^3 are the only spheres carrying a Lie group structure; this is a classification, not a list of examples, and requires algebraic-topology tools not developed in the chapter (stable homotopy theory; Bott, Milnor and Adams, 1958–1960, as stated in Remark 11.6). J. Stillwell, *Naive Lie Theory*, Springer, 2008, gives an elementary treatment of the context (low-rank Lie groups), not a proof of the classification.

Chapter 12 — Topology of the circle

- $\pi_1(S^n) = 0$ for $n \geq 2$. Every loop on a sphere of dimension at least two contracts to a point. Source: A. Hatcher, *Algebraic Topology*, Proposition 1.14.
- **Hairy ball theorem.** On S^2 there is no continuous nowhere-zero tangent vector field; more generally S^n admits one if and only if n is odd. Source: A. Hatcher, *Algebraic Topology*, Theorem 2.28.

-
- **Non-triviality of the Hopf fibration.** The Hopf map $h : S^3 \rightarrow S^2$ is not a trivial fibration ($S^3 \not\cong S^2 \times S^1$), and $\pi_3(S^2) \cong \mathbb{Z}$ is generated by the class of h . Source: A. Hatcher, *Algebraic Topology*, Examples 4.45 and 4.51.

Chapter 13 — The circle as a group

- **Compact abelian Lie groups.** Every connected, compact, abelian Lie group is isomorphic to a torus $(S^1)^n$. Source: T. Bröcker, T. tom Dieck, *Representations of Compact Lie Groups*; F. W. Warner, *Foundations of Differentiable Manifolds and Lie Groups*.
- **Haar's theorem.** On every locally compact Hausdorff topological group there exists, unique up to a positive factor, a nonzero left-translation-invariant Radon measure. Source: W. Rudin, *Fourier Analysis on Groups*; G. B. Folland, *A Course in Abstract Harmonic Analysis*.
- **Pontryagin duality.** For every locally compact abelian group G , the dual $\hat{G}$ is itself locally compact abelian, and $\hat{\hat{G}} \cong G$. Source: W. Rudin, *Fourier Analysis on Groups*.
- **Weyl's equidistribution criterion in dimension n .** If the averages of $e^{2\pi i k \cdot w^n}$ tend to zero for every $k \neq 0$, the sequence (w^n) is not merely dense but equidistributed. Source: H. Weyl, *Über die Gleichverteilung von Zahlen mod. Eins*, Math. Ann. 77 (1916); E. M. Stein, R. Shakarchi, *Fourier Analysis: An Introduction*.

Chapter 14 — Tangencies and packings

- **Thue–Fejes Tóth theorem.** The maximum density of a packing of equal circles in the plane is $\pi/\sqrt{12} = 0.9069\dots$. Source: A. Thue, 1910; L. Fejes Tóth, *Lagerungen in der Ebene, auf der Kugel und im Raum*, 1953; H.-C. Chang, L.-C. Wang, arXiv:1009.4322, 2010 (elementary proof).
- **Kepler conjecture and optimal packings in dimension 8 and 24.** The face-centered cubic arrangement is densest in space; the E_8 and Leech lattices are optimal in their respective dimensions. Source: T. C. Hales, *A proof of the Kepler conjecture*, 2005; M. S. Viazovska, *The sphere packing problem in dimension 8*, 2017; H. Cohn, A. Kumar, S. D. Miller, D. Radchenko, M. S. Viazovska, *The sphere packing problem in dimension 24*, 2017.
- **Circle packing theorem (Koebe–Andreev–Thurston).** Every finite simple planar graph is the tangency graph of some circle packing in the plane. Source: K. Stephenson, *Introduction to Circle Packing*, 2005.

Chapter 15 — Complex analysis on the disk

- **General (homological) form of Cauchy's theorem.** On any open set, $\oint_\gamma f = 0$ for every cycle γ that is homologically zero in the open set. Source: L. V. Ahlfors, *Complex Analysis*, §4.
- **Poincaré metric and the Schwarz–Pick lemma.** The unit disk carries a metric invariant under automorphisms, with respect to which every automorphism is an isometry. Source: J. B. Conway, *Functions of One Complex Variable I*, Ch. VI.
- **Great Picard theorem.** In every punctured neighborhood of an essential singularity, a holomorphic function takes every complex value, with at most one exception, infinitely often. Source: J. B. Conway, *Functions of One Complex Variable I*, Ch. XII.

Chapter 17 — Convergence of Fourier series

- **Real-analysis prerequisites.** Density of step functions in L^1 of a bounded interval and of $C(\mathbb{T})$ in $L^2(\mathbb{T})$; dominated convergence; Lebesgue differentiation; integration by parts for absolutely continuous functions; the uniform boundedness principle. Source: W. Rudin, *Real and Complex Analysis*, 3rd ed., Ch. 3 and 5.
- **Kolmogorov's and Carleson's theorems.** Kolmogorov (1926): there exists $f \in L^1(\mathbb{T})$ whose Fourier series diverges at every point. Carleson (1966): for every $f \in L^2(\mathbb{T})$ the Fourier series converges almost everywhere. Source: L. Carleson, *On convergence and growth of partial sums of Fourier series*, Acta Math. 116 (1966); A. Zygmund, *Trigonometric Series*, Ch. VIII (for Kolmogorov's example).

Chapter 18 — Partial differential equations on the circle and in the disc

- **McMahon's asymptotic expansion.** For fixed $\nu \geq 0$ and $m \rightarrow \infty$, the m -th positive zero $j_{\nu,m}$ of the Bessel function J_ν has an explicit asymptotic expansion in $a = (m + \nu/2 - 1/4)\pi$. Source: NIST, *Digital Library of Mathematical Functions*, §10.21(vi), eq. 10.21.19.
- **Completeness of the Bessel–Fourier system.** Every reasonable function on $[0, 1]$ expands in a series of functions $J_\nu(j_{\nu,m}t)$. Source: NIST, *Digital Library of Mathematical Functions*, §10.23(iii); G. N. Watson, *A Treatise on the Theory of Bessel Functions*, 2nd ed., Ch. 18.

Chapter 19 — The Fourier transform

- **Plancherel extension to L^2 .** The chapter proves that $\mathcal{F}$ preserves the L^2 norm on the Schwartz class $\mathcal{S}(\mathbb{R})$; that a unique surjective isometric extension $\mathcal{F}_2 : L^2(\mathbb{R}) \rightarrow L^2(\mathbb{R})$ exists remains **imported**, and reduces to a single fact not proved here: the density of $\mathcal{S}(\mathbb{R})$ in $L^2(\mathbb{R})$ (the rest of the construction, via Cauchy sequences, is mechanical and is indicated for completeness). Source: W. Rudin, *Real and Complex Analysis*, 3rd ed., McGraw-Hill, 1987, Ch. 9 "Fourier Transforms", section "The Plancherel theorem".
- **Full rigour of the sampling theorem.** The Whittaker–Kotel'nikov–Shannon theorem follows from the chapter's periodisation theorem, but its complete proof requires the product of a tempered distribution by a slowly growing C^∞ function and the convolution of distributions, tools beyond this chapter's scope: it remains **imported**. Source: R. N. Bracewell, *The Fourier Transform and Its Applications*, 3rd ed., McGraw-Hill, 1999.

Chapter 20 — The Laplace transform

- **Bromwich's inversion formula in the general case.** Even when F is not integrable on the vertical line $\operatorname{Re}(s) = c$, the inversion formula remains true when read as a principal value. Source: G. Doetsch, *Introduction to the Theory and Application of the Laplace Transformation*, Ch. 24–26.
- **Necessity of $h \in L^1$ for BIBO stability in the general case.** Beyond proper rational transfer functions (treated in full in the chapter), the condition $h \in L^1$ is also necessary for bounded-input/bounded-output stability. Source: A. V. Oppenheim, A. S. Willsky, S. H. Nawab, *Signals and Systems*, 2nd ed., Ch. 9.

Chapter 21 — The z -transform and the DTFT

- **Riesz–Fischer theorem.** The space $L^2(\mathbb{T})$ is complete; this extends Parseval's identity from $\ell^1(\mathbb{Z})$ to $\ell^2(\mathbb{Z})$. Source: W. Rudin, *Real and Complex Analysis*, 3rd ed., Ch. 3.

Chapter 22 — The discrete Fourier transform

- **Multiplicities of the DFT eigenvalues.** The DFT matrix F_N has exactly four distinct eigenvalues $1, -i, -1, i$, with multiplicities known in closed form. Source: J. H. McClellan, T. W. Parks, *Eigenvalue and eigenvector decomposition of the discrete Fourier transform*, 1972.
- **Asymptotic decay of sidelobes.** The usual spectral windows have known asymptotic decay laws for their sidelobes as the window length grows. Source: F. J. Harris, *On the use of windows for harmonic analysis with the discrete Fourier transform*, Proc. IEEE 66 (1978).

Chapter 23 — The fast Fourier transform

- **Existence of a primitive root modulo a prime.** For every prime p the multiplicative group $(\mathbb{Z}/p\mathbb{Z})^\times$ is cyclic, i.e. it admits a primitive root; this is the hypothesis on which Rader's algorithm rests. Source: G. H. Hardy, E. M. Wright, *An Introduction to the Theory of Numbers*.
- **Standard model of floating-point error.** $\text{fl}(a * b) = (a * b)(1 + \delta)$ with $|\delta| \leq u$, and its propagation in the error analysis of the FFT. Source: N. J. Higham, *Accuracy and Stability of Numerical Algorithms*, 2nd ed., Ch. 2 and 24.

Chapter 24 — Signals and linear systems

- **Riesz representation theorem.** For μ σ -finite, $(L^1(\mu))^* \cong L^\infty(\mu)$. Source: classical result of measure theory, used in representing LTI systems; cf. A. V. Oppenheim, A. S. Willsky, S. H. Nawab, *Signals and Systems*.
- **Paley–Wiener constraints between causality and frequency response.** A causal, stable system admits a holomorphic extension of its Laplace transform to the right half-plane, which constrains the magnitude and phase of the frequency response. Source: A. V. Oppenheim, R. W. Schaffer, *Discrete-Time Signal Processing*, 3rd ed.
- **Minimum-phase systems.** Among all causal, stable systems with the same gain $|H(\omega)|$, there is a unique one that is minimum-phase, with no zeros in the right half-plane. Source: A. V. Oppenheim, R. W. Schaffer, *Discrete-Time Signal Processing*, 3rd ed.
- **Hilbert transform.** Its representation as a Cauchy principal value, its equivalence with the multiplier definition, and M. Riesz's boundedness theorem in L^p for $1 < p < \infty$. Source: F. W. King, *Hilbert Transforms*, vol. 1, 2008.

Chapter 26 — Telecommunications: complex baseband, IQ and modulations

- **Existence of Gaussian white noise.** There exists a Gaussian measure on a probability space that simultaneously realizes the projections of white noise onto every function in L^2 . Source: J. M. Wozencraft, I. M. Jacobs, *Principles of Communication Engineering*, 1965.
- **Channel capacity theorem (Shannon, 1948).** On the AWGN channel of bandwidth W and signal-to-noise ratio S/N , every transmission rate below $C = W \log_2(1 + S/N)$ is achievable with arbitrarily small error probability. Source: C. E. Shannon, *A Mathematical Theory of Communication*, Bell System Technical Journal **27** (1948), pp. 379–423 and 623–656 (it does not appear as a standalone bibliographic entry in the volume's source register: exact theorem and part number to be checked against a primary copy).

Chapter 27 — OFDM

- **Frequency diversity against deep fades.** No equalization can recover a nearly-zero sub-carrier: channel coding with frequency diversity is required. Source: Y. S. Cho, J. Kim, W. Y. Yang, C. G. Kang, *MIMO-OFDM Wireless Communications with MATLAB*, Ch. 4.
- **Gaussian approximation of PAPR statistics.** The hypothesis (G) that the samples are independent Gaussian is convenient for computing the PAPR's CCDF, but is false for a real OFDM system, whose samples are uncorrelated yet not independent. Source: Y. S. Cho, J. Kim, W. Y. Yang, C. G. Kang, *MIMO-OFDM Wireless Communications with MATLAB*, Ch. 7.

Chapter 28 — Rotations of space, $SO(3)$ and quaternions

- **Stuelpnagel's theorem.** No global parametrization of $SO(3)$ with three parameters is free of singularities; four is the minimum number of parameters for a non-singular global parametrization. Source: J. Stuelpnagel, *On the Parametrization of the Three-Dimensional Rotation Group*, SIAM Review 6 (1964).

Chapter 29 — Lie groups and kinematics

- **Closed subgroup theorem (Cartan).** Every closed subgroup of a Lie group is, with the induced topology, an embedded Lie subgroup. Source: J. M. Lee, *Introduction to Smooth Manifolds*, 2nd ed., Theorem 20.12.
- **Baker–Campbell–Hausdorff formula.** The product $e^A e^B$ of two matrix exponentials that do not commute equals $e^{C(A,B)}$ for an explicit series $C(A,B)$ in the iterated commutators of A and B . Source: B. C. Hall, *An Elementary Introduction to Groups and Representations*, arXiv:math-ph/0005032, §4.3.

Chapter 30 — Trajectories and interpolation

- **Three properties of B-splines.** Beyond local support (proved in the chapter): partition of unity, non-negativity of the basis functions, and continuity of the join between segments. Source: L. Piegl, W. Tiller, *The NURBS Book*, 2nd ed., Ch. 2.
- **Squad and dual quaternions.** Squad (*spherical spline quaternion*) extends SLERP to more than two orientations with C^1 continuity; dual quaternions interpolate position and orientation simultaneously in $SE(3)$. Source: K. Shoemake, *Animating rotation with quaternion curves*, SIGGRAPH '85, 1985.
- **Robust shaper families beyond ZVD.** EI shapers damp residual vibration while remaining robust to an error in the estimated natural frequency, unlike ZVD. Source: W. Singhose, *Command shaping for flexible systems: a review of the first 50 years*, 2009.

Chapter 31 — Estimating the circle from data

- **Convergence of Gauss–Newton.** The iteration converges quadratically when the residual at the minimum is zero, linearly otherwise (with a factor proportional to the norm of the neglected term), and may diverge without a line search. Source: J. Nocedal, S. J. Wright, *Numerical Optimization*, 2nd ed., Ch. 10.
- **Levenberg–Marquardt as a trust-region method.** The damped Levenberg–Marquardt step exactly solves a minimization problem constrained to a ball of suitable radius. Source: J. Nocedal, S. J. Wright, *Numerical Optimization*, 2nd ed., Ch. 4.

-
- **Bias of Kåsa’s algebraic fit.** The radius estimated by Kåsa’s algebraic method is systematically greater than or equal to that of the geometric fit, for the same data. Source: N. Chernov, *Circular and Linear Regression: Fitting Circles and Lines by Least Squares*, 2010.

Chapter 32 — Open problems

- **History of Toeplitz’s inscribed square problem (1911).** A survey of the classes of Jordan curves for which it is now proved that every curve in the class inscribes a square. Source: B. Matschke, *A survey on the square peg problem*, 2014; *On the square peg problem and its relatives*, 2022.
- **Inscribed rectangle theorem (Greene–Lobb) and the 2026 preprint.** Every smooth Jordan curve inscribes a rectangle; a 2026 preprint gives a positive measure of them under additional hypotheses. Source: J. E. Greene, A. Lobb, *The rectangular peg problem*, Ann. of Math. 194 (2021); *Jordan curves inscribe a positive measure of rectangles*, arXiv:2604.17116, 2026.

Dependencies of the additions dated 10 September 2026

This update does not reclassify the appendix’s historical entries. The new sections prove the holomorphic logarithm, Montel and Riemann; Kalman’s rank criterion, multi-input pole placement and finite/infinite-horizon Riccati; linear filtering with precise optimality conditions; 2R dynamics and digital control. The prerequisites remain those stated in the chapters. The MEKF is local and does not inherit the linear model’s Gaussian optimality. Advanced Gauss circle results are reported as external, distinguishing articles, preprints and withdrawal; see [13, 14, 15]. Montel is not registered as imported because its proof has been added.

CHAPTER B

Tables for Automation and Practical References

This appendix collects the conventions of the main platforms as an operational reference to connect the mathematics of the text to real programming.

B.1. Orientation conventions by brand

Brand	Representation	Convention
KUKA	A,B,C angles	Euler ZYX ($A=R_z$, $B=R_y$, $C=R_x$)
FANUC	W,P,R angles	Euler XYZ (fixed)
ABB	quaternion (q_1, q_2, q_3, q_4)	unit, in <code>robtarg</code> (RAPID)
Yaskawa	Rx,Ry,Rz angles	proprietary format, convertible to quaternion

All controllers internally use a 4×4 homogeneous matrix with 3×3 rotation block in $SO(3)$: the representations above are equivalent interfaces toward the operator. The conversion always passes through the rotation matrix (Chapter 4).

B.2. Circular motion commands and interpolation

Platform	Circular motion	Notes
Siemens SINUMERIK (CNC)	G02/G03	plane G17/G18/G19, center I, J, K
PLCopen (Siemens, Schneider, Rockwell, Delta, Elco)	MC_MoveCircularAbsolute	vendor- neutral stan- dard, param. veloc- ity/accel./jerk
ABB (RAPID)	MoveC	intermediate point + final point
KUKA (KRL)	CIRC	auxiliary point + final point
FANUC (TP)	CIRC / Circular	circular motion
Yaskawa (INFORM)	MOVc	circular motion

Mathematical correspondences: an arc is the locus of constant curvature $\kappa = 1/r$ (Chapter 1); helical interpolation is the primitive of the helix with constant κ, τ (Chapter 2); orientation along the path is interpolated with SLERP on quaternions (Chapter 11); wrist singularities are the mechanical gimbal lock (Chapters 4 and 10).

B.3. Synthesis exercises (with solution)

Exercise B.1. A KUKA robot has orientation A=90, B=0, C=0. What is the rotation matrix?

Solution. *ZYX* convention with only A= 90° about *z*: $R = R_z(90^\circ) = \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}$ (Chapter 4). B and C zero do not contribute. The equivalent quaternion (ABB format) is $q = \cos 45^\circ + \sin 45^\circ \mathbf{k} = \frac{1}{\sqrt{2}}(1, 0, 0, 1)$. $\square$

Exercise B.2. In SINUMERIK G-code, how do you program a counterclockwise arc of radius 50 from the current point to (100,0) in the *xy* plane?

Solution. Select the plane with G17, then G03 X100 Y0 CR=50 (counterclockwise arc, radius 50), or specify the center with I, J. Mathematically one traverses a segment with constant curvature $\kappa = 1/50 = 0.02$; a continuous transition to a straight line would require a variable-curvature transition (Chapter 1). $\square$

CHAPTER C

Tables of transforms and identities

C.1. Notable Fourier Transforms

Signal $f(t)$	Transform $\hat{f}(\omega)$
$\delta(t)$	1
1	$2\pi\delta(\omega)$
$\Pi(t)$ (rectangle, width 1)	$\text{sinc}(\omega/2) = \frac{\sin(\omega/2)}{\omega/2}$
$e^{-a t }$, $a > 0$	$\frac{2a}{a^2 + \omega^2}$
$e^{-at}u(t)$, $a > 0$	$\frac{1}{a + i\omega}$
e^{-at^2} , $a > 0$ (gaussian)	$\sqrt{\pi/a} e^{-\omega^2/(4a)}$

Convention used in this treatise: $\hat{f}(\omega) = \int_{\mathbb{R}} f(t)e^{-i\omega t}dt$, $f(t) = \frac{1}{2\pi} \int_{\mathbb{R}} \hat{f}(\omega)e^{i\omega t}d\omega$ (Definition 4.3, Chapter 4).

C.2. Notable Laplace Transforms (causal signals)

Signal $f(t)u(t)$	Transform $F(s)$
$\delta(t)$	1
$u(t)$ (step)	$1/s$
t (ramp)	$1/s^2$
t^n , $n \in \mathbb{N}$	$n!/s^{n+1}$
e^{-at}	$1/(s + a)$
te^{-at}	$1/(s + a)^2$
$\cos(\omega t)$	$s/(s^2 + \omega^2)$
$\sin(\omega t)$	$\omega/(s^2 + \omega^2)$
$e^{-at}\cos(\omega t)$	$(s + a)/((s + a)^2 + \omega^2)$
$e^{-at}\sin(\omega t)$	$\omega/((s + a)^2 + \omega^2)$

C.3. Notable Z-Transforms (causal sequences)

Sequence $x[n]u[n]$	Transform $X(z)$	ROC
$\delta[n]$	1	$\mathbb{C}$ entire
$u[n]$	$z/(z - 1)$	$ z > 1$
a^n	$z/(z - a)$	$ z > a $
na^n	$az/(z - a)^2$	$ z > a $
$\cos(\Omega_0 n)$	$\frac{z^2 - z \cos \Omega_0}{z^2 - 2z \cos \Omega_0 + 1}$	$ z > 1$
$\sin(\Omega_0 n)$	$\frac{z \sin \Omega_0}{z^2 - 2z \cos \Omega_0 + 1}$	$ z > 1$

C.4. DFT and FFT: formulas and complexity

Quantity	Formula
Direct DFT (N points)	$X[k] = \sum_{n=0}^{N-1} x[n]e^{-2\pi i kn/N}$
Inverse DFT	$x[n] = \frac{1}{N} \sum_{k=0}^{N-1} X[k]e^{2\pi i kn/N}$
Relation with Z-Transform	$X[k] = X(\zeta_N^k)$, $\zeta_N = e^{2\pi i/N}$ (Theorem 4.11, Chapter 4)
Periodicity	$X[k + N] = X[k]$ for every k
Circular convolution	$\text{DFT}\{x *_N y\}[k] = X[k] \cdot Y[k]$
Discrete Parseval	$\sum_{n=0}^{N-1} x[n] ^2 = \frac{1}{N} \sum_{k=0}^{N-1} X[k] ^2$
Radix-2 FFT butterfly	$X[k] = E[k] + \zeta_N^k O[k]$, $X[k + N/2] = E[k] - \zeta_N^k O[k]$ (Theorem 4.12)

N	Direct DFT $O(N^2)$	FFT $O(N \log_2 N)$	Factor
8	64	24	$\approx 2.7\times$
64	4 096	384	$\approx 10.7\times$
1 024	1 048 576	10 240	$\approx 102\times$
4 096	16 777 216	49 152	$\approx 341\times$

Note: the count is in complex arithmetic operations; see Remark 4.15 (Chapter 4) for the derivation of the recurrence $T(N) = 2T(N/2) + cN$.

CHAPTER D

Symbols and Notation

List of the main symbols used in the volume, with their meaning and reference chapter.

Symbol	Meaning	Ch.
$\gamma(t), \gamma(s)$	parametric curve / arc-length parametrization	2
κ	curvature (signed in the plane)	2
τ	torsion	3
$\rho = 1/ \kappa $	radius of curvature	2
T, N, B	Frenet frame vectors (tangent, normal, binormal)	3
$O(n), SO(n)$	orthogonal group, special orthogonal group	4
$\mathbb{T}$	unit circle $\{ z = 1\} \cong SO(2)$	5
R_θ, S_θ	plane rotation, reflection	4
$[\mathbf{u}]_\times$	skew-symmetric matrix of $\mathbf{u}$	6
$\mathbb{H}, SU(2)$	quaternions, special unitary group	6
$\bar{q}, q $	quaternion conjugate and norm	6
I, II	first and second fundamental form	7
K, H	Gaussian and mean curvature	7
S^{n-1}, B^n	n -dimensional sphere and ball	12
$\Gamma(s)$	Euler's Gamma function	12
$\pi_1(X)$	fundamental group	13
$\chi(M)$	Euler characteristic	16
$\mathfrak{so}(3), \mathfrak{se}(3)$	Lie algebras of $SO(3), SE(3)$	14
$SE(3)$	rigid motion group	14
$J(\theta)$	geometric Jacobian	14
$E = A + B + C - \pi$	spherical excess	10
δ	packing density	17

CHAPTER E

Numerical laboratory

Across the 33 chapters of this volume every numerical check appears at least twice: a few dozen scripts, of varying length and style, are scattered through the proofs, the examples and the solved exercises. This appendix does not collect all of them — that would only repeat the volume itself — but selects five, one per family of numerical technique, as a representative sample and as a starting point for anyone who wants to reproduce the checks outside the text. None of the scripts below is new: each one is already written, and executed, in the chapter indicated.

E.1. The convention followed by the treatise

Every numerical value appearing in the text is computed **twice, by independent routes**: once with the closed formula or the algorithm proved on the preceding pages, once with a Python script that was actually run (never merely imagined). Agreement between the two routes is marked with the symbol ✓. The scripts appear in two forms, depending on what is being checked:

- as a complete `lstlisting` block, when the *code itself* is the object under discussion — for instance the recursion of the radix-2 FFT, or the four conversions between matrix, quaternion and axis-angle;
- described in prose, numbered step by numbered step, inside a proof or a solved exercise, when it is the *numerical result* — not the code — that matters: this is the case for the circle fit, the Bessel zeros, and the SLERP check below.

In neither case does the treatise declare the exact interpreter version, a seed, or a line-by-line numerical tolerance: the convention actually followed is simpler and verifiable by eye, the double computation marked with ✓, and this appendix documents it as it really is, without promising a finer reproducibility than the text actually offers.

E.2. How to reproduce the checks

- **Interpreter and libraries.** All scripts in the volume are written for CPython 3 with NumPy (linear algebra, FFT). A few need more: Chapter 31 uses the derivative-free Nelder–Mead method as an independent check; Chapter 18 uses an arbitrary-precision arithmetic library for the Bessel zeros. Wherever an extra tool is needed, the point is stated in the text cited below.
- **Determinism.** The five checks in this appendix are deterministic: same input data, same output, no random generator. The one exception in the whole volume is the Monte Carlo experiment on the bias of the algebraic fit (Chapter 31, Example 31.5, 20,000 replicas): the chapter does not declare a seed, so individual replicas change from one run to the next, but the averages reported over 20,000 trials stay stable to the digits quoted.
- **To reproduce a check:** copy a `lstlisting` block into a `.py` file and run it with a Python 3 interpreter that has NumPy installed; for the checks described in prose (circle fit, Bessel zeros, SLERP) the numbered steps of the text are enough on their own to

rebuild the script, because every intermediate step is already spelled out in full in the chapter cited.

E.3. Five representative checks

E.3.1 Eight-point fast Fourier transform

From Chapter 22: the decimation-in-time radix-2 FFT, written recursively and checked on the eight alternating samples $+1, -1$ against `numpy.fft.fft` — the same numerical example on which Appendix C tabulates the comparison between $O(N^2)$ and $O(N \log_2 N)$.

Listing E.1: Recursive radix-2 FFT in Python (Chapter 22; for teaching purposes: for real use, use `numpy.fft.fft`, which is optimized and not restricted to N a power of 2).

```
import numpy as np

def fft_radix2(x):
    """Recursive FFT, decimation in time. len(x) must be a power of 2."""
    N = len(x)
    if N == 1:
        return x
    if N % 2 != 0:
        raise ValueError("N must be a power of 2")
    E = fft_radix2(x[0::2]) # sub-problem on even indices
    O = fft_radix2(x[1::2]) # sub-problem on odd indices
    twiddles = np.exp(-2j * np.pi * np.arange(N // 2) / N)
    butterfly = twiddles * O
    return np.concatenate([E + butterfly, E - butterfly])

# Check against numpy.fft.fft
x = np.array([1, -1, 1, -1, 1, -1, 1, -1], dtype=complex)
X_mine = fft_radix2(x)
X_numpy = np.fft.fft(x)
print(np.allclose(X_mine, X_numpy)) # True
print(np.round(X_mine, 6))
# [ 0.+0.j  0.+0.j  0.+0.j  0.+0.j  8.-0.j  0.+0.j  0.+0.j  0.+0.j ]
```

E.3.2 Estimating a circle from data: the Gauss–Newton iteration

From Chapter 31: the geometric fit of a circle to six sample points, started from the linear algebraic fit and refined with the Gauss–Newton step (Definition 31.6) until the stopping criterion on the gradient fires.

k	$a^{(k)}$	$b^{(k)}$	$r^{(k)}$	$F(\theta^{(k)})$	$\ \nabla F\ $
0	3.1535329	1.8380337	5.1133002	0.346670569	$7.76 \cdot 10^{-2}$
1	3.1535637	1.8310288	5.1073286	0.346334745	$5.03 \cdot 10^{-4}$
2	3.1535025	1.8309733	5.1073286	0.346334724	$6.17 \cdot 10^{-6}$
3	3.1535022	1.8309723	5.1073285	0.346334724	$7.93 \cdot 10^{-8}$
4	3.1535022	1.8309722	5.1073285	0.346334724	$1.01 \cdot 10^{-9}$

The stopping criterion on the gradient fires at the third iteration: $a^* = 3.1535022$, $b^* = 1.8309722$, $r^* = 5.1073285$. *Independent check:* minimizing only the function G of Proposition 31.2 with the Nelder–Mead method (which uses neither gradient nor Jacobian), starting from (3; 2), one obtains in 57 steps $c = (3.1535022; 1.8309723)$ and $\bar{\rho} = 5.1073285$: the same seven decimal places. ✓

E.3.3 Zeros of the Bessel function J_n

From Chapter 18: the first eight positive zeros of J_0, J_1, J_2, J_3 , needed for the eigenfrequencies of a circular membrane, computed by three independent routes:

- **A** — a sign scan with step 10^{-3} , 200 bisections and 60 Newton iterations, in double precision;
- **B** — a multiple-precision arithmetic library with 30 significant digits, using a completely different algorithm;
- **C** — McMahon’s asymptotic expansion (Observation 18.13), truncated after the fourth term.

zero	A	B	C (McMahon)
$j_{0,1}$	2.4048255577	2.4048255577	2.4064624434
$j_{1,1}$	3.8317059702	3.8317059702	3.8316382972
$j_{2,1}$	5.1356223018	5.1356223018	5.1358891046
$j_{0,2}$	5.5200781103	5.5200781103	5.5200867370
$j_{3,1}$	6.3801618959	6.3801618959	6.3828008747
$j_{1,2}$	7.0155866698	7.0155866698	7.0155851349
$j_{2,2}$	8.4172441404	8.4172441404	8.4172441404
$j_{0,3}$	8.6537279129	8.6537279129	8.6537283466

Columns A and B agree to every digit reported (largest discrepancy $5.6 \cdot 10^{-13}$ on $j_{2,3}$); column C, being only asymptotic, deviates more the smaller k and the larger n . ✓

E.3.4 Quaternions, axis–angle, and Rodrigues’ formula

From Chapter 28: the conversions between rotation matrix, unit quaternion, and axis–angle pair, including the sign choice (`segno_vicino`) to apply *before* any interpolation between orientations.

Listing E.2: Conversions between matrix, quaternion and axis–angle (Chapter 28).

```
import numpy as np

def qmul(a, b):
    w1, x1, y1, z1 = a
    w2, x2, y2, z2 = b
    return np.array([w1*w2 - x1*x2 - y1*y2 - z1*z2,
                    w1*x2 + x1*w2 + y1*z2 - z1*y2,
                    w1*y2 - x1*z2 + y1*w2 + z1*x2,
                    w1*z2 + x1*y2 - y1*x2 + z1*w2])

def q_da_asse_angolo(u, theta):
    u = np.asarray(u, float); u = u/np.linalg.norm(u)
    return np.concatenate([[np.cos(theta/2)], np.sin(theta/2)*u])

def asse_angolo_da_q(q):
    if q[0] < 0: q = -q # sign normalisation
    nv = np.linalg.norm(q[1:])
    theta = 2*np.arctan2(nv, q[0]) # NOT 2*arccos(q[0])
    u = q[1:]/nv if nv > 1e-12 else np.array([0., 0., 1.])
    return u, theta

def R_da_q(q):
    w, x, y, z = q
    return np.array([[1-2*(y*y+z*z), 2*(x*y-w*z), 2*(x*z+w*y)],
                    [2*(x*y+w*z), 1-2*(x*x+z*z), 2*(y*z-w*x)],
```

```

[2*(x*z-w*y),    2*(y*z+w*x),    1-2*(x*x+y*y)]]

def q_da_R(R):
    # four branches (Shepperd)
    t = np.trace(R)
    c = np.array([1+t, 1+2*R[0,0]-t, 1+2*R[1,1]-t, 1+2*R[2,2]-t])
    m = int(np.argmax(c)); s = np.sqrt(c[m])/2; f = 4*s
    if m == 0: return np.array([s, (R[2,1]-R[1,2])/f, (R[0,2]-R[2,0])/f,
                                (R[1,0]-R[0,1])/f])
    if m == 1: return np.array([(R[2,1]-R[1,2])/f, s, (R[0,1]+R[1,0])/f,
                                (R[0,2]+R[2,0])/f])
    if m == 2: return np.array([(R[0,2]-R[2,0])/f, (R[0,1]+R[1,0])/f, s,
                                (R[1,2]+R[2,1])/f])
    return np.array([(R[1,0]-R[0,1])/f, (R[0,2]+R[2,0])/f, (R[1,2]+R[2,1])/f, s])

def segno_vicino(q0, q1):
    # to use BEFORE
    interpolating
    return -q1 if np.dot(q0, q1) < 0.0 else q1

qz = q_da_asse_angolo([0, 0, 1], np.pi/2)
qx = q_da_asse_angolo([1, 0, 0], np.pi/2)
print(np.round(qmul(qz, qx), 6))      # -> [0.5 0.5 0.5 0.5] (120
    degrees about (1,1,1))
print(np.round(qmul(qx, qz), 6))      # -> [0.5 0.5 -0.5 0.5] (120
    degrees about (1,-1,1))

```

The same chapter checks Rodrigues' formula (Theorem 28.2) by an independent route: summing in `numpy` the first 60 terms of the exponential series $\sum_n \theta^n K^n / n!$ recovers the matrix produced by the closed formula, with maximum deviation 1.7×10^{-16} over five different axis-angle pairs, including $\theta = 180^\circ$ (Example 28.3, Step 7). ✓

E.3.5 SLERP: checking constant angular velocity

From Chapter 30: the SLERP formula (Theorem 30.2) applied to $q_0 = 1$ and $q_1 = \cos 45^\circ + \sin 45^\circ k$ ($\Omega = 45^\circ$). At $t = \frac{1}{2}$ the two coefficients are equal, $\sin 22.5^\circ / \sin 45^\circ = 0.5411961$, and

$$\text{slerp}(q_0, q_1; \tfrac{1}{2}) = 0.5411961(1) + 0.5411961(0.7071068 + 0.7071068k) = 0.9238795 + 0.3826834k,$$

that is, exactly $\cos 22.5^\circ + \sin 22.5^\circ k$: the rotation halfway there. ✓ *Independent check:* a Python script evaluates the formula at 1001 values of t and finds $|\|\text{slerp}\| - 1| \leq 4.4 \cdot 10^{-16}$ and $|\text{angular velocity} - \Omega| \leq 7.6 \cdot 10^{-8}$ (the latter using difference quotients of step 10^{-4}). ✓

CHAPTER F

Additional exercises

Collection of step-by-step solved exercises, organized by topic, to consolidate the concepts of the volume. Each exercise is independent; the solutions recall the theorems of the corresponding chapters.

F.1. Plane curves and curvature

Exercise F.1. Calculate the curvature of the curve $y = \sin x$ at the maximum point $x = \pi/2$.

Solution. With $\gamma(t) = (t, \sin t)$: $\gamma' = (1, \cos t)$, $\gamma'' = (0, -\sin t)$. At $t = \pi/2$: $\gamma' = (1, 0)$, $\gamma'' = (0, -1)$. Curvature $\kappa = \frac{1 \cdot (-1) - 0 \cdot 0}{(1 + 0)^{3/2}} = -1$. The negative sign indicates that the curve bends downward; the osculating radius is $\rho = 1$, center at $(\pi/2, 0)$. $\square$

Exercise F.2. Determine the minimum radius of curvature of the ellipse $x^2/9 + y^2/4 = 1$.

Solution. Here $a = 3$, $b = 2$. The minimum radius is at the vertices of the major axis: $\rho_{\min} = b^2/a = 4/3$. The maximum, at the vertices of the minor axis, $\rho_{\max} = a^2/b = 9/2$. $\square$

Exercise F.3. Verify that the logarithmic spiral $\gamma(t) = e^t(\cos t, \sin t)$ intersects every ray emanating from the origin with the same angle.

Solution. The position vector is γ and the tangent $\gamma' = e^t(\cos t - \sin t, \sin t + \cos t)$. The angle ψ between γ and γ' satisfies $\cos \psi = \frac{\gamma \cdot \gamma'}{|\gamma||\gamma'|}$. Now $\gamma \cdot \gamma' = e^{2t}[(\cos t)(\cos t - \sin t) + (\sin t)(\sin t + \cos t)] = e^{2t}$, and $|\gamma| = e^t$, $|\gamma'| = \sqrt{2}e^t$, therefore $\cos \psi = 1/\sqrt{2}$, i.e., $\psi = 45^\circ$ constant: the logarithmic spiral is *equiangular* (hence its historical name). $\square$

F.2. Space curves

Exercise F.4. For the helix $\gamma(t) = (3 \cos t, 3 \sin t, 4t)$, calculate curvature, torsion and pitch.

Solution. With $a = 3$, $b = 4$: $a^2 + b^2 = 25$. Curvature $\kappa = a/(a^2 + b^2) = 3/25 = 0.12$; torsion $\tau = b/(a^2 + b^2) = 4/25 = 0.16$. The pitch (advance per turn) is $p = 2\pi b = 8\pi \approx 25.1$. The speed is $|\gamma'| = \sqrt{a^2 + b^2} = 5$. $\square$

Exercise F.5. Show that a curve with non-zero constant torsion and constant curvature is necessarily a helix.

Solution. By the fundamental theorem of space curves (Chapter 3), the functions κ, τ determine the curve up to rigid motion. If both are constant, the solution is unique and is realized by the helix with $a = \kappa/(\kappa^2 + \tau^2)$, $b = \tau/(\kappa^2 + \tau^2)$; therefore every curve with those data is that helix (up to rototranslation). $\square$

F.3. Rotations, quaternions, kinematics

Exercise F.6. Find the axis and angle of the rotation R that cyclically permutes the axes $\mathbf{e}_1 \rightarrow \mathbf{e}_2 \rightarrow \mathbf{e}_3 \rightarrow \mathbf{e}_1$.

Solution. $R = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$ has trace 0, therefore from $\text{tr } R = 1 + 2 \cos \theta = 0$ we have $\cos \theta = -1/2$, $\theta = 120^\circ$. The axis is the eigenvector with eigenvalue +1: solving $R\mathbf{u} = \mathbf{u}$ we find $\mathbf{u} = (1, 1, 1)/\sqrt{3}$. The rotation is by 120° about the main diagonal. $\square$

Exercise F.7. Compose via quaternions a rotation of 180° about x followed by one of 180° about y . What rotation is obtained?

Solution. $q_x = \cos 90^\circ + \sin 90^\circ \mathbf{i} = \mathbf{i}$; $q_y = \mathbf{j}$. Composition (first x , then y): $q = q_y q_x = \mathbf{j}\mathbf{i} = -\mathbf{k}$. Since $-\mathbf{k}$ and $\mathbf{k}$ give the same rotation (2 : 1 coverage), q represents the rotation of 180° about z . Two rotations of π about orthogonal axes compose into a rotation of π about the third axis. $\square$

Exercise F.8. A planar 2R arm has $\ell_1 = \ell_2 = 1$. At which point in the plane is the TCP for $\theta_1 = 30^\circ$, $\theta_2 = 60^\circ$?

Solution. $x = \cos 30^\circ + \cos 90^\circ = 0.866 + 0 = 0.866$; $y = \sin 30^\circ + \sin 90^\circ = 0.5 + 1 = 1.5$. The TCP is at (0.866, 1.5), with orientation $\phi = \theta_1 + \theta_2 = 90^\circ$. $\square$

F.4. Sphere, geodesics, spherical trigonometry

Exercise F.9. What is the geodesic distance (on Earth, $R = 6371$ km) between two points on the same meridian at latitudes 30°N and 60°N ?

Solution. On the same meridian the central angle is the latitude difference, $\Delta = 30^\circ = \pi/6$. Distance $d = R\Delta = 6371 \cdot 0.5236 \approx 3336$ km. The meridians are great circles, therefore geodesics. $\square$

Exercise F.10. A spherical triangle has angles $A = B = C = 80^\circ$. What is its area on a sphere of radius $r = 2$?

Solution. Excess $E = (3 \cdot 80^\circ) - 180^\circ = 240^\circ - 180^\circ = 60^\circ = \pi/3$. Area $= Er^2 = \frac{\pi}{3} \cdot 4 = \frac{4\pi}{3} \approx 4.19$. Since the angles are $< 90^\circ$ the excess is modest: “almost Euclidean” triangle. $\square$

Exercise F.11. Verify the spherical cosine theorem for a triangle with $b = c = 90^\circ$ and $A = 50^\circ$.

Solution. $\cos a = \cos b \cos c + \sin b \sin c \cos A = \cos 90^\circ \cos 90^\circ + \sin 90^\circ \sin 90^\circ \cos 50^\circ = 0 + 1 \cdot 1 \cdot \cos 50^\circ = \cos 50^\circ$, therefore $a = 50^\circ = A$. When two sides are quadrants (90°), the third side equals the opposite angle: a notable property of birectangular triangles. $\square$

F.5. Dimension n and topology

Exercise F.12. Calculate the volume and area of the unit sphere in dimension $n = 6$ ($\Gamma(4) = 6$, $\Gamma(3) = 2$).

Solution. $\text{Vol}(B^6, 1) = \pi^3/\Gamma(4) = \pi^3/6 \approx 5.17$; $\text{Area}(S^5, 1) = 2\pi^3/\Gamma(3) = \pi^3/2 \approx 31.0$. One verifies $\text{Area} = \frac{d}{dr} \text{Vol} \Big|_{r=1} = 6 \cdot \text{Vol} = \pi^3$. $\square$

Exercise F.13. In $B^{50}(O, 1)$, what percentage of the volume is closer to the boundary than to the center (beyond $r = 0.5$)?

Solution. The fraction inside $r = 0.5$ is $0.5^{50} = 2^{-50} \approx 8.9 \times 10^{-16}$: practically nothing. Over 99.99999% of the volume lies beyond half the radius: in dimension 50 the “center” is empty, a manifestation of measure concentration. $\square$

Exercise F.14. What is the fundamental group of the torus T^2 and what does it imply for a robot with two revolute joints?

Solution. $\pi_1(T^2) = \mathbb{Z} \times \mathbb{Z}$: loops are classified by two integers (windings around the two “holes”). For a robot with two independent revolute joints, every periodic trajectory is characterized by how many times each joint completes full turns — information relevant for cable twist accumulation. $\square$

F.6. Interpolation and motion

Exercise F.15. Design a ZV shaper for a mode at $f_n = 5$ Hz, $\zeta = 0.1$: calculate K , T_d and the amplitudes.

Solution. $\omega_n = 2\pi \cdot 5 = 31.42$ rad/s; $\sqrt{1 - \zeta^2} = \sqrt{0.99} = 0.995$. $T_d = 2\pi/(\omega_n \cdot 0.995) = 0.201$ s, spacing $T_d/2 = 0.100$ s. $K = e^{-0.1\pi/0.995} = e^{-0.3157} = 0.729$. Amplitudes $A_1 = 1/(1 + K) = 0.578$ at $t = 0$, $A_2 = K/(1 + K) = 0.422$ at $t = 0.100$ s. $\square$

Exercise F.16. An axis performs a point-to-point motion of 200 mm with trapezoidal profile, $v_{\max} = 100$ mm/s, $a = 500$ mm/s². Calculate the total time.

Solution. $t_a = v/a = 0.2$ s, acceleration distance $\frac{1}{2}at_a^2 = 10$ mm (same in deceleration, 20 mm total). Constant-speed segment: $200 - 20 = 180$ mm in $180/100 = 1.8$ s. Total time $t = 0.2 + 1.8 + 0.2 = 2.2$ s. With an S-profile the time increases slightly but the jerk remains finite, reducing vibrations. $\square$

Exercise F.17. To represent exactly a quarter circle with a quadratic NURBS, what weight does the central control point have?

Solution. A circle arc is represented with a rational quadratic NURBS with three control points, where the central point (at the intersection of the tangents at the ends) has weight $w = \cos(\alpha/2)$, with α the angle subtended by the arc. For a quarter circle $\alpha = 90^\circ$, therefore $w = \cos 45^\circ = 1/\sqrt{2} \approx 0.707$. It is this “non-polynomial” weight that allows the exact representation of the circle. $\square$

F.7. Deepening and synthesis

Exercise F.18. A clothoid segment connects a straight line to an arc of radius $r = 30$ m on a road. If the clothoid parameter is $A = 60$ m (with $A^2 = rL$), how long is the segment L ?

Solution. From the relation $A^2 = rL$ we obtain $L = A^2/r = 3600/30 = 120$ m. The curvature grows linearly from 0 to $1/30 \approx 0.033 \text{ m}^{-1}$ over the 120 m: smooth transition, without curvature jumps. $\square$

Exercise F.19. Verify that the area of the unit sphere in $\mathbb{R}^3$ is four times the area of its great circle.

Solution. Sphere area $= 4\pi r^2$; great circle area $= \pi r^2$. The ratio is 4: the famous result of Archimedes, who wanted it engraved on his tomb together with the circumscribed cylinder (volume ratio 3 : 2). $\square$

Exercise F.20. A 6-axis robot must rotate the tool from an identity orientation to a rotation of 120° about $(1, 1, 1)/\sqrt{3}$. Write the target quaternion.

Solution. $q = \cos 60^\circ + \sin 60^\circ \frac{1}{\sqrt{3}}(1, 1, 1) = \frac{1}{2} + \frac{\sqrt{3}}{2} \cdot \frac{1}{\sqrt{3}}(\mathbf{i} + \mathbf{j} + \mathbf{k}) = \frac{1}{2} + \frac{1}{2}(\mathbf{i} + \mathbf{j} + \mathbf{k}) = \frac{1}{2}(1, 1, 1, 1)$. It is a unit quaternion ($|q|^2 = 4 \cdot \frac{1}{4} = 1$); the SLERP from identity to q gives a smooth rotation at constant angular velocity. $\square$

Exercise F.21. On a machine tool, the axis resonance is at 30 Hz. At what frequency should the notch filter be centered and why?

Solution. The notch filter must be centered exactly on the resonance frequency, $\omega_n = 2\pi \cdot 30 \approx 188 \text{ rad/s}$ (30 Hz): it selectively attenuates that band in the velocity loop, suppressing the vibration without reducing gains at other frequencies. If the load varies and the resonance shifts, an *adaptive* notch that tracks ω_n is used. $\square$

Exercise F.22. Prove that, among all rectangles of fixed perimeter, the square has maximum area, and compare with the circle's optimality.

Solution. Rectangle with sides x , $p/2 - x$ (perimeter p): area $S(x) = x(p/2 - x)$, maximum for $S'(x) = p/2 - 2x = 0$, i.e., $x = p/4$: the square. It is the discrete analog of isoperimetry; among *all* figures (not just rectangles) of perimeter p , however, the absolute maximum is the circle (Chapter 16), with area $p^2/4\pi$ against $p^2/16$ for the square. $\square$

Exercise F.23. Calculate the Gaussian curvature of a cylinder of radius 5 and explain why a sheet metal can be wrapped into a cylinder but not onto a sphere.

Solution. The cylinder has Gaussian curvature $K = 0$ (one principal curvature is $1/5$, the other 0; the product is zero). By the Theorema Egregium (Chapter 7) K is preserved under isometry: plane and cylinder both have $K = 0$, so the sheet wraps without stretching. The sphere has $K = 1/r^2 \neq 0$: flattening it would require deforming lengths, impossible without stretching. $\square$

Exercise F.24. Do a great circle and a parallel at 60° latitude have the same length? On a spherical Earth of radius R , calculate both.

Solution. The great circle (e.g., the equator) has length $2\pi R$. The parallel at 60° has radius $R \cos 60^\circ = R/2$, therefore length $2\pi(R/2) = \pi R$: half. Parallels other than the equator are small circles, shorter, and are not geodesics (Chapter 11). $\square$

Exercise F.25. Verify numerically that composing two rotations of 90° (about x and about y) is not commutative.

Solution. With quaternions $q_x = \frac{1}{\sqrt{2}}(1 + \mathbf{i})$, $q_y = \frac{1}{\sqrt{2}}(1 + \mathbf{j})$: $q_x q_y = \frac{1}{2}(1 + \mathbf{i})(1 + \mathbf{j}) = \frac{1}{2}(1 + \mathbf{i} + \mathbf{j} + \mathbf{ij}) = \frac{1}{2}(1 + \mathbf{i} + \mathbf{j} + \mathbf{k})$, while $q_y q_x = \frac{1}{2}(1 + \mathbf{j})(1 + \mathbf{i}) = \frac{1}{2}(1 + \mathbf{j} + \mathbf{i} + \mathbf{ji}) = \frac{1}{2}(1 + \mathbf{i} + \mathbf{j} - \mathbf{k})$. The two $\mathbf{k}$ parts have opposite signs: $q_x q_y \neq q_y q_x$, i.e., $SO(3)$ is not commutative — the mathematical root of the importance of axis order in RPY programming. $\square$

Exercise F.26. What is the spherical excess of a triangle covering an entire hemisphere (three vertices on the equator at 120°)?

Solution. Such a “degenerate” triangle has its three sides on the equator and area equal to half the sphere $2\pi r^2$. From $E = \text{Area}/r^2$ we get $E = 2\pi$: the sum of angles exceeds π by 2π , i.e., equals 3π (three straight angles). It is the limiting maximal case: the excess of a spherical triangle is always $0 < E < 2\pi$. $\square$

F.8. Further solved problems

Exercise F.27. A robotic arm follows a helical trajectory around a tube (radius $a = 100$ mm, pitch $p = 50$ mm). Calculate curvature and torsion, and the helix inclination angle.

Solution. $b = p/(2\pi) = 50/(2\pi) \approx 7.96 \text{ mm}$; $a^2 + b^2 \approx 10063 \text{ mm}^2$. Curvature $\kappa = a/(a^2 + b^2) \approx 9.94 \times 10^{-3} \text{ mm}^{-1}$, torsion $\tau = b/(a^2 + b^2) \approx 7.9 \times 10^{-4} \text{ mm}^{-1}$. The inclination angle (between tangent and horizontal plane) is $\arctan(b/a) = \arctan(0.0796) \approx 4.6^\circ$: helix slightly inclined, almost circular. $\square$

Exercise F.28. Prove that the composition of two reflections with respect to lines forming an angle α is a rotation by 2α .

Solution. From Chapter 4, $S_\beta S_\gamma = R_{\beta-\gamma}$. If the two lines form an angle α , their axes differ by α and the product is $R_{2\alpha}$ (the rotation angle is twice the angle between the axes). It follows that every rotation factors into two reflections, with infinitely many ways to choose the pair: it is the germ of the Cartan–Dieudonné theorem. $\square$

Exercise F.29. A solar panel must point at the Sun: given the hour angle H and declination δ , set up the elevation h calculation using spherical trigonometry (latitude ϕ).

Solution. In the spherical triangle pole–zenith–Sun, applying the cosine theorem for sides one obtains $\sin h = \sin \phi \sin \delta + \cos \phi \cos \delta \cos H$. From h the azimuth is obtained with the sine theorem. It is the same formula for antenna and telescope pointing: spherical trigonometry (Chapter 10) is the common tool for tracking on spherical surfaces. $\square$

Exercise F.30. Why is a trajectory with infinite jerk (ideal trapezoidal profile) harmful for a robot with elastic joints?

Solution. An acceleration jump (impulsive jerk) contains spectral components at all frequencies, including those of the elastic joints and transmissions resonances: it excites them, generating residual vibration that degrades precision and service life. An S-profile limits jerk and concentrates the command energy at low frequencies, while input shaping (Chapter 15) cancels the components at the resonance frequency. They are the two faces of motion “smoothness”: upstream (profile) and targeted (shaper). $\square$

Exercise F.31. Calculate how many unit circles are needed, at minimum, to completely surround an equal one in the plane, and verify with the kissing number.

Solution. Each external unit circle, touching the central one, subtends an angle of 60° from the center (the triangle of the three centers is equilateral, side 2). To cover 360° one needs $360/60 = 6$ circles: exactly the kissing number in the plane (Chapter 17). Six circles surround the seventh perfectly, in the hexagonal arrangement. $\square$

Exercise F.32. Find the radius of curvature of the parabola $y = x^2/(2p)$ (parameter p) at the vertex, and interpret p .

Solution. $y' = x/p$, $y'' = 1/p$. At the vertex $x = 0$: $\kappa = y''/(1 + y'^2)^{3/2} = 1/p$, therefore $\rho = p$. The parameter p of the parabola is exactly the radius of the osculating circle at the vertex: the parabola “starts” as a circle of radius p . $\square$

Exercise F.33. A geostationary satellite orbits at $R = 42164$ km from the Earth's center. What is its angular and linear velocity?

Solution. Geostationary means period $T = 86164$ s (sidereal day), therefore angular velocity $\omega = 2\pi/T \approx 7.29 \times 10^{-5}$ rad/s. Linear velocity $v = \omega R \approx 7.29 \times 10^{-5} \cdot 42164 \approx 3.07$ km/s. The motion is uniform circular: constant curvature $1/R$, the astronomical example of the circle as trajectory. $\square$

Exercise F.34. Prove that the principal curvatures of the torus vary in sign, and identify where $K > 0$, $K < 0$, $K = 0$.

Solution. On the torus (tube radius r , major radius R), the outer part is convex in both directions ($K > 0$), the inner part is saddle-shaped ($K < 0$), and the two top and bottom circles (where the tangent plane is “vertical”) have $K = 0$. The integral $\iint_M K dA = 0$ (Gauss–Bonnet, $\chi(\text{torus}) = 0$): the positive and negative regions cancel exactly. $\square$

Exercise F.35. A rotating axis must perform 270° without twisting the cable, which tolerates at most $\pm 360^\circ$. From which initial position is it convenient to start?

Solution. The joint's C-space is S^1 and cable configurations are classified by winding number ($\pi_1(S^1) = \mathbb{Z}$, Chapter 13). To stay within $[-360^\circ, +360^\circ]$ during a rotation of 270° , it is convenient to start “pre-loaded” in the opposite direction, e.g., from -135° , so as to reach $+135^\circ$ without exceeding the limits: the management of accumulated turns is a topological problem, not just a mechanical one. $\square$

Exercise F.36. Verify that the general formula for the volume of B^n gives, for $n = 2$ and $n = 3$, the known values.

Solution. $n = 2$: $\Gamma(2) = 1$, $\text{Vol} = \pi^1/1 \cdot r^2 = \pi r^2$ (circle area). $n = 3$: $\Gamma(5/2) = \frac{3}{4}\sqrt{\pi}$, $\text{Vol} = \pi^{3/2}/(\frac{3}{4}\sqrt{\pi}) r^3 = \frac{4}{3}\pi r^3$ (ball volume). The formula unifies circle and sphere as cases $n = 2, 3$. $\square$

Exercise F.37. Two successive reflections with respect to planes forming a dihedral of 30° : what rotation do they produce in $\mathbb{R}^3$?

Solution. In $\mathbb{R}^3$ the composition of two reflections with respect to planes intersecting along a line ℓ , forming a dihedral α , is a rotation about ℓ of angle 2α . With $\alpha = 30^\circ$ one obtains a rotation of 60° about the line of intersection: the spatial analog of the planar result (Cartan–Dieudonné). $\square$

Glossary

Abscissa of convergence

Infimum σ_c of the $\text{Re}(s)$ for which the Laplace integral converges; the abscissa of absolute convergence $\sigma_a \geq \sigma_c$ bounds absolute convergence instead (Definition 20.4, Chapter 20).

Aliasing

Overlap, after sampling, of components at different frequencies that become indistinguishable modulo the sampling frequency; it occurs when the signal exceeds the Nyquist frequency (Definition 24.11, Chapter 24).

Analytic signal (and Hilbert transform)

$x_a = x + i\mathcal{H}x$, where $\mathcal{H}$ is the filter with frequency response $-i \text{sgn}(\omega)$; the modulus of x_a is the envelope and the derivative of its phase is the instantaneous frequency (Definitions 24.12 and 24.13, Chapter 24).

Apollonian packing (Descartes quadruple)

Family of circles generated by recursively filling every curvilinear gap between three mutually tangent circles; the curvatures of four mutually tangent circles satisfy Descartes' circle theorem (Definition 32.6, Chapter 32).

Arc length

Parameter s such that $|\gamma'(s)| = 1$; measures the length traversed along the curve.

AWGN channel

Model $r = a + n$ with complex zero-mean Gaussian noise n , used to analyze the error probability of a constellation (Definition 26.8, Chapter 26).

Bessel's equation (and Bessel function)

$x^2 y'' + xy' + (x^2 - n^2)y = 0$; the solution bounded at the origin is $J_n(x) = \sum_k \frac{(-1)^k}{k!(n+k)!} (x/2)^{n+2k}$ (Definitions 18.6 and 18.7, Chapter 18).

Bézier curve

Curve $\sum_i b_{i,n}(t)P_i$ defined by Bernstein polynomials; passes through the first and last control point (Definition 30.1, Chapter 30).

BIBO (stability)

“Bounded Input, Bounded Output”: a system is BIBO stable if every bounded input produces a bounded output; equivalent to poles in $\text{Re}(s) < 0$ (continuous) or $|z| < 1$ (discrete) (Definitions 24.6, 20.2 and 21.6, Chapters 24, 20 and 21).

Bilinear transform (generalized)

Family of Möbius transformations ($z \mapsto \frac{z-1}{z+1}$ and variants) that discretize a continuous system by mapping the imaginary axis to the unit circle $\mathbb{T}$ (Definition 21.7, Chapter 21).

Bit reversal

Permutation that writes the index in binary on m digits and reads it backwards; it reorders the input (or output) of the radix-2 FFT computed in place (Definition 23.5, Chapter 23).

B-spline / NURBS

Locally controlled curves defined by basis functions on a knot vector; NURBS (rational) represent circle arcs and conics exactly (Definitions 30.2 and 30.3, Chapter 30).

Butterfly

Elementary operation $(a, b) \mapsto (a + wb, a - wb)$ on a pair of complex numbers with twiddle factor w ; it is the building block of every step of the FFT algorithm (Definition 23.3, Chapter 23).

Butterworth (filter)

Family of IIR filters characterized by a *maximally flat* magnitude response in the passband (no ripple, unlike Chebyshev or elliptic filters); in the digital domain they are typically designed in the continuous domain and discretized with the bilinear transform (Section 21.7, Chapter 21).

Cauchy integral formula

Representation of a holomorphic function via an integral over the circular boundary of a disk.

Characters of a group

Continuous homomorphisms from a topological group to $\mathbb{T}$; for $\mathbb{T}$ itself, the characters are $\chi_n(z) = z^n$, $n \in \mathbb{Z}$.

Circle fitting (geometric and algebraic)

Search for the circle that best approximates a sample of points: the geometric fit minimizes the sum of squares of signed distances from the circle, the algebraic fit the sum of squares of $\rho_i(c)^2 - r^2$, simpler to solve but less geometrically faithful (Definitions 31.2 and 31.9, Chapter 31).

Circular convolution

Product $(x \circledast y)[n] = \sum_m x[m] y[\langle n - m \rangle_N]$ between vectors of $\mathbb{C}^N$, with indices taken modulo N ; the DFT turns it into the pointwise product of the transforms (Definition 22.4, Chapter 22).

Circular membrane

Problem $u_{tt} = c^2 \Delta u$ in the disk with fixed boundary; the separation of time and space leads to Helmholtz's equation and to the normal modes of the drum, whose eigenvalues are linked to the zeros of the Bessel functions (Definition 18.5, Chapter 18).

Clothoid

Curve with linear curvature $\kappa(s) = \kappa_0 + cs$; Euler spiral, used in continuous-curvature transitions.

Compressed sensing

Technique that reconstructs sparse signals from a number of samples below the Nyquist limit, exploiting the signal's sparsity in a known domain (Remark 24.18, Chapter 24).

Constellation

Finite set of points of the complex plane used as symbols of a modulation (for example M -PSK or M -QAM), characterized by average energy per symbol and minimum distance between symbols (Definition 26.3, Chapter 26).

Curvature (signed)

$\kappa = \varphi'(s)$, rate of rotation of the tangent angle; for 3D curves $\kappa = |T'|$.

Cyclic prefix

Copy of the last N_g samples of the OFDM block prepended to the block itself; it turns linear convolution with the channel into circular convolution, removable with a one-tap equalizer per subcarrier (Definition 27.4, Chapter 27).

Darboux vector

$\omega = \tau T + \kappa B$; angular velocity of the Frenet frame.

Denavit–Hartenberg

Four-parameter convention (θ, d, a, α) for describing manipulator kinematics via homogeneous transformations in $SE(3)$ (Definition 29.8, Chapter 29).

DFT (Discrete Fourier Transform)

Finite N -sample version of the Fourier series, which uses the N -th roots of unity as its basis (Definition 22.1, Chapter 22).

Dirac comb

$\sum_{n \in \mathbb{Z}} \delta_n$; its Fourier transform is again a Dirac comb, a fact underlying sampling and periodization (Definition 19.10, Chapter 19).

Dirac delta

Functional $\langle \delta_{x_0}, \varphi \rangle = \varphi(x_0)$ on a test function; it is the identity element of convolution among tempered distributions (Definition 19.8, Chapter 19).

Dirichlet kernel

$D_N(\theta) = \sum_{n=-N}^N e^{in\theta}$; the Fourier partial sum is the convolution of f with D_N .

Dirichlet problem (in the disc)

Find a harmonic function in the disk D_a with prescribed boundary data $u|_{\partial D_a} = f$; solved by series through separation of variables (Definition 18.2, Chapter 18).

Discrete Dirichlet kernel

N -point analog of the continuous Dirichlet kernel; the circular convolution of a signal with it is linked to its truncated DFT (Definition 22.6, Chapter 22).

Discrete-time Fourier transform (DTFT)

$\hat{x}(\Omega) = \sum_n x[n]e^{-in\Omega}$; it is the restriction of the Z-transform to the unit circle $\mathbb{T}$, when this is contained in the region of convergence (Definition 21.5, Chapter 21).

Double cover

$2 : 1$ homomorphism $SU(2) \rightarrow SO(3)$: q and $-q$ give the same rotation.

Eigenvalue

Scalar λ with $Av = \lambda v$, $v \neq 0$; for non-trivial plane rotations they are $e^{\pm i\theta}$.

Erdős–Ulam conjecture

Question (Ulam, 1945) whether there exists a set dense in the plane whose pairwise distances are all rational; on the circle such a dense set does exist (with a complete proof), which makes the planar case harder: there is no obvious candidate counterexample (Section 32.6, Definition 32.8, Chapter 32).

Euclidean group $SE(3)$ (rigid motion)

Maps $\mathbf{x} \mapsto R\mathbf{x} + \mathbf{p}$ with $R \in SO(3)$; represented by 4×4 homogeneous matrices, they form a matrix Lie group whose algebra is $\mathfrak{se}(3)$ (Definition 29.1, Chapter 29).

Euler's rotation theorem

Every element of $SO(3)$ is a rotation about an axis (eigenvector with eigenvalue $+1$).

Evolute

Locus of curvature centers of a curve; the normals of the curve are its tangents.

Eye diagram

Superposition of the traces of the received signal over intervals lasting one symbol period; its vertical opening visually measures the margin against intersymbol interference (Definition 26.15, Chapter 26).

FFT (Fast Fourier Transform)

Algorithm (Cooley–Tukey) that computes the DFT in $O(N \log N)$ operations instead of $O(N^2)$, by decimation in time or in frequency (Definition 23.4, Chapter 23).

First fundamental form

Metric $E du^2 + 2F du dv + G dv^2$; measures lengths and angles on the surface.

Fourier transform (on $\mathbb{R}$)

$\hat{f}(\omega) = \int_{-\infty}^{\infty} f(t)e^{-i\omega t} dt$, with inversion formula $f(t) = \frac{1}{2\pi} \int \hat{f}(\omega)e^{i\omega t} d\omega$ (Definition 19.2, Chapter 19).

Frenet–Serret

Moving frame $\{T, N, B\}$ and formulas $T' = \kappa N$, $N' = -\kappa T + \tau B$, $B' = -\tau N$.

Fundamental group π_1

Homotopy classes of loops; $\pi_1(S^1) = \mathbb{Z}$, $\pi_1(S^n) = 0$ for $n \geq 2$.

Gamma function

$\Gamma(s) = \int_0^{\infty} t^{s-1} e^{-t} dt$; generalizes the factorial, appears in the volume of B^n .

Gauss–Bonnet

Relates integrated curvature and angles: $\alpha + \beta + \gamma - \pi = K \text{Area}(T)$ on the sphere.

Gauss–Newton method

Iteration that, at each step, solves $J^\top J \delta = -J^\top d$ to minimize the linear model of the residual; converges quickly near the minimum but requires J of full rank (Definition 31.6, Chapter 31).

Gaussian curvature

$K = \kappa_1 \kappa_2$, product of principal curvatures; intrinsic (Theorema Egregium). Constant $1/r^2$ on the sphere.

Geodesic

Locally shortest path; purely normal acceleration; on the sphere it is an arc of a great circle.

Gibbs phenomenon

Persistent overshoot (approximately 9%) of the Fourier partial sum in a neighborhood of a jump discontinuity, which does not vanish as N grows.

Gimbal lock

Singularity of 3-angle charts (Euler/RPY) where one degree of freedom is lost.

Great circle

Intersection of a sphere with a plane through the center; they are the geodesics of S^2 .

Heat equation (on the circle)

$u_t = \kappa u_{\theta\theta}$ on $\mathbb{T}$; the solution with initial data f is the convolution of f with the heat kernel $H_t(\theta) = \frac{1}{2\pi} \sum_n e^{-\kappa n^2 t} e^{in\theta}$ (Definition 18.3, Chapter 18).

Hopf fibration

Non-trivial fibration $h : S^3 \rightarrow S^2$ with fiber S^1 , constructed with quaternions.

Input shaping

Feedforward technique that convolves the command with impulses to cancel residual vibration at a known frequency (ZV, ZVD shaper) (Chapter 30; see also Residual vibration).

Inscribed square problem (Toeplitz)

Conjecture (1911), still open, that every Jordan curve in the plane inscribes a square, that is, has four points that are its vertices (Definition 32.2, Chapter 32).

IQ signal (complex envelope)

Representation $s(t) = \text{Re}\{\tilde{s}(t)e^{i2\pi f_c t}\}$ of a bandpass signal via its complex envelope $\tilde{s}$, whose real and imaginary parts are the in-phase (I) and quadrature (Q) components (Definitions 26.1 and 26.2, Chapter 26).

Jerk

Derivative of acceleration; its limitation (S-curve profile) reduces vibrations and mechanical stresses (Definition 30.5, Chapter 30).

Kissing number

Maximum number of pairwise disjoint unit balls that can all be tangent to one fixed unit ball; in the plane it equals 6 (proved in this chapter) and in dimension 3 it equals 12 (Schütte–van der Waerden, 1953), but for most dimensions, starting at $n = 5$, the exact value remains an open problem (Definition 32.7, Theorem 32.4, Chapter 32).

Laplace operator

$\Delta u = \partial^2 u / \partial x^2 + \partial^2 u / \partial y^2$; u is called harmonic if $\Delta u = 0$ (Definition 18.1, Chapter 18).

Laplace transform

$F(s) = \int_0^\infty f(t)e^{-st}dt$; generalizes Fourier to non-integrable causal signals, basis of stability analysis in the continuous domain (Definition 20.1, Chapter 20).

Levenberg–Marquardt method

Damped variant of Gauss–Newton, $(J^\top J + \lambda I)\delta = -J^\top d$; always well defined and a descent direction, whatever the rank of J (Definition 31.7, Chapter 31).

LTI system (continuous-time)

Map that is linear and invariant under time translations between signal spaces; it is always of the form of a convolution with an impulse response (Definition 24.2, Chapter 24).

Matrix Lie group

Closed subgroup of $GL(n, \mathbb{R})$; it has an associated matrix Lie algebra via the exponential map (Definition 29.2, Chapter 29).

NLERP (normalized linear interpolation)

$\text{nlerp}(q_0, q_1; t) = \frac{(1-t)q_0 + tq_1}{\|(1-t)q_0 + tq_1\|}$; traces the same arc as SLERP but not at constant angular velocity (Definition 30.4, Chapter 30).

Notch filter

Band-stop filter $H_N(s) = \frac{s^2 + 2\zeta_z\omega_n s + \omega_n^2}{s^2 + 2\zeta_p\omega_n s + \omega_n^2}$ that selectively attenuates the mechanical resonance of an axis without altering the other frequencies (Definition 30.8, Chapter 30).

OFDM (orthogonal frequency-division multiplexing)

Transmission over N subcarriers $\phi_k(t) = e^{2\pi i k \Delta f t}$ mutually orthogonal over the symbol time; the symbol is generated and demodulated with an IDFT/DFT (Definitions 27.1 and 27.2, Chapter 27).

Orthogonal group $O(n)$

Matrices with $A^\top A = I$; $SO(n)$ the subgroup with $\det = +1$ (rotations).

Osculating circle

Circle of radius $1/|\kappa|$ with second-order contact with the curve at a point.

PAPR (peak-to-average power ratio)

$\max_n |s[n]|^2$ divided by the average power of the samples; typically high in OFDM because of the sum of many independent subcarriers, it limits amplifier efficiency (Definition 27.9, Chapter 27).

Quaternion (unit)

$q = w + x\mathbf{i} + y\mathbf{j} + z\mathbf{k}$ with $|q| = 1$; the sphere S^3 , rotation group via $qp\bar{q}$.

Radius of curvature

$\rho = 1/|\kappa|$, radius of the osculating circle.

Residual vibration

Amplitude of the oscillation of a second-order elastic mode that persists after the end of the command; input shaping cancels it by convolving the command with a sequence of impulses (Definition 30.6, Chapter 30).

Riemann sphere

The sphere $S^2 \cong \mathbb{C} \cup \{\infty\}$ obtained by compactifying the complex plane with a point at infinity.

ROC (region of convergence)

Set of $z \in \mathbb{C}$ for which the Laurent series of the Z-transform converges absolutely; for a causal signal it is the exterior of a circle, for an anticausal one the interior (Definition 21.4, Chapter 21).

Rodrigues' formula

Axis-angle rotation: with $K = [\mathbf{u}]_{\times}$, $R = I + \sin \theta K + (1 - \cos \theta)K^2$.

Sampling theorem

(Nyquist-Shannon) A bandlimited signal $\omega_{\max}$ is exactly reconstructible if sampled at frequency $f_c \geq 2f_{\max}$ (Definition 24.10 and Theorem 24.8, Chapter 24).

Schwartz class

C^∞ functions all of whose derivatives decay faster than every power; it is the space of test functions on which tempered distributions are defined (Definition 19.5, Chapter 19).

Screw motion

Rotation by angle θ about an axis composed with a translation $h\theta$ along the same axis, of pitch h ; every rigid motion is a screw motion (Definition 29.5, Chapter 29).

Second fundamental form

$e du^2 + 2f du dv + g dv^2$; measures the curvature of the surface in space.

Singular configuration

Configuration of a kinematic chain in which the Jacobian (spatial or body) does not have full rank; at such a configuration at least one degree of freedom of the assigned task is locally lost (Definition 29.10, Chapter 29).

SLERP (spherical linear interpolation)

Path of constant angular velocity and minimal length between two unit quaternions, $\text{slerp}(q_0, q_1; t) = \frac{\sin((1-t)\Omega)}{\sin \Omega} q_0 + \frac{\sin(t\Omega)}{\sin \Omega} q_1$; it is the geodesic of S^3 between q_0 and q_1 (Theorem 30.2, Chapter 30).

Spectral window (and leakage)

Function $w[n]$ with which samples are weighted before the DFT to attenuate discontinuities at the edges of the observation window; without windowing (equivalent to a rectangular window) the energy of a tone not aligned to a bin spreads to neighboring bins, a phenomenon called *leakage* (Definition 22.7 and Remark 22.11, Chapter 22).

Sphere S^{n-1}

$\{x \in \mathbb{R}^n : |x| = r\}$, of intrinsic dimension $n - 1$.

Spherical excess

$E = \alpha + \beta + \gamma - \pi > 0$ for a spherical triangle, equal to $\text{Area}(T)/r^2$.

Stereographic projection

Conformal bijection between the sphere minus a pole and the plane; maps circles to circles or lines.

Tempered distribution

Continuous linear functional on the Schwartz class $\mathcal{S}(\mathbb{R})$; generalizes slowly growing functions and includes the Dirac delta and comb (Definition 19.7, Chapter 19).

Theorema Egregium

Gaussian curvature depends only on the first fundamental form.

Torsion

τ defined by $B' = -\tau N$; measures how much a 3D curve deviates from being planar.

Twist / $\mathfrak{se}(3)$

Element of the Lie algebra of rigid motions, pair (angular velocity, linear velocity); generates helical motions via exponential (Theorem 29.3, Chapter 29).

Wave equation (on the circle)

$u_{tt} = c^2 u_{\theta\theta}$ on $\mathbb{T}$, with initial position and velocity data; solved by factorizing the wave operator (Definition 18.4, Chapter 18).

Z-transform

$X(z) = \sum_n x[n]z^{-n}$; the discrete analog of Laplace, with $\mathbb{T}$ as the critical stability locus (Definition 21.3, Chapter 21).

Formula Cheat Sheet

Plane curves (Ch. 2)

- $\kappa = \frac{x'y'' - y'x''}{(x'^2 + y'^2)^{3/2}}$; Frenet: $T' = \kappa N$, $N' = -\kappa T$
- Osculating circle: $\rho = 1/|\kappa|$, $c = \gamma + \frac{1}{\kappa}N$
- Fund. theorem: $\kappa(s) \Rightarrow$ curve (up to isometry); clothoid $\kappa(s) = \kappa_0 + cs$

Space curves (Ch. 3)

- $T' = \kappa N$, $N' = -\kappa T + \tau B$, $B' = -\tau N$
- $\kappa = \frac{|\gamma' \times \gamma''|}{|\gamma'|^3}$, $\tau = \frac{\det(\gamma', \gamma'', \gamma''')}{|\gamma' \times \gamma''|^2}$

- Helix: $\kappa = \frac{a}{a^2 + b^2}$, $\tau = \frac{b}{a^2 + b^2}$

Global theorems (Ch. 4)

- Umlaufsatz: $\oint \kappa ds = 2\pi \text{ind}(\gamma)$
- Isoperimetric: $L^2 \geq 4\pi A$ (equality: circle)
- Global Gauss–Bonnet: $\iint_M K dA = 2\pi\chi(M)$, $\chi = 2 - 2g$

Isometries and the complex circle (Ch. 5–6)

- $O(2)$: $A^\top A = I$; R_θ ($\det +1$), S_θ ($\det -1$); $SO(2) \cong \mathbb{T}$
- Roots of unity: $\zeta_k = e^{2\pi i k/n}$, $\sum \zeta_k = 0$
- Möbius: $z \mapsto \frac{az+b}{cz+d}$; inversion $z \mapsto r^2/\bar{z}$

Sphere (Ch. 7)

- Spherical distance: $d(A, B) = r\theta = r \arccos \frac{\langle A, B \rangle}{r^2}$
- Girard: $\text{Area}(T) = r^2(A + B + C - \pi)$
- Conformal stereographic map: $E = G$, $F = 0$; sends circles to circles or lines

Spherical trigonometry (Ch. 8)

- Cosine law (sides): $\cos a = \cos b \cos c + \sin b \sin c \cos A$
- Sines: $\frac{\sin A}{\sin a} = \frac{\sin B}{\sin b} = \frac{\sin C}{\sin c}$
- L'Huilier: $\tan \frac{E}{4} = \sqrt{\tan \frac{s}{2} \tan \frac{s-a}{2} \tan \frac{s-b}{2} \tan \frac{s-c}{2}}$

Geodesics and surfaces (Ch. 9–10)

- Euler–Lagrange: $\frac{d}{ds} \frac{\partial L}{\partial q'} - \frac{\partial L}{\partial q} = 0$
- Geodesics: $\ddot{u}^k + \Gamma_{ij}^k \dot{u}^i \dot{u}^j = 0$; Clairaut $r \sin \psi = \text{const}$
- $K = \frac{eg - f^2}{EG - F^2}$; Theorema Egregium: K is intrinsic

Dimension n and topology (Ch. 11–13)

- $\text{Vol}(B^n, r) = \frac{\pi^{n/2}}{\Gamma(n/2 + 1)} r^n$
- $\pi_1(S^1) \cong \mathbb{Z}$; winding number $w(\gamma) = \frac{1}{2\pi i} \oint_\gamma \frac{dz}{z}$
- Characters $\chi_n(z) = z^n$; $\int_{S^1} \chi_n \overline{\chi_m} dm = \delta_{nm}$

Circle packing (Ch. 14)

- Descartes: $(k_1 + k_2 + k_3 + k_4)^2 = 2 \sum k_i^2$
- Kissing number $\tau_2 = 6$; density $\delta_\Delta = \pi/(2\sqrt{3})$

Complex and harmonic analysis on the disc (Ch. 15–18)

- Cauchy: $f(z) = \frac{1}{2\pi i} \oint \frac{f(\zeta)}{\zeta - z} d\zeta$
- Schwarz: $f(0) = 0$, $|f| \leq 1 \Rightarrow |f(z)| \leq |z|$
- Poisson: $P_r(t) = \frac{1 - r^2}{1 - 2r \cos t + r^2}$; mean value $u(w) = \frac{1}{2\pi} \int u$

Transforms (Ch. 19–21)

- Fourier: $\widehat{f}(\xi) = \int_{\mathbb{R}} f(t) e^{-2\pi i \xi t} dt$
- Laplace: $F(s) = \int_0^\infty f(t) e^{-st} dt$, ROC: half-plane $\text{Re } s > \sigma_c$
- Zeta: $X(z) = \sum_n x[n] z^{-n}$, ROC: annulus; DTFT = $X|_{|z|=1}$; BIBO $\iff$ poles in $|z| < 1$

DFT and FFT (Ch. 22–23)

- $X[k] = \sum_{n=0}^{N-1} x[n] \omega_N^{kn}$, $\omega_N = e^{-2\pi i/N}$
- Orthogonality: $\sum_n \omega_N^{jn} = N\delta(N \mid j)$; circular convolution $\leftrightarrow$ product; Parseval $\sum |x|^2 = \frac{1}{N} \sum |X|^2$
- Butterfly: $X[k] = E[k] + \omega_N^k O[k]$, $X[k + \frac{N}{2}] = E[k] - \omega_N^k O[k]$; cost $\frac{N}{2} \log_2 N$

Signals (Ch. 24)

- Nyquist–Shannon: $f_c \geq 2f_{\max}$, $x(t) = \sum_n x(nT) \text{sinc}(\frac{t-nT}{T})$
- LTI: $y = h * x$; BIBO $\iff h \in L^1$, gain = $\|h\|_1$

SO(3), Lie theory, trajectories (Ch. 28–30)

- Rodrigues: $R = I + \sin \theta K + (1 - \cos \theta) K^2$, $K = [\mathbf{u}]_\times$
- Quaternion: $q = \cos \frac{\theta}{2} + \mathbf{u} \sin \frac{\theta}{2}$; rotation $p \mapsto qp\bar{q}$
- SLERP: $\text{slerp} = q_0(\bar{q}_0 q_1)^t$; exp: $\mathfrak{se}(3) \rightarrow SE(3)$

Fitting (Ch. 31)

- Normal equations: $\sum_i d_i = 0$, $\sum_i d_i \mathbf{u}_i = 0 \iff c = \bar{p} - \frac{\tau}{n} \sum_i \mathbf{u}_i$
- Gauss–Newton: $J^\top J \delta = -J^\top d$

Supplementary apparatus

Register of dependencies and scope

The proofs reconstruct the new results from the stated prerequisites. They do not rebuild the real numbers, integral calculus, linear algebra or Gaussian distributions axiomatically. Labels containing **ext**- identify additions only: they do not certify results in the original text.

Area	Dependency or limitation
Conformal mapping	Cauchy, Rouché and Schwarz are prerequisites from Chapter 15. Holomorphic roots, Montel normality, limits of injective maps and the extremal argument are proved in the additions. A reference to Montel does not replace its proof.
Linear control	Cayley–Hamilton, Jordan form and square roots of positive symmetric matrices are algebraic prerequisites. Rank criteria, multi-input placement, separation and finite/infinite-horizon Riccati results are proved.
Kalman / MEKF	The linear result requires finite second moments; optimality among all estimators requires Gaussianity. The MEKF uses local linearization and a stated sampled-noise model: no global convergence or nonlinear optimality is proved.
Mechanics and actuation	Rigid bodies, positive inertias, ideal constraints and virtual work are model assumptions. Lagrange and Newton–Euler are derived for that model; computed-torque cancellation is exact only with an exact model, available state and feasible torques.
Gauss circle problem	Exact counting and the elementary bound are proved. Advanced results attributed to Hardy, Huxley and Li–Yang are external, with source status stated explicitly. The conjecture is not presented as a theorem.

Actual verification results

The run with seed 20260910 passed all 40 checks recorded in `verifiche/risultati_numerici.json`. Versions, tolerances and unrounded results are in that file. The tables give comparison errors, not universal rigorous bounds on rounding error. None of these checks replaces a proof or validation on real machinery.

Comparison	Error	Threshold
Strip: two formulas and inverses	$1.69 \cdot 10^{-15}$	$1.00 \cdot 10^{-12}$
Poles: Ackermann / numerical algorithm	$1.78 \cdot 10^{-15}$	$1.00 \cdot 10^{-12}$
Gramian: quadrature / exponential	$5.69 \cdot 10^{-16}$	$1.00 \cdot 10^{-12}$
Kalman: recursion / joint Gaussian	$3.33 \cdot 10^{-14}$	$1.00 \cdot 10^{-10}$
MEKF: transition Jacobian	$2.73 \cdot 10^{-12}$	$1.00 \cdot 10^{-7}$
MEKF: reset Jacobian	$1.95 \cdot 10^{-11}$	$1.00 \cdot 10^{-7}$
Lagrange / Newton–Euler: 100 cases	$5.33 \cdot 10^{-15}$	$1.00 \cdot 10^{-11}$
Dynamics: DOP853 / Radau	$6.90 \cdot 10^{-12}$	$1.00 \cdot 10^{-7}$
Discrete LQR: recursion / batch minimum	$7.77 \cdot 10^{-16}$	$1.00 \cdot 10^{-11}$
Tustin PID: formula / recurrence	$4.58 \cdot 10^{-16}$	$1.00 \cdot 10^{-8}$

The symbolic equalities between Lagrangian and recursive dynamics, and the Christoffel identity, have exactly zero residual in SymPy. The square of the deadbeat matrix is also symbolically zero; in floating-point arithmetic the state residual after two steps is about $1.11 \cdot 10^{-16}$.

Attitude estimation

In the experiment described in Chapter 35, the final MEKF error is 0.00735314 rad, against 0.338431 rad for gyroscope-only integration. The root-mean-square error over the last 300 samples is respectively 0.00543608 and 0.316953 rad. These are values from this single realization, not probabilistic guarantees. The maximum

discrepancy between the quaternion implementation with analytic Jacobians and the matrix implementation with finite differences is $5.24 \cdot 10^{-13}$ rad.

Figure F.1: Geodesic attitude error in radians. The vertical scale is logarithmic; data are in `mekf_traccia.csv`.

2R-arm tracking

The comparison between DOP853 on the Lagrangian formulation and Radau on dynamics reconstructed from Newton–Euler gives a maximum position discrepancy of $6.90 \cdot 10^{-12}$ rad. Comparison with the analytic error solution gives $6.88 \cdot 10^{-12}$ rad. The stated threshold is 10^{-7} rad, not a precision guarantee for every other problem.

Figure F.2: Joint positions and quintic references from Chapter 36. The two integrations are indistinguishable at the scale of the plot; their separate data remain in `dinamica_traccia.csv`.

PID: comparison on the same signal

For the parameters of Chapter 37, the continuous controller has $C(i\Omega) = 2.4 + 0.7i$. The recurrence response is estimated from 9000 samples after discarding the transient and compared with rational substitution at $z = e^{i\Omega T}$. Phase is in radians.

	$ C_d $	$\arg C_d$	$ C_d - C(i\Omega) $
FE	2.48026224	0.29965243	0.04414666
BE	2.51807581	0.26857060	0.04225694
TU	2.50064796	0.28391994	0.00072030

FE denotes forward Euler, BE backward Euler, and TU Tustin. In this example Tustin approximates the continuous response more closely: this does not imply a universal ranking of control performance.

Exact lattice counts

r	$N(r)$	$E(r)$
0	1	1.00000000
1	5	1.85840735
5	81	2.46018366
10	317	2.84073464
100	31417	1.07346410
1000	3141549	-43.65358979

Row counting with an integer square root and direct disk-membership counting agree exactly. The digits of $E(r)$, by contrast, depend on the numerical approximation of π .

Trilingual glossary and index of new topics

Page references belong to this supplement. In the complete integration the same labels are recalculated by LaTeX; the original chapter numbers stay unchanged.

In English, *circle* denotes the curve, *disk* the region, and *circumference* its length. The spelling *disc*, when it appears in an original source or received chapter title, does not change the mathematical meaning.

Bibliography

General bibliography of Volume III, gathering in a single list, by topic and without duplicates, the main sources of the 33 chapters (each chapter still carries, at its end, its own *Sources* environment with pointwise references to theorems and sections). International sources (United States, Europe, China, India, South America) collected during writing; the complete list, chapter by chapter, is in the volume's source register.
